Because of the many advantages for both the mother and the baby, the number of deliveries performed each year with use of subarachnoid (spinal) block, caudal block, epidural block, and pudendal block anesthesias is steadily increasing. When a subarachnoid, caudal, or epidural block is administered, vasoconstrictor drugs may be used intravenously or intramuscularly to prevent or correct a precipitous fall in blood pressure. If local infiltration of the perineum or pudendal block is used, the local anesthetic solution often contains a vasoconstrictor drug to prolong analgesia and prevent rapid absorption of the local anesthetic agent. During or immediately after the delivery of a baby, it is not unusual for an oxytocic drug to be given.

Too few physicians are aware that a severe, persistent, dangerous hypertension and even rupture of a cerebral blood vessel which may cause brain damage and hemiplegia can result from the combined effect of a vasoconstrictor and an oxytocic drug which have been administered to a patient within three to six hours of one another. Further study of this problem was prompted by the admission on Nov. 8, 1957, of a patient who had sustained a subarachnoid hemorrhage due to rupture of an intracranial aneurysm within two hours after delivery. The patient had received a caudal block; when the caudal block was initiated, a vasoconstrictor drug was administered prophylactically intramuscularly to prevent any fall in blood pressure. An oxytocic agent was administered at the time of placental delivery.

Method of Study

On Oct. 1, 1952, the department of anesthesiology at the Virginia Mason Hospital initiated a 24-hour record-keeping system of all obstetric anesthesias administered there that has continued to date. All anesthesias are administered by physician anesthetists, and these anesthesias and much of the obstetric data are recorded on a key sort-type record.[1] Most of the deliveries are performed with use of regional block procedures.

From the Department of Anesthesiology, the Mason Clinic and Virginia Mason Hospital.

Read before the Section on Obstetrics and Gynecology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 10, 1959.

When the patient mentioned above was admitted on Nov. 8, 1957, it was decided to review the 10,383 obstetric anesthesias which had been administered since 1952, and, as from November, 1957, all cases were to be studied carefully. Particular care was taken to record the medicaments administered, blood pressure, pulse rate, and other data on the hospital chart and the key sort record of each patient.

A screening of the obstetric anesthesia records from October, 1952, to November, 1957, revealed that of 10,383 anesthesias administered in deliveries, about 62% (6,400) had been continuous caudal analgesias. The rest of the mothers had received epidural block, spinal block, or general anesthesia. During this period, the percentage of deliveries in which continuous caudal block was administered had risen from 29% in 1952 to 82% in 1957.[1] Of a total of 2,135 obstetric anesthesias administered in 1958, 1,750 (82%) were continuous caudal blocks.[1] Inasmuch as continuous caudal analgesia was used in the majority of cases, and since at least 98% of these patients had, at initiation of the caudal block, received a vasoconstrictor drug to prevent hypotension as well as an oxytocic drug at the time of placental delivery, it was decided to include in this study only mothers who had received continuous caudal block anesthesias.

Analysis of Thirty-four Cases of Postpartum Hypertension in Relationship to Drugs Administered During Labor, November, 1957, to April, 1958

Drugs	No. of Patients
Vasoconstrictor and oxytocic	
Methoxamine and ergonovine maleate	21
Methoxamine and methylergonovine	6
Methoxamine and oxytocin	1
Methoxamine and oxytocin and methylergonovine	1
Total	29
Oxytocic (only)	
Ergonovine maleate	2
Methylergonovine	1
Oxytocin	1
Total	4
None	1
Total	34

Results

From October, 1952, to May, 1955, about 2,200 patients who received continuous caudal block analgesia were given a prophylactic dose of 25 to 50 mg. of ephedrine sulfate. From May, 1955, to November, 1957, about 4,200 patients who were delivered under continuous caudal block received a prophylactic intramuscular dose of 8 to 12 mg. of methoxamine (Vasoxyl) hydrochloride. The latter drug was substituted for the ephedrine sulfate primarily because of its longer duration of action. At the time of delivery of the placenta, most of these 6,400 patients received ergonovine (Ergotrate) maleate, 1/320 grain (0.23 mg.), or methylergonovine (Methergine) maleate, 0.2 mg., while a few received oxytocin (Pitocin), 10 units. Unfortunately, the incidence of postpartum hypertension in these 6,400 patients is unknown. Although some patients complained of headache, the seriousness and significance of this symptom was not recognized, because no grave sequelae developed. Therefore, only symptomatic treatment was instituted, and accurate data concerning the headache (i. e., its duration and whether or not it was associated with hypertension) were not recorded.

From November, 1957, to April, 1958, 741 patients received caudal block analgesia, and each drug used and its relationship to subsequent symptoms was carefully recorded. The records revealed that 737 (99.5%) of these patients received a prophylactic dose (8 to 12 mg.) of methoxamine hydrochloride at initiation of the caudal block and an oxytocic drug, primarily ergonovine maleate (1/320 grain) or methylergonovine maleate (0.2 mg.), at *the time of placental delivery. Thirty-four* (4.6) of the 741 patients developed postpartum hypertension, with systolic blood pressures of 140 mm. Hg or higher. Fourteen of these patients developed diastolic blood pressures of about 90 mm. Hg, and 20 developed diastolic pressures of 100 mm. Hg or higher. The last one in this series of patients who developed postpartum hypertension from administration of this combination of drugs ruptured an aneurysm. This event terminated the routine prophylactic administration of a vasoconstrictor drug.

Analysis of the drugs given to the 34 hypertensive patients showed that (1) 29 had received methoxamine (8-12 mg.) prophylactically and an oxytocic drug (ergonovine maleate, 1/320 grain [0.23 mg.]; or methylergonovine maleate, 0.2 mg., or oxytocin, 10 units, or both); (2) 4 patients had not been given a vasoconstrictor drug, because toxemia was suspected, but had received an oxytocic drug; and (3) one patient had received neither a vasoconstrictor nor an oxytocic drug (see table). The dose of the methoxamine hydrochloride did not seem to be of significance, 15 patients having received 10 mg. of the drug, 9 patients 12 mg., and 5 patients 8 mg. The average interval from administration of the vasoconstrictor drugs to the onset of hypertension was one hour and 51 minutes, with a range from 50 minutes to six hours and 50 minutes. The average interval from administration of the oxytocic drugs to the onset of hypertension was 39½ minutes, with a range from 10 to 80 minutes.

Headache, the *most common symptom* of these patients, occurred in about 80% of cases. It was severe, incapacitating, difficult to relieve, and involved the frontal, parietal, and occipital areas of the head. Some of the patients were irritable; a few seemed disoriented.

The 741st patient during this phase of the study sustained a *subarachnoid hemorrhage*. This 28-year-old multiparous patient was admitted at full term, in normal labor. Her obstetric anesthesia record and her prenatal chart showed nothing unusual. She had received methoxamine hydrochloride, 10 mg. intramuscularly, at 12:15 a. m., at initiation of the continuous caudal anesthesia. Three subsequent injections of the anesthetic drug, at about 45-minute intervals, were administered uneventfully, and she had a normal delivery. After delivery of the placenta at 2:40 a. m., ergonovine maleate, 1/320 grain, was given intramuscularly. She was normotensive (blood pressure of 120/76 mm. Hg) prior to, during, and at completion of the delivery.

Inspection of the nurses' notes revealed that shortly after the patient was returned to her room, at 3:00 a. m., her blood pressure rose to 150/70 mm. Hg. At 3:15 a. m. the hypertension became severe, with a blood pressure of 180/120 mm. Hg, at which time she complained of severe headache. This was known to the nurse in charge, who notified the obstetrician; he, in turn, ordered intramuscular administration of 75 mg. of meperidine (Demerol) hydrochloride. Apparently during the next five minutes the aneurysm ruptured, because by 3:20 a. m. she had difficulty in speaking. The department of anesthesiology was notified at 4:15 a. m., at which time her blood pressure was 162/100 mm. Hg. She was then given chlorpromazine hydrochloride, 12.5 mg., intravenously. Her blood pressure returned to within normal limits (130/60 mm. Hg) almost immediately.

About eight hours later a neurological examination was performed: motor aphasia, right-sided facial weakness, weakness in the arms, and a positive Babinski sign on the right side were present. The spinal fluid was grossly bloody. Recovery of this patient has been slow. At the time of writing she has motor aphasia and is receiving speech training.

Comment

While hypertension and even subarachnoid hemorrhage are known to occur during any stage of pregnancy, regardless of the quality of the obstetric care given or the anesthetic technique used, they are more apt to develop during the last trimester and in the postpartum period.[2] This discussion is limited primarily to the hazards of the hypertension which may develop in the postpartum period when administration of a regional block anesthetic is accompanied by combined use of a vasoconstrictor and an oxytocic drug.

Etiology of Postpartum Hypertension.—Known physiological and pharmacological mechanisms may produce sudden postpartum hypertension from either relative or actual overloading of the total vascular compartment. The known physiological causes are the hypervolemia normally present during pregnancy and the sudden shift of blood from the uterine vascular space after delivery. The known pharmacological causes are (1) constriction of the blood vessels due to administration of a vasoconstrictor drug, given to prevent or correct a fall in blood pressure which results from administration of a regional block procedure, (2) contraction of the uterus which is effected by use of an oxytocic drug, and (3) vasoconstrictor effect of an oxytocic drug on the blood vessels. It must be stressed that the synergistic and additive vasoconstrictive effects of a vasoconstrictor and an oxytocic drug, when both are given, may be far out of proportion to the expected reaction to separate administration of either of these drugs.[3]

In addition to the above known possible causes of overloading of the cardiovascular system, other as yet unknown intrinsic factors may be involved in some of these cases, for a few patients received neither a vasoconstrictor nor an oxytocic drug.

Treatment of Postpartum Hypertension.—It was obvious almost from the beginning of the phase of the study which started in November, 1957, that the problem of postpartum hypertension resulting from the combined use of a vasoconstrictor and an oxytocic drug had to be treated not only symptomatically but definitively. The patients' headaches were intolerable and the hypertension dangerous. Neither the severe, persistent headache nor the hypertension was relieved by therapy with codeine, magnesium sulfate, meperidine hydrochloride, morphine, alkaloids of opium (Pantopon), phenobarbital (Luminal) sodium, or promethazine (Phenergan) hydrochloride either alone or in various combinations.

Because of the adrenolytic action of chlorpromazine (Thorazine) hydrochloride, it was decided to find out whether it would resolve the severe hypertension resulting from the combined use of a vasoconstrictor and an oxytocic drug. The intravenous route was selected, because these patients must be treated immediately if serious sequelae, e. g., hemiplegia, are to be avoided. Chlorpromazine hydrochloride (25 mg.) was given intravenously for the first time to a former nurse employee of the hospital who had developed postpartum hypertension with a blood pressure of 180/130 mm. Hg, a severe headache, and signs of mild disorientation. Methoxamine hydrochloride (12 mg.) had been given at initiation of the caudal anesthesia three hours prior to delivery, and ergonovine maleate (1/320 grain) had been given at the time of placental delivery. After administration of the chlorpromazine hydrochloride, the patient's blood pressure promptly returned to a normal of 120/70 mm. Hg and remained normal, but she became unresponsive for several hours, presumably because of the effect of the chlorpromazine. Her failure to respond was attributed to that drug, because she showed no evidence of a complication, such as cerebral accident, resulting from the hypertension, when she had recovered from the effects of the chlorpromazine eight hours later. Therefore, the dose given to other patients has ranged from 12.5 to 15 mg. This is given immediately intravenously, at a rate of 2.5 mg. every 15 seconds, until there is either a satisfactory reduction in blood pressure or 12.5 to 15 mg. of the drug has been given.

To calibrate the administration of the chlorpromazine hydrochloride, 1 cc. (25 mg.) of the drug is diluted to 10 cc. in a 10-cc. syringe by the addition of 9 cc. of isotonic sodium chloride solution or distilled water. Then each cubic centimeter of solution contains 2.5 mg. of chlorpromazine hydrochloride and may easily be injected as stated. If, after injection of 15 mg. of chlorpromazine hydrochloride, the patient's blood pressure has not fallen to normal, at least two minutes should be allowed to pass before more of the drug is given. Intravenous administration of chlorpromazine hydrochloride must be carefully done, especially if the effects of a subarachnoid block, an epidural block, or a caudal block are still present. Too large a dose of chlorpromazine or too rapid administration, or both, in the presence of one of these types of analgesia, may result in a precipitous fall in blood pressure.[3]

The indications for treatment with chlorpromazine hydrochloride are sustained elevation of the systolic blood pressure above normal, e. g., an increase of 30 to 40 mm. Hg or a sustained diastolic pressure of 90 mm. Hg or more, or both, with or without a severe, persistent headache. It is believed that the rise in diastolic pressure is the most significant component in the elevations of blood pressure and that the sustained elevation of the diastolic pressure is responsible for severe headache and rupture of a cerebral blood vessel. The onset of the effect of chlorpromazine hydrochloride has been rapid, usually occurring in less than two minutes. Ten patients in all have received chlorpromazine hydrochloride. In nine patients the blood pressure has returned to normal and remained so, but one patient, in whom the drug was effective but whose blood pressure rose again with subsequent oral administration of ergonovine maleate, 1/320 grain, required another injection of 12.5 mg. of chlorpromazine hydrochloride.

Need for Prophylactically Given Vasoconstrictor Drugs.—It was once believed that, since vasoconstrictor drugs did no particular harm in the patient who showed no evidence of disorders such as eclampsia, they could be given prophylactically to insure that the systolic blood pressure would not fall below 80 mm. Hg during labor; this, of course, was done to prevent fetal anoxemia.[4] Because of the severe sequelae from the combined use of a vasoconstrictor and oxytocic drug, the real need for prophylactic administration of a vasoconstrictor drug was determined in each of our patients.

From April, 1958, to October, 1958, the routine prophylactic use of vasoconstrictor drugs was discontinued and 727 caudal blocks were administered. Hypotension was treated when it occurred. Sixty-four (8.8%) of these patients developed hypotension with a systolic blood pressure of 80 mm. Hg or less. The fall in blood pressure was easily corrected. Sixty-two patients received ephedrine sulfate, 15 mg. intravenously and 35 mg. intramuscularly. Two received methoxamine hydrochloride, 12 mg. intramuscularly. There were no instances of fetal distress in babies delivered from these mothers. Ephedrine sulfate was selected as the preferred vasoconstrictor drug in most of these patients, since its duration of action is shorter than that of methoxamine hydrochloride.

During this period there were 15 (2%) instances of hypertension. Three patients had received ephedrine sulfate to correct hypotension due to caudal anesthesia induced one hour prior to their delivery but were not given an oxytocic drug at the time of delivery. Nine patients had received oxytocic drugs only (five were given ergonovine maleate, 1/320 grain, and four methylergonovine maleate, 0.2 mg.). Three patients had received neither drug. None of these 15 patients had severe hypertension and none met the requirements for treatment with chlorpromazine hydrochloride; had any of them met the requirements stated previously, the drug would have been administered.

Summary and Conclusions

Nine patients who had postpartum hypertension with rupture of a cerebral vessel after injection of a vasoconstrictor drug, or an oxytocic drug, or both, have been cited in the literature.[5] Nonetheless, from our experience and discussion of this problem with other physicians, it seems reasonable to conclude that most physicians are not aware of the dangers of administration of a vasoconstrictor in conjunction with an oxytocic drug. The factors that must be stressed are as follows: 1. If possible, postpartum hypertension due to the combined effect of a vasoconstrictor and an oxytocic drug must be prevented. The clinical severity of the symptoms of hypertension makes this desirable; the possibility of a subarachnoid hemorrhage makes it mandatory. 2. Prophylactic administration of vasoconstrictor drugs should be omitted when regional block anesthesia is used in vaginal delivery. When this was done, the incidence of hypertension dropped from 4.6 to 2%. Hypotension was not a problem in these patients. In a case in which a vasoconstrictor drug was used to correct hypotension due to the administration of caudal block anesthesia, the obstetrician was notified and he refrained from giving an oxytocic drug. While oxytocin has been recommended in preference to ergonovine or methylergonovine maleate when use of a vasoconstrictor drug is necessary, this study indicates that it, too, can be dangerous. 3. The physician anesthetist, the obstetrician, and, in particular, the nurses must be made aware of this problem and its significance. The nurse must immediately notify either the obstetrician or the physician anesthetist when hypertension or headache occurs in a patient. When sudden, marked elevation of blood pressure, particularly of the diastolic component, occurs, prompt treatment with chlorpromazine hydrochloride is mandatory. 4. While this paper deals primarily with administration of continuous caudal block anesthesia and vaginal delivery, the hazards of the concomitant use of a vasoconstrictor and an oxytocic drug exist regardless of the type of anesthesia induced or whether or not it is given to pregnant women or other patients.

Postpartum hypertension, frequently unrecognized in the form of a severe headache, is a general hazard accompanying delivery which can result in cerebrovascular injury. In a study of about 8,000 deliveries that had been performed under continuous caudal block analgesia, the complete and detailed records of 741 patients pointed to the conclusion that the combined effect of a vasoconstrictor and an oxytocic drug, given three to six hours apart at initiation of the caudal block and at the time of placental delivery, respectively, led to severe hypertension in 34 (4.6%) of 741 patients, one of whom also suffered cerebrovascular injury. Treatment with chlorpromazine hydrochloride, to prevent the severe and disabling complications of postpartum hypertension, is essential. These findings suggest that the need for prophylactic administration of vasoconstrictor drugs in conjunction with caudal block analgesia in obstetrics is doubtful.

RELATION OF DRUG RESISTANCE TO ENZYME ACTIVITY AMONG COLIFORM BACTERIA

NEW APPROACH TO PROBLEM

Harry Seneca, M.D., Hans H. Zinsser, M.D.
and
John K. Lattimer, M.D., New York

Aerobacter aerogenes, which readily undergoes mutations that increase its resistance to antibiotics, is also able to exist on certain substrates on which Escherichia coli cannot exist. Since Esch. coli mutates less readily and has less capacity for developing forms resistant to antibiotics, the question arises whether this relationship between mutability and substrate-preferences is generally valid. Fifty-one varieties of bacteria were grouped according to their ability to decompose urea and citrate in culture mediums and then tested for susceptibility to six antibacterial agents. Although some discrepancies were found, the suggested principle generally held true. Therefore the finding of citrase and urease activity in an organism is of practical significance. The fact that these enzyme systems are so important to some organisms suggests a new avenue of attack on drug-resistant infections.

Among bacteria commonly found in urologic patients there has been rapid development of resistance to all antibiotics available for clinical therapy.[1] This has led us to analyze, in greater detail, the type of metabolism manifested in particular by Aerobacter, Proteus, and Pseudomonas organisms. It has seemed logical to correlate the escape of these organisms from antibiotic control with their adaptation to survival on the relatively simple substrates to be found in high concentration in urine. Notable among the substrates of value for bacterial nutrition are urea, ammonium ion, and citrate ion. We have made a detailed analysis of the enzymatic capacities of organisms, provided from patients at the Squier Urological Clinic, to utilize ammonia, urea, and citrate. More subtle facets of vitiation of some antibiotics by the high salt concentrations present in the urine, such as the phosphate antagonism to the tetracyclines, have not been studied in detail but will form the basis for additional studies.

From the Department of Urology, Columbia University College of Physicians and Surgeons, and Presbyterian Hospital.

The capacity to mutate rapidly, shown by us in strains of Aerobacter aerogenes, may be linked to the simple substrates on which A. aerogenes can exist, but this is not easily susceptible of proof from the data available to us. Clinically it is apparent, however, that Escherichia coli, which is unable to mutate with ease and probably has a lower rate of mutation, is unable to exist on the simple substrates which A. aerogenes can tolerate. Bacterial mutation induced by changes in the available substrates has been evidenced by the antagonisms of these by other naturally occurring substrates.[2] There is excellent correlation between the capacity to utilize both citrate and urea and the capacity to develop resistant forms.

Methods

Antibacterial spectrums were determined with use of the tube dilution method for establishing the minimum inhibitory concentrations (MIC) of several antibiotics (tetracycline, chloramphenicol, erythromycin, and a combination of equal amounts of penicillin and streptomycin) and two antibacterial chemicals (sulfadiazine and nitrofurantoin). These drugs were serially diluted in sterile Kahn tubes containing 0.5 ml. of brain-heart infusion broth. To each tube was then added 0.5 ml. of inoculum of overnight culture diluted 10^{-3} in brain-heart infusion broth, in the case of the antibiotics and nitrofurantoin, and 10^{-10} for sulfadiazine. Final concentrations for sulfadiazine ranged from 5 to 0.19 mg., and for the other drugs from 100 to 0.19 mcg., per milliliter. These tubes were incubated overnight and readings for drug susceptibility were taken.

An enzyme profile, which made use of their ability to split urea and utilize citrate either in combination or singly, was determined for each of the varieties of bacteria tested. Variations in the amount of urease activity were also taken into account.

In the test for ability to split urea, a urea agar medium was employed and the test for citrase activity on the medium was done on a citrate agar medium.[3] Slants of urea agar and citrate agar were streaked from broth cultures and readings were taken after 24, 48, 72, and 96 hours of incubation at 37 C. The following categories were differentiated: no growth, growth, change of color of slant, and change of color of both slant and butt of the culture tube. If urea was split by the organism, the phenol red indicator caused the medium to become red. When there was excessive urease activity manifested, the entire medium became red; but if the urease activity was on a limited scale, only the slant became red. In the citrate medium, the indicator was bromothymol blue. When the citrate in the medium was utilized, it indicated the presence of citrase activity, which caused the medium to become blue (the original color of the medium was green). Some bacteria showed no evidence of citrase or urease activity on these mediums.

Results

In table 1 the bacteria tested are provisionally classified on the basis of ability to split urea or utilize citrate, or both. The group-1 organisms both split urea and utilized citrate, and their urease activity was the greatest of any of the strains tested, as manifested by the fact that not only the slant but also the butt of the tube underwent a color change because of the indicator in the medium, even under reduced aerobic conditions. In this group were the strains of highly resistant B. proteus organisms recovered from the urinary tracts of patients at the Columbia-Presbyterian Medical Center and designated in the table as B. proteus columbiensis, with several strains designated by the names Reilly or Dobriner or such numbers as 271 and 198, plus the letters CP (Columbia-Presbyterian). According to Bergey, these organisms are Proteus vulgaris, Proteus rettgeri, and Proteus mirabilis. All of these strains were highly resistant to most of the drugs tested. A strain of B. proteus OX2, obtained from the U. S. Army, also fell into this group, although, as far as is known, this strain has never been exposed clinically to any antibiotics.

Group 2 was made up of organisms which split urea; in which the urease activity was of only moderate intensity, causing a color change in only the slant of the culture; but which also utilized citrate. Aerobacter aerogenes was the member of this group which showed the maximum drug resistance. Klebsiella pneumoniae also showed both urea-splitting activity (mild) and citrate-utilizing ability but was only moderately resistant to the drugs tested. We cannot yet say whether this organism represents an exception which runs contrary to the proposed thesis that capacity for drug resistance and these enzyme activities exist together or whether this organism has an unsuspected capacity for developing resistance to high levels of drugs. Some strains of Pseudomonas aeruginosa have urease and citrate activity.

Organisms in both groups 3 and 4 split urea but failed to utilize citrate. Those in group 3 differed from group 4 in that they showed less intense urease activity. In group 3 was B. proteus morganii and in group 4, B. proteus OX 19.

Organisms in group 5 did not split urea but did utilize citrate. The most resistant members of this group tested were strains of Pseudomonas aeruginosa, which definitely represented an exception to the thesis and were highly resistant to the drugs used but seemed highly sensitive to colistine methanesulfonate. Also in group 5 were Vibrio cholerae, strains of Inaba and Ogawa and a nonagglutinable vibrion, organisms of the genus Salmonella, and Alcaligenes fecalis. These organisms also utilized citrate and did not split urea but were relatively more sensitive to sulfadiazine, tetracycline, and chloramphenicol.

In group 6 were organisms which neither split urea nor utilized citrate. This group contained Escherichia coli, Eberthella typhosa, Shigella dysenteriae, Vibrio cholerae El Tor, and B. proteus OXK. This group as a whole showed high susceptibility to tetracycline and chloramphenicol and variable susceptibility to sulfadiazine.

Comment

When each new antibiotic has been introduced, we have classified it on the basis of its antibacterial spectrum (see figure). With increasing usage of any one drug the spectrum of each drug has been reduced.[4] The fact that an orderly arrangement of organisms and drugs can be made suggests a fundamentally shared capacity in the organisms susceptible to the particular drug and in the host receiving them.

It is recognized that many more strains of these various families of organisms must be surveyed in order to test the suggested hypothesis that the capacity for drug resistance and urease and citrase activity usually exist together. Thus far, with the exception of Klebsiella and certainly Pseudomonas, it appeared that the bacteria which were active splitters of urea and utilizers of citrate either were drug-resistant or mutated easily to drug-resistant forms. Those organisms which only split urea (such as B. proteus morganii and OX 19) showed less tendency to mutate to highly drug-resistant forms than those which both split urea and utilized citrate. The same was true of the organisms which only utilized citrate, but these organisms in general tended to be more drug-susceptible than those which split urea as well. Those organisms which neither split urea nor utilized citrate tended to be much more drug-susceptible, and in other experiments thus far in this laboratory it has not been possible to produce mutants which were resistant to high levels of drugs, among the organisms in this group. The susceptibilities are shown in table 2.

Further discrepancies exist in groups 2 and 5, in that some strains in group 2, e. g., Klebsiella pneumoniae, which utilized citrate and split urea are drug-susceptible, while in group 5, in which only citrate is utilized but urea is not split, Ps. aeruginosa is drug-resistant, while V. cholerae, Salmonella, and A. fecalis are drug-susceptible.

Summary

Urologic infections with drug-resistant strains of Bacillus proteus, Aerobacter aerogenes, and Pseudomonas aeruginosa constitute a serious clinical problem. These families of bacteria have been demonstrated to mutate more rapidly to highly drug-resistant forms than such organisms as Escherichia coli. These particular bacteria also show enzymatic activity not demonstrated by Esch. coli. This is manifested, for example, by the splitting of urea (by urease) by some of these bacteria and by the capacity to utilize citrate as the sole source of carbon (via citrase) by still other bacteria of this group. The mechanism which permits these enzymes to act on substrates in their environment may be related not only to the presence of these enzymes within some of the bacteria, but also to differences in permeability of the bacterial cell membrane which permit these enzymes to act on the substrate.

The presence of citrase activity has long been used as a means of identifying Ps. aeruginosa, and it now appears possible that quantitative and qualitative aerobic and anaerobic differences in urea-splitting ability may be a means for identifying and further subdividing the varieties of B. proteus, A. aerogenes, and Ps. aeruginosa.

Urease and citrase activity may be related to the capacity of these bacteria to mutate more readily to forms which are resistant to high levels of antibiotics. If further observation proves this to be consistently true, it may open the door to a new avenue of attack by way of these enzyme systems, which could have considerable therapeutic value in our campaign against the rising tide of drug-resistant infections.

BACTERICIDAL ULTRAVIOLET RADIATION IN THE OPERATING ROOM

TWENTY-NINE-YEAR STUDY FOR CONTROL OF INFECTIONS

Deryl Hart, M.D., Durham, N. C.

Twenty-three years of experience with ultraviolet radiation in operating rooms has led to the conviction that this method of decontaminating the air is both effective and safe. There have been no serious or permanent deleterious effects on the eyes or skin of the operating room personnel, but there has been a striking reduction in postoperative complications and deaths attributable to infections. Fatal infections in clean operative wounds numbered 17 in the 5½ years preceding, and only 2 in the 5 years following, the adoption of ultraviolet radiation for this purpose. Records of 4,585 operations and of nearly 700 postoperative deaths during a 10½-year period were analyzed and showed a striking superiority of results in the operating rooms in which ultraviolet radiation was used. With properly chosen fixtures, properly placed, radiation at wave lengths from 253.7 to 290.0 mμ can be delivered with an intensity of 18 to 30 microwatts per square centimeter at the operative site. No evident permanent damage to personnel or patients has been detected during 23 years of daily use of such radiation in either the one original or the 15 now used operating rooms so equipped.

With the present widespread distribution of antibiotic-resistant staphylococci, the surgeons, hospitals, and patients, insofar as these organisms are concerned, are on the way back to where they were before the introduction of sulfonamides and antibiotics. However, we in the Duke Hospital have had no serious staphylococcic problem in the operating room since 1936, because, in our opinion, of the continuous use of ultraviolet radiation both during and between operations to control, in this area, the spread of bacteria by way of the air. The many recent reports in the literature listing a relatively high percentage of wounds infected with staphylococci, the universal concern over the present and potential dangers from these organisms, the apparent lack of information about the role of the air as a route of bacterial spread despite many reports in the literature, and the lack of knowledge in published work on the control of airborne infections by the use of ultraviolet radiation in the operating rooms bring this problem forcibly to our attention.

A recent article,[1] duplicating some of my published work, emphasizes the importance of carriers, their role in the contamination of the air, and the value of ultraviolet radiation in killing the bacteria in the air. The authors stated that its use between operations will cut down the bacteria count and allow each operation to start with bacteria-free air. However, it is also stated that, "Because of the deleterious effects of such rays on the eyes and skin of operating room personnel, it is not practicable to continually irradiate the entire operating room during an operation." This again emphasized the importance of presenting at this time a summary of experience with the use of ultraviolet radiation in the operating room at Duke Hospital during operative procedures for the past 23 years. The results obtained indicate that ultraviolet radiation and other measures used to limit the spread of bacteria by way of the air can go far toward solving the problem of bacterial contamination in clean operative wounds and eliminating the resultant so-called unexplained infections, which are usually with staphylococci.

Early Attempts to Control Unexplained Infections

During the period from July 21, 1930, to Jan. 15, 1936, *infections in these "clean" operative incisions*, predominantly with Staphylococcus aureus, were a continuous problem in the Duke Hospital and caused 17 deaths (1.3% of the patients having "clean" operations of the types analyzed). There was a definite tendency of fatal wound infections to occur in groups after "clean" operations performed without ultraviolet radiation. These occurred during the cooler months when there are periods of high staphylococcic and at times hemolytic streptococcic contamination of the upper respiratory tracts and the air of occupied areas. All of these infections were overwhelming, leaving no doubt as to the cause of death (meningitis, 7; proved septicemia, 5; suspected septicemia [with chills but without demonstrated positive blood culture], 2; extensive local invasion without proved positive blood culture, 3; and peritonitis, 2).[2] The following organisms were cultured from these patients (wound, spinal fluid, or blood), the numbers indicating the number of patients infected with the given organism: hemolytic Staphylococcus aureus, 9; Staphylococcus aureus, 5; Staphylococcus albus (meningitis), 2; gram-positive cocci in clumps (meningitis), 1; beta hemolytic streptococci, 4; gram-positive Diplococcus, 1;

From the Department of Surgery, Duke University School of Medicine.

Escherichia coli communior, 1. Mixed infections accounted for a total number of organisms greater than the number of patients infected. Each of the three patients having an orthopedic operation had a mixed infection, all with beta hemolytic streptococci, while two showed in addition Staph. aureus and one Escherichia coli. One patient having a laparotomy was infected (both wound and peritoneum) with Staph. aureus and beta hemolytic streptococci.

There were periodic exacerbations in the infection rate, and on two occasions (see table 1, 1933-1934 and 1935-1936) these were of sufficient severity to cause curtailment of operations in patients requiring extensive procedures, except in those with urgent conditions. At first we held the false impression that the rooms were primarily contaminated, and we attempted to rid them of bacteria by cleaning, but we were soon convinced that the occupants were the primary source of the offending organisms and that the room and air contaminants were derived from the occupants.

Table 1.—*Fatal Infections in Clean Operative Wounds, Duke Hospital, July 21, 1930, to Jan. 15, 1936 Without and Jan. 15, 1936, to Jan. 15, 1941, With Use of Ultraviolet Radiation*

* Isolated occurrences.

† Isolated occurrences—infections probably limited by the use of ultraviolet radiation in most large clean operations.

While attempting to control this "old problem" we reevaluated every step of the "then generally accepted" aseptic technique.[2] At frequent intervals cultures were taken to check everything connected with the activity—sterile supplies, uniforms, gowns, masks, shoes, water, floors, walls, the Celotex ceiling in adjacent corridors, the hands of the personnel, and the skin of the patient, before preparation, after preparation, and at the end of the operative procedures. Cultures were also taken at frequent intervals to show any contamination of the incoming and outgoing air, the ventilating system, the air in the operating rooms, and the air of many other areas of the hospital.[2] Cultures of the upper respiratory tracts of personnel and patients were taken in an attempt to identify persistent carriers of pathogenic bacteria, with the objective of eliminating them from the operating room. This was done to reduce these infections and to determine the importance of carriers as a source of the air contamination and wound infections.[3]

Even though no serious defects were found, other than the frequent presence of carriers, the inadequacy of masks, and the constant air contamination, all techniques were made more rigid in every way and special emphasis was placed on the following additional requirements. All personnel, and not just the doctors and nurses, were given, each day, freshly laundered uniforms, free of pathogenic bacteria. Masks covering the mouth and nose were worn at all times by everyone entering the operating room area, and during extensive operative procedures double masks were worn. No talking was permitted during an operation. Extensive operations were performed only as first operations in the morning; if not urgent they were delayed until the summer or at least until cultures showed that the air contamination was low. Visitors were not permitted and personnel was kept to the minimum.

In addition, the Celotex ceiling in the corridors of the operating suite was replaced by plaster for more effective and easier cleaning; double doors were installed to limit air currents from the rest of the hospital; the operating rooms were ventilated with air under pressure and free of bacteria; they were painted frequently; and the walls and ceilings were washed weekly or more often. It soon became apparent that without any treatment other than ventilation, the air of the unoccupied room became almost free of settling bacteria within a few hours[3] and that in the rooms in which the floor was cleaned with an antiseptic solution, bacteria could not be stirred up in appreciable numbers by mechanical agitators such as electric fans.

Correlation of Wound Infections with Contaminants from Respiratory Tract

However, with human occupancy, the air contamination rose rapidly.[4] Furthermore, cultures showed that the air in the occupied operating rooms was the most heavily contaminated of any area in the hospital, that the contaminants were predominantly staphylococci, and that the degree of this contamination was directly related to the time of the year, the number of occupants, and the duration of occupancy. This contamination could be reduced by increasing the volume of washed and filtered air which was delivered to the room practically free of organisms.[5] Culture plates exposed to the outside air near the air intake on the roof of our hospital, located in the country with wooded surroundings, showed predominantly fungi and nonpathogenic bacteria and practically no staphylococci.[5a] It was shown, to our satisfaction, that this condition of air contamination in the operating room was brought about by occupancy and that these rooms were not otherwise unduly contaminated. It was further shown by cultures in over 30 hospitals in the United States that this was a widespread, if not universal, condition.[5a]

It was soon shown that the respiratory tract contamination of personnel and patients with Staph. aureus was lower in the summer months, with fewer carriers, and higher in the colder months, with a greater percentage of carriers.[6] There was a direct correlation between the respiratory tract contamination of the occupants, the air contamination of the occupied rooms, and the percentage of infections in clean wounds, all of which showed simultaneous peaks, with the infection rate at times reaching epidemic proportions (table 1).[7]

These studies have extended from 1930 to the present time, and as a result we at the hospital have introduced a number of additions to our aseptic precautions, some important and some of questionable value, while others have been found to be unnecessary and have been discontinued. After the development of a technique to control the spread of bacteria by way of the air, many of these requirements were relaxed, and there was no appreciable return to the previous high infection rate.

Addition of Ultraviolet Radiation to Aseptic Technique

During 1934 and 1935, preliminary studies[8] on the effect of bactericidal ultraviolet radiation on bacteria, fungi, and animal tissues were carried out. In 1936 bactericidal ultraviolet radiation was introduced into the operating room on an experimental basis, with the first operation on a patient performed in such a field on Jan. 15. Since that time, infections in clean wounds have been almost eliminated. During the next five years there were only two deaths from infections in clean wounds (craniotomy, April 20, 1936, and radical neck dissection, Dec. 9, 1937), but ultraviolet radiation was not used during either of these operations. However, the use of ultraviolet radiation in most of our extensive clean operations (2,600) during this time gave protection to patients for whom it was used and may have accounted for the absence of other fatal infections, particularly at the time of these deaths. For what might have occurred during periods of high air contamination, see the groupings of fatal infections in table 1. Not one of these 19 fatal infections followed operations performed in May, June, July, or August, when the air contamination is uniformly low; six occurred in a period of 72 days (the months of November, December, and January) during the colder season of 1933-1934 and three in a period of 36 days (Sept. 16 to Oct. 22) in the autumn of 1935 when the air contamination was demonstrated to be high.[9] (There are in the literature periodic reports on air contamination with pathogenic or at times "pyogenic" bacteria. These soon became lost in the mass of publications and have been ignored to a great extent.) Both of these severe epidemics caused us to restrict extensive operative procedures unless treatment was urgent, a step which probably saved additional patients from infection and possible death.

Each of the two fatalities in January, 1934, followed an operation at the time considered to be urgent. The first was for carcinoma of the breast, for which a physician member of the family wanted immediate operation despite the known danger from heavy contamination of the air in the operating room. The second patient had extremely severe trigeminal neuralgia (tic douloureux) and was operated on only after two previous admissions at five-day intervals with unsuccessful attempts to obtain relief by alcohol injections. After the fatalities in October, 1935, patients already admitted for extensive procedures such as thoracoplasties were discharged until the next summer or until completion of the installation of ultraviolet radiation in an operating room before having their operations.

Further analysis of table 1 shows that of the 17 deaths occurring before the use of ultraviolet radiation, only 2 were isolated occurrences separated from other such deaths by intervals of from five to nine months, while the other 15 showed some grouping tendency as to time but not as to service, except in the epidemic in 1933-1934 when there were three deaths on the thoracic service after extrapleural thoracoplasties. During the same period, however, there was one such death each on the general, orthopedic, and neurological services, demonstrating that these infections were caused by a general condition present in all operating rooms. It has been demonstrated[2] repeatedly that heavy air contamination is a general and not a local condition, rising and falling in all operating rooms simultaneously but not necessarily to the same degree. During periods with a high infection rate, there was an increase in the percentage of nose and throat carriers of Staph. aureus in the hospital population, at times up to 80%.[4a] It was also recognized that one constant, heavy nose and throat carrier of highly pathogenic bacteria can contaminate the air wherever he goes and is a constant hazard in the operating room.

During the years 1936 through 1946, various aspects of this study were presented before surgical groups and published in over 15 articles in several journals. Also, three scientific exhibits were shown, each of which received some recognition (first award at the Southern Medical Association meeting in 1936, honorable mention at the American Medical Association Annual Meeting in 1937, and the silver medal [second award] at the A. M. A. Annual Meeting in 1942, at which time comparative results covering five and one-half years without and five years with use of ultraviolet radiation were presented).[7a] This work as presented and published can be divided into the following four main divisions: (1) background investigations to determine the most common source and route of spread of the offending organisms; (2) procedures, including the use of ultraviolet radiation, for reducing the spread of these organisms by way of the air and limiting the seeding of the open wound; (3) safeguards necessary to protect patients and personnel exposed to ultraviolet radiation, making it possible to use this during the operation; and (4) results obtained by controlling the spread of bacteria by way of the air in the operating room.

Background Investigations.—In investigations of the source of the organisms and the route of spread the following points were brought out. There was continuous sedimentation of organisms, predominantly staphylococci from the air of the occupied room.[10] The incoming washed and filtered air supplied was relatively free of bacteria.[11] The bacterial flora in the outside air were predominantly fungi and nonpathogenic bacteria and were different from the flora in the air of the operating rooms, predominantly staphylococci, the group of organisms causing most of the wound infections.[4b] The concentration of the staphylococci in the air could be reduced by forced ventilation but not sufficiently to protect the wound from seeding with these organisms in sufficient numbers to cause suppuration in an appreciable percentage of patients.[12] Contamination of the air with staphylococci, with resultant seeding of the open wound, depended on the presence or recent presence of human beings in the area. With cessation of occupancy, the air contamination diminished rapidly. In the well-kept operating room and in the absence of human beings, air contamination could not, by mechanical agitation of the air, be built up to the former level attained during occupancy.[13]

The air of the operating room showed the highest level of staphylococcic contamination of any area in the hospital in which cultures were made, probable because of the greater concentration of people.[2] The concentration of this bacterial contamination of the air varied with the number of occupants,[5a] the time of year (which influenced the number of carriers),[13] and the percentage of carriers and the degree (type and number of the organisms) of contamination of their upper respiratory tracts.[2]

Control of Contamination.—Studies concerned with procedures for the control of air contamination showed the following facts. The average mask, even when two are worn, is inadequate to control air contamination.[14] Talking increases the build-up of the air contamination even when conventional masks are worn.[15] We were unable to develop a mask which was an efficient bacterial filter and which at the same time permitted free respiratory exchange.[15] The wearing of a helmet and use of suction beneath this to remove from the room the exhaled air containing bacteria was tried but found to be impractical.

Forced ventilation with clean air, by a process of dilution, reduced but did not, in the presence of continuing contamination from occupants, reduce adequately the level of this air contamination.[16] With occupancy, in the absence of ultraviolet radiation, the level of air contamination was built up so rapidly that little was accomplished by freeing the air of the operating room of most bacteria by (*a*) sedimentation followed by antiseptic mopping, requiring a longer period of closure without occupancy; (*b*) forced ventilation and a dilution process to supplement sedimentation, requiring a shorter period of closure without occupancy; or (*c*) sterilization of the air with ultraviolet radiation, a procedure which requires only a short period of unoccupied closure.[14a]

Direct exposure of staphylococci sprayed on a Petri dish of blood agar and exposed to ultraviolet radiation (24-30 microwatts per square centimeter) at the operative site for one to five minutes killed over 99% of the organisms, the variation in time required depending on the density of the inoculation and the presence or absence of clumping.[17] Many bacteria and fungi tested were killed with a suitable exposure to an intensity of ultraviolet radiation that could be used safely in the operating room.[18] With this intensity of radiation, 24-30 microwatts per square centimeter at the operative site in the occupied operating room during use, the viable colonies of organisms seeding on an exposed flat surface (Petri dish of blood agar) during one hour and surviving continued exposure were reduced in different parts of the room from 80 to about 95%, the variations depending on the type of installation and the intensity of distribution.[17] With this intensity of radiation at the operative site, the viable colonies of organisms seeding on a Petri dish of blood agar exposed in any part of the room and shielded from the radiation were reduced by over 75%, with use of a suitable intensity distribution. Most of the organisms in the air were killed in the air, apparently others were attenuated,[19] and most of the rest were killed after seeding on an exposed culture plate or other surface.[20]

Sterilization of the air within the air ducts is of value if air is being recirculated and the contaminating organisms are not removed by the air-conditioning system.[5a] However, such an installation will not give adequate protection, since it has been shown that the use of all fresh air, free of bacteria, did not reduce the bacterial content of air in the occupied operating room to a level which rendered it safe for all large operations.[11] Indirect radiation of only a part of the air in the operating room (with shading of the patient and of the head area of the personnel) was of some value but did not sufficiently reduce the number of viable organisms (only 30 to 50%) to afford adequate protection for the open wound. The radiation killed the organisms and did not inhibit their growth by its effect on the culture mediums.[4b]

Safeguards for Patient and Personnel.—The eyes of the personnel must be protected from direct radiation by shading (an eye shade is adequate) and should be protected from reflected radiation by glasses (any type of glass other than special glass made for transmission of ultraviolet rays is adequate). Otherwise, they may be burned to such a degree as to require local anesthesia. However, we have never detected any permanent damage to the cornea, lens, or conjunctiva, even though many of the personnel wear no glasses but only an eye shade, and some persons have been using ultraviolet radiation during operations for over 23 years.[17] The eyes of the patient must be protected by closure and covering with suitable material (a routine procedure employed by anesthetists during general anesthesia, but some form of protection must be used during the entire time of exposure to ultraviolet radiation).[17]

For frequent and long periods of exposure, the skin of the personnel and patient should be covered or shaded. However, an exposure of several hours is tolerated with only an erythema. There is considerable variation in the reaction, depending on the pigmentation of the individual person. No blisters have occurred and no evident permanent damage has been detected during the past 23 years of daily use in the one original to the 15 presently used operating rooms so equipped. There are many sun screen lotions that block varying percentages of the radiation. These can be used but should be suitably tested to determine whether they offer protection from radiation at 2,537 to 2,900 A. Some of these are quite effective, but they are not necessary, even though the circulating operating room personnel may not cover their arms and never cover their hands. These persons limit the total amount of exposure to which they are subjected by occupying the area of low intensity of radiation at the periphery of the room, when their duties permit.[14a] The exposed tissues (those of experimental animal and patient such as skin, peritoneum, muscle, brain, and spinal cord) have never, to our knowledge, been damaged seriously during the time necessary for our operative procedures, with use of an intensity of 18 to 30 microwatts per square centimeter at the operative site. With or without the use of ultraviolet radiation, it is desirable to protect exposed tissues from drying, and covering for this purpose also protects them from exposure to the radiation.[21]

Operating rooms with high ceilings permit the radiation units to be mounted at a greater distance above the patient and personnel. Such mountings require a larger output of radiation in order to obtain an intensity of 18 to 30 microwatts at the operative site. As compared to the units mounted at a lower level, these give a very high intensity in the upper air, where bacteria are carried by convection currents, a much lower intensity on the heads of the personnel, and a higher intensity on the floor and the periphery of the room. Such an intensity distribution gives a greater reduction in the bacterial contamination of the air of the entire room and at the same time simplifies the problem of protecting the personnel, by exposing their heads to a lower intensity and by making it easier to shade their eyes, since the rays come from a higher level.[12]

Table 2.—*Infections and Deaths from Infected Wounds After Clean Operations Performed With and Without Bactericidal Radiation, from July 21, 1930, to Jan. 16, 1941*

*Rate of infection in this group was low, since most of the patients having operations likely to become infected were in the larger group in which ultraviolet radiation was used (2,460 primary incisions and 140 reopened wounds).

†The use of ultraviolet radiation was extended to operations which, by their nature, were contaminated, and there were in addition over 200 such operations not included in this chart.

‡The arrows indicate the comparative results without (above) and with ultraviolet radiation (below).

§Reopened wounds have a potential source of contamination from bacteria entering either during the previous operation or along the skin sutures between operations. Although there was great improvement after the use of ultraviolet radiation in these operations, the results were not as good as for the clean primary incisions.

Results in Reducing the Frequency and Severity of Infections

Results.—The results obtained by the use of ultraviolet radiation have been the elimination of deaths from unexplained infections in clean wounds (tables 1 and 2), a reduction in the infection rate in clean operations (table 3), fewer systemic and local reactions in patients having clean operations and not showing signs of gross suppuration (fig. 1 and 2),[7a] and a reduction in the number of infections and the severity of reactions in patients with grossly contaminated wounds. The condition of the wound as well as the amount and type of bacterial seeding influenced the infection rate, but in all types of wounds great improvement was brought about by the use of ultraviolet radiation to limit seeding of the wound and the exposed sterile field.

To obtain the statistics on results, the records of patients having 4,585 operations performed during the period of July 31, 1930, through Jan. 15, 1941, were analyzed. In these, the ratio of operations performed with to those without ultraviolet radiation was about 3:2 (table 2). Also, to be certain that no death from an infection in a clean wound (table 1) was missed, the record of every patient who died (almost 700) after a surgical operation (46,369) during this 10½-year period was analyzed according to the cause of death.

Table 3.—*Comparison of Postoperative Infection Rates With and Without Use of Ultraviolet Radiation for Different Types of Clean Operations, July 21, 1930, Through Jan. 15, 1941*

	Infection, %	
	Without Radiation	With Radiation
Thoracoplasty, first stage, and radical mastectomy	32.0	0.35
Orthopedic	16.5	0.74
Neurosurgical	9.0	0.22
Herniorrhaphy*	8.3*	0.00
Thyroidectomy	1.8	0.00
All operations	11.6	0.24

* Group includes inguinal, femoral, umbilical, and postoperative hernias.

Deaths from Unexplained Infections: When ultraviolet radiation was not used, the postoperative mortality from overwhelming infection after clean operations was 1.12% (19 deaths after 1,782 operations: craniotomy, 7; first stage thoracoplasty, 4; second stage thoracoplasty, 1; laparotomy in debilitated patients with ascites, 2; radical neck dissection, 1; radical mastectomy, 1; arthroplasty of hip, 1; fusion of knee, 1; and osteotomy of femur, 1). Of the group developing infections, 9.18% died (19 deaths after 207 infections) (table 2). In contrast to this, when ultraviolet radiation was used there was no death from infection after about 2,600 such operations (primary incisions and reopened wounds) performed between Jan. 15, 1936, and Jan. 15, 1941 (table 2).

Reduction in Percentage of Infections: When ultraviolet radiation was not used in the operating rooms at Duke Hospital, and despite all our efforts and precautions, the infection rate in clean cases was 11.6% (207 infections, 1,782 operations) (tables 2 and 3). Most of these were mild or moderate, but many were severe, as indicated by the mortality (9% of those infected) (table 2). One hundred twenty-two positive cultures were obtained from these wounds and recorded in the charts, with five patients showing mixed infections, giving a total of 127 organisms cultured.[7a] (Frequently, in the early cases, a culture was not taken if the infection was mild, and many of the orthopedic patients were in a cast until after discharge. The infection was found on return for an office visit but a culture was not taken.) Only 11 of these wounds showed an infection without staphylococci being present (streptococcus, 2 [1 also showing Esch. coli]; Esch. coli, 3; Bacillus proteus, 2; Bacillus subtilis, 2; Pseudomonas aeruginosa, 1; and gram-positive diplococcus, 1).[7a] The percentage of infections and their severity were influenced by many factors, including

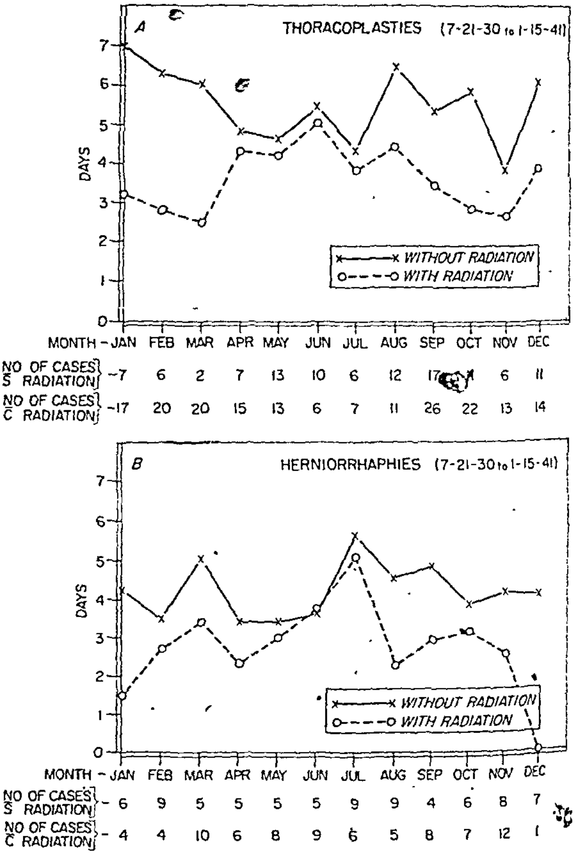

Fig. 1.—Average duration of temperature elevation for patients operated on each month with and without radiation. Greatest reduction brought about by use of ultraviolet radiation occurred during periods when air contamination was high, and least reduction occurred during periods when air contamination was low. During latter period, bacteria-laden perspiration not controlled by ultraviolet radiation was factor in wound contamination. Only once in these 24 recordings did average duration of temperature elevation for any irradiated group equal or exceed average for comparable nonirradiated group (hernia repairs during June by one-tenth of a day).

the susceptibility of the areas exposed (e. g., meninges), the magnitude of the operation, the trauma produced, the effectiveness of procedures for hemostasis, the presence of drains or other foreign material, the amount of motion in the wound after operation, the amount of bacterial inoculation, and, probably most important of all, the virulence of the seeded organisms versus the local and systemic resistance of the patient.

As contrasted to this, in patients with clean primary incisions in which ultraviolet radiation was used, the infection rate was only one-fourth of 1% (6 infections after 2,460 operations)[22] (tables 2 and 3) and most of the infections that occurred were mild.[23] In this group there was no death attributable to infection. Seven organisms (Staph. aureus, two; hemolytic Staph. aureus, two; Staph. albus, one; beta hemolytic streptococci, one; and organism undetermined, one) were obtained from five patients, the culture from one patient showing no growth while two patients had a mixed infection. After the 140 operations involving reopening of a wound, there were nine infections, with only eight identified organisms (Staph. aureus, three; hemolytic Staph. aureus, three; and Staph. albus, two); one patient's culture showed no growth (table 2).

Results in Reducing Local and Systemic Reactions

Fewer Systemic and Local Reactions.—As an additional method of evaluating ultraviolet radiation for air sterilization or, more correctly, "air sanitation" as an addition to aseptic technique, a comparison was made of the reactions of patients after operations performed in a field of ultraviolet radiation with the reactions of others having operations performed with use of a similar technique but without ultraviolet radiation.[21] As examples of this, the findings are given here for two types of operations—first stage thoracoplasty (extensive operations with severe trauma and poor hemostasis, with extensive areas of tissue exposed to seeding, and with much postoperative motion in the wound) and inguinal herniorrhaphy (less extensive operations with minimal trauma and good hemostasis, limited tissue exposed to seeding, and little postoperative motion in the wound). Every patient in each group operated on during the period July 21, 1930, through Jan. 15, 1941, was included.

In order that a totally objective analysis be obtained, the temperature charts, previously recorded by the nurses as part of their routine care of the patients, were analyzed, first, as to duration of any postoperative temperature elevation above the preoperative level (fig. 1) and, second, as to the percentage of postoperative temperature elevations above 37.5 C (99.5 F) recorded during eight days after operation (fig. 2).[24] The patients having each type of operation were further divided into 12 groups by month of operation to permit correlation of any improvement in the patient's reaction with the possible reduction in the level of bacterial contamination of the air of the operating room. The average duration of the postoperative temperature elevation above the preoperative level and the percentage of recordings showing some elevation were much less in the groups in which ultraviolet radiation had been used (fig. 1 and 2), the percentage of improvement showing some relationship to the improvement possible in the contamination of the air. That is to say, the greatest improvement occurred during the colder months, when the air contamination was high.

In these comparisons, the ultraviolet-irradiated groups showed only slight improvement over the nonirradiated groups in both duration and elevation of temperature during the warmer months when the air contamination was normally low, but bacteria-laden perspiration in the uncooled operating rooms in that period was profuse and a source of wound contamination not controlled by ultraviolet radiation. Cultures from the skin or gown, wet with perspiration, at times showed innumerable colonies,[24] most frequently of Staph. albus. These organisms were, in general, only mildly pathogenic but were capable of producing a local and systemic reaction usually short of visible evidence of sup-

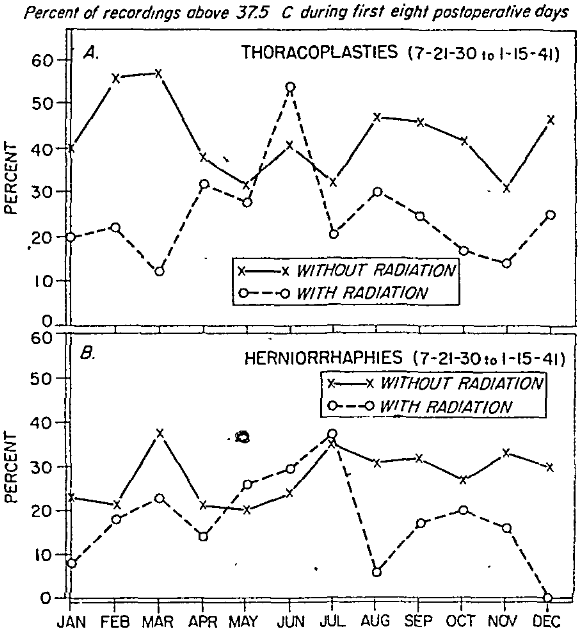

Fig. 2.—Comparison of temperature reactions after operations performed with and without bactericidal radiation. For each group of patients every temperature recording above 37.5 C was tabulated and plotted as percentage of total number of temperatures taken in group during first eight days after operation (4, 8, and 12 o'clock, day and night). For patients undergoing thoracoplasties, there was only one month (June) and for those undergoing herniorrhaphies three months (May, June, and July) in which percentage of temperature elevations above 37.5 C (99.5 F) in irradiated patients was slightly greater than percentage of each elevation in nonirradiated groups. All of these were in warmer months, when contaminated perspiration in uncooled operating rooms of that time may have been more serious route of wound inoculation than air, with its low contamination with pathogenic bacteria.

puration. However, if either the patient or one of the staff has a virulent skin contaminant, this may be a source of serious infection.

Improvement in Grossly Contaminated Wounds.—While we do not as yet have statistics for proof, the composite clinical impression of the surgeons is that, even for the patients having an operation which necessarily gives a contaminated wound (e. g., open resections of the gastrointestinal tract and pneumonectomy), the number and severity of infections and other local and systemic reactions have been reduced greatly by the use of ultraviolet radiation. The general, thoracic, neurological, and orthopedic surgeons at Duke Hospital now use ultraviolet radiation routinely in such operations, believing it desirable not to mix the flora already present within the patient with exogenous flora from the contaminated air. The latter, predominantly staphylococci, either alone or in combination, are probably, in most instances, more pathogenic for the patient and, therefore, liable to induce a greater reaction.

Comment

To those of us who went through the trying experiences with infections at Duke Hospital from 1930 to 1936, the results obtained by the use of ultraviolet radiation have been nothing short of miraculous. Each surgeon who has used this radiation has done so by his own request, and whenever it has been introduced on any service at Duke Hospital, the improvement in results has been immediate and continuous. No member of the staff who has once started using this addition to aseptic technique has given it up, and we now have 15 operating rooms so protected.

Within the past few months, I have been asked repeatedly why, if we still use ultraviolet radiation, no recent reports have been given in the literature. Others have told me that in conversations the statement has been made to them that we must have given it up since we no longer publish reports on the subject. The explanation for our silence is that after the presentations listed, the last of which came out in 1946, it was my opinion that our findings had been presented adequately and that the need for, the effectiveness of, and the safety of ultraviolet radiation as a part of aseptic technique had been proved. Furthermore, it was our opinion that if members of the profession chose to accept the heavy seeding with viable pathogenic bacteria sedimenting from the contaminated air and then to attempt to control the growth of these bacteria by the use of the newly introduced "miracle drugs" rather than to kill the bacteria in the air before they entered the wound, little would be accomplished by further presentations of the same or supplementary data.

Most members of the profession consulted at that time did not consider the air to be an important route of bacterial spread, doubted the value of ultraviolet radiation in the operating room, and considered its use during the operation to be, at the least, a nuisance, requiring for the personnel protection which might be mildly annoying, and, at the most, a handicap in operating and a hazard to themselves, the other personnel, and the patient. they believed, furthermore, that, with the new chemicals and antibiotics available to control infections, such precautions were unnecessary.

However, for our own work in the Duke Hospital, all the surgeons on the general, thoracic, neurological, and orthopedic services, who perform most of the clean extensive operations in which there is most likelihood of infection from contamination in the air, have continued to use ultraviolet radiation in the operating room routinely. Having seen the great reduction in the adverse postoperative reactions brought about by controlling this route of bacterial dissemination and seeding of the clean wounds, they have extended its use to all extensive procedures, including those in which there is gros contamination. It has always been our opinion tha keeping pathogenic bacteria out of a clean woun is preferable to trying to control their growth or t kill them after they enter, a subject we conside closed to argument. With the present widesprea distribution of antibiotic-resistant staphylococc prevention of such *contamination* is now all th more important.

Since our last publication, infections in clea undrained wounds at Duke Hospital have bee extremely rare. When occurring, they have in mos cases been mild, and fatalities from such infection have been almost, if not entirely, nonexistent. (I d not know of a single such death in a case in whic ultraviolet radiation has been used, but all record are being carefully reviewed with regard to this.

It is suggested that anyone having a problem with infections in clean operative wounds expose a Petri dish of blood agar near the operativ site during those procedures in which infectio is most likely to occur and then incubate and determine the bacteria type settling from the ai When a wound becomes infected, the organisms obtained from the wound should be compared with those recovered from the air on the culture plate to see if they are the same. An operating room should be equipped with a suitable intensity distribution of ultraviolet radiation and kept protected continuously with radiation, and the bacteria settling from the air during an operation and near the operative site should be cultured and compared again with similar cultures taken under similar conditions but without the use of this radiation. The infection rate for similar operations performed by the same team, at the same time of year, with and without bactericidal radiation, should be compared. With this information, the decision as to the source of clean wound contamination and the value of ultraviolet radiation can be fairly made.

Summary

In the Duke Hospital so-called unexplained infections in clean operative wounds not only have been explained but have been eliminated, to a great extent, by a variety of measures aimed at limiting the contamination of the air with pathogenic bacteria, and by the use of ultraviolet radiation to kill the remaining bacteria that inevitably get into the air and, by sedimentation, onto exposed surfaces. We have thus reduced greatly the spread of viable pathogenic organisms in the operating rooms by way of the air, regardless of their origin.

We consider the air route of spread to be the greatest factor in the seeding of clean operative wounds and exposed sterile supplies with pathogenic bacteria and therefore to be responsible for most of the so-called unexplained infections in clean operative wounds today.

Despite the high rate of operative wound infections reported, the universal contamination of the air in occupied closed areas and the effectiveness, safety, and ease of use of ultraviolet radiation in the operating room, the air in the operating room is almost universally ignored, except for two procedures. The first is the use of inadequate masks, which produce a false sense of security, since they may stop the large droplets but not the droplet nuclei of bacteria which contaminate the air. Second is the use of air conditioning, which does not reduce adequately the contamination of the air in the operating room. Adopted for cooling and humidity control, air conditioning eliminates or reduces the amount of bacteria-laden perspiration in the hotter months and provides at all times better ventilation with large quantities of air which should be relatively free of bacteria, thus reducing the concentration of pathogenic bacteria given off by the occupants of the room and floating in the air. It should be evident that control of bacterial spread by way of the air will, during the operation, protect the open wounds from heavy inoculation with exogenous pathogenic bacteria floating in the air, regardless of their source (respiratory tract; contaminated room; shoes, linens, and blankets; air from other areas; or air delivered in a contaminated condition from the ventilating system). Since contact inoculations have been eliminated, to a great extent, sterilization of the air will close the last big gap in our aseptic technique.

Before 1936 we were unable to prevent a high percentage of infections, predominantly with staphylococci, in clean operative wounds .At times, the number of infections was so great and they were so severe that limitations were placed on accepting patients for extensive clean operations. In contrast to this experience, since 1936, when we began the use of ultraviolet radiation to control the spread of airborne bacteria, such operating room infections have been all but eliminated. We now have 15 operating rooms equipped with bactericidal ultraviolet radiation in the Duke Hospital.

On the basis of our experience in the continuous control of these infections over a period of 23 years on a large surgical service, without permanent or serious injury to personnel or patient by the use of this agent, we again recommend that bactericidal ultraviolet radiation be used continuously as an addition to aseptic operating room technique. By this means, we have controlled the spread of pathogenic bacteria by way of the air with the result that we have eliminated most of the so-called unexplained infections and have kept under control the antibiotic-resistant staphylococci and other bacteria in the operating rooms in the Duke Hospital.

This study was aided by a grant from the National Institutes of Health.

The ultraviolet equipment was supplied, for purposes of investigation, by the Lamp Division of Westinghouse Electric Corporation, Pittsburgh.

◆

MASCULINIZATION OF FEMALE FETUS DUE TO USE OF ORALLY GIVEN PROGESTINS

Lawson Wilkins, M.D., Baltimore

A markedly masculinized female infant is readily mistaken for a hypospadic male or for a normal male with simple cryptorchism. This congenital condition is sometimes caused by virilizing adrenal hyperplasia, but data here presented show that it has also frequently resulted from administration of progestins to mothers in treating habitual or threatened abortion. Seventy cases of fetal masculinization of female infants associated with the oral administration of progestins to their mothers are analyzed. Thirty-one followed the use of 17-α-ethinyltestosterone, and 35 followed the use of 17-α-ethinyl-19-nortestosterone. In 25 cases the mothers were given estrogens with the progestins in order that the estrogen might offset the virilizing effect of the progestin, but the evidence showed that the estrogens did not prevent fetal masculinization. These data do not argue against the use of progesterone, for the progestins concerned in all cases were synthetic.

Female pseudohermaphroditism due to congenital virilizing adrenal hyperplasia is a well-known condition.[1] The abnormality of sex differentiation is confined to partial masculinization of the external genitalia, while the ovaries are normal and the genital ducts are differentiated along the normal female pattern, forming vagina, uterus, and fallopian tubes. Embryonic masculinization of the external genitalia results in an enlarged phallus, which may or may not be associated with varying degrees of fusion of the labioscrotal folds. If little or no fusion occurs, separate vaginal and urethral orifices are visible. Fusion results in the formation of a urogenital sinus whose opening is either funnel-shaped or slit-like or in the form of a small meatus at the base or even on the shaft or tip of the phallus. Such a female infant may be readily mistaken for a hypospadic male or even a normal male infant with simple cryptorchism.

Fetal masculinization of the external genitalia with identical anatomic findings occurs also in females who do not have any adrenal abnormality. Unlike patients with the adrenogenital syndrome, these infants do not have elevated levels of urinary 17-ketosteroids and, as they grow older, they do not show progressive virilization with precocious growth of sexual hair and accelerated growth and osseous development. At puberty normal feminization, with menstruation and ovulation, occurs.

The diagnosis of female pseudohermaphroditism not due to adrenal abnormality depends on demonstration in the buccal smear of the "chromatin-positive" type of nuclei which are found in normal females[2] and on the finding of normal levels of 17-ketosteroids in the urine. When a urogenital sinus is present, it is generally advisable to perform a urethroscopic examination to demonstrate the communicating vagina and to observe the cervix. With high degrees of masculinization it may b advisable to perform an exploratory laparotomy t exclude the possibility of true hermaphroditism with mixed testes and ovaries, which is an exceedingly rare condition.

In 1958 my colleagues and I[2b] reported 17 instances of nonadrenal female pseudohermaphroditism, 12 of which occurred in infants born o mothers who, because of habitual or threatened abortions, had received 17-α-ethinyltestosterone (ethisterone, pregneninolone), a synthetic, orally given progestin, during gestation. This compound ha

been used for about 15 years under such trade names as Progestoral, Pranone, and Lutocylol. In this paper warning was given that a newer progestin, 17-α-ethinyl-19-nortestosterone, marketed as Norlutin, might have even greater masculinizing effects on the fetus.

Report of Cases

Seventy cases of fetal masculinization of female infants associated with the oral administration of progestins to their mothers are presented. All of these cases fulfilled the diagnostic criteria discussed above. Twenty-three of these patients were studied by myself in the pediatric endocrine clinic of the Harriet Lane Home. Seventeen cases were reported on by Grumbach and co-authors,[3] and one case each by Moncrieff,[4] Hayles and Nolan,[5] and Reilly and co-authors.[6] Jacobson[7] observed 17 cases in his obstetric practice. The rest of the cases were brought to my attention by other colleagues. In visiting various clinics throughout the United States I have heard of many more cases, but I do not have sufficiently accurate data to include them in this study.

* Labioscrotal fusion: ++++ urogenital sinus opening on shaft or tip of phallus; +++ urogenital sinus with small meatus at base of phallus; ++ urogenital sinus with slit-like or funnel-shaped orifice; + slight posterior fusion, separate vaginal and urethal orifices.
† Maternal virilization: V = deepening of voice; H = hirsutism of face; A = acne; C = clitoral enlargement.

Table 1 lists 34 cases associated with the use of 17-α-ethinyltestosterone. Table 2 shows 35 cases in which Norlutin, 17-α-ethinyl-19-nortestosterone, had been given and one case in which Enovid (norethynodrel and ethinylestradiol 3-methyl ether) had been used. The phallic enlargement, designated "+" or "++" (tables 1 and 2), consisted of hypertrophy of the corpus and glans and was not merely hyperplasia of the prepuce. In general, the degree of hypertrophy was considerably less than that usually seen in cases of congenital virilizing hyperplasia of the adrenal. In some cases the organ was not sufficiently conspicuous to make amputation advisable. Some of the infants having high degrees of labioscrotal fusion (for designation of the degrees of fusion see footnotes to tables 1 and 2) had been mistaken for males at birth and had been raised as such. With both 17-α-ethinyltestosterone and Norlutin, fusions occurred only when administration of the drug was begun before the 12th week of gestation. Phallic enlargement can result when androgenic activity is exerted over a sufficient period at any time during fetal or postnatal life.

The 34 cases of masculinization associated with administration of 17-α-ethinyltestosterone were observed in infants born between the years 1950 and 1959; the 36 infants whose mothers had been given Norlutin or Enovid were all born in 1958 and 1959. Although the daily doses of 17-α-ethinyltestosterone ranged from 20 to 250 mg., seven of the mothers had received 100 to 250 mg. daily. The doses of Norlutin ranged from 10 to 40 mg. per day, and high degrees of masculinization were observed with doses as small as 15 mg. daily. It is of particular interest that Jacobson[7] found that of 53 female infants born to mothers to whom he had given Norlutin in doses between 10 and 40 mg. per day, 17 showed masculinization, some in high degrees. Two mothers who had received 17-α-ethinyltestosterone, three who had received Norlutin, and one who had received Enovid showed mild androgenic manifestations, such as deepening of the voice, facial hair, and acne, which disappeared after the termination of pregnancy.

These findings indicate that (1) high degrees of masculinization occur with much smaller doses of Norlutin than of 17-α-ethinyltestosterone and (2) there has been a higher incidence of masculinized infants born to mothers who have received Norlutin than to those given 17-α-ethinyltestosterone.

Mode of Action

As shown in table 3, in 70 of 101 cases of nonadrenal female pseudohermaphroditism reported the mother had received one of the orally given progestins during gestation and in 15 cases testosterone or one of its androgenic derivatives. The probable mode of action of the orally given synthetic progestins has been discussed in previous communications.[8]

† Maternal virilization: V = deepening of voice; H = hirsutism of face; A = acne; C = clitoral enlargement.

It has been demonstrated that testosterone and its known androgenic analogs, when administered to pregnant animals, can bring about masculinization of the fetus; in addition, 14 cases of fetal masculinization due to administration of these drugs to pregnant women have been reported.[9] It is probable that fetal masculinization may result from doses so small that they do not cause androgenic manifestations in the mothers or in normal adults. This may be due to increased sensitivity of the fetal end-organs or to impairment of the degradation and disposal of these steroids by the fetus. We have studied a highly virilized female infant from Vancouver, British Columbia, whose mother, from the 8th to the 39th week of pregnancy, had received one pill daily containing only 3 mg. of 17-methyltestosterone and 0.01 mg. of 17-ethinylestradiol. Moncrieff [4] has reported on two patients whose mothers received two or three of these same pills daily (6 or 9 mg. of methyltestosterone).

17-α-ethinyltestosterone, Norlutin, and Enovid are chemically similar to 17-methyltestosterone, since all have the 17-OH group in the beta position. 17-α-ethinyltestosterone has been shown to have androgenic effects in animals. In 1942 Courrier and Jost [10] reported that its administration to pregnant rabbits caused masculinization of the female fetus. This was confirmed in 1947 by Jost [11] in additional experiments. Recently, Revesz and co-workers[12] have brought about fetal masculinization by administration of 0.5 mg. of Norlutin daily and of 0.25 mg. of medroxyprogesterone (6-methyl-17-acetoxy-progesterone) to pregnant rats, although daily doses of 200 mg. of progesterone had no masculinizing effects. It would seem that both 17-α-ethinyltestosterone and Norlutin, and probably Enovid, are androgenic. Norlutin seems to be much more androgenic than 17-α-ethinyltestosterone. Even though bioassays may show that these compounds are relatively weak in terms of their androgenic effects on adults, they are sufficiently potent when they cross the placenta to masculinize the relatively sensitive end-organs of the developing fetus. It is no longer necessary to assume that the mothers who give birth to masculinized females metabolize these steroids abnormally. The fact that not all the offspring of mothers who received these drugs during gestation are affected may be due to differences in placental transmission or fetal sensitivity.

The question whether estrogens and progesterone can play a role in fetal masculinization has been raised. It will be noted that in 16 of our cases in which 17-α-ethinyltestosterone was given and in 9 in which Norlutin was used, the mothers received in addition either diethylstilbestrol (Stilbestrol), conjugated equine estrogens (Premarin), or 17-α-hydroxyprogesterone caproate. In some cases the diethylstilbestrol was given in very large doses. These substances certainly did not prevent fetal masculinization. Bongiovanni and co-authors,[13] reported on four masculinized female infants whose mothers had received diethylstilbestrol in doses of 5 to 75 mg. per day. In a previous communication we[2b] reported on two cases in which the mothers had been given only progesterone intramuscularly, over short periods of time, in doses which did not seem excessive. In addition, we have now observed four masculinized female infants whose mothers had received no medication of any kind, and there are similar cases in the literature.

There is no evidence that musculinization of the fetus is due to a direct androgenic action of progesterone itself.[12] Jost[14] recently restudied purified progesterone and could demonstrate no androgenic activity. One may postulate, however, that mothers of masculinized infants who have received no treatment and those treated with progesterone may metabolize either endogenous or exogenous progesterone abnormally to form androgens, since progesterone may be a precursor of both androgens and corticosteroids. The mothers who received diethylstilbestrol alone may belong to this group of abnormal progesterone metabolizers. On the other hand, Bongiovanni and co-workers'[13] suggestion that diethylstilbestrol may stimulate the fetal adrenal to increase the output of androgens cannot be refuted. Further work needs to be done in this field.

Comment

I am not qualified to discuss the debatable efficacy of progestational steroids or estrogenic compounds in the prevention of abortions. If they are valuable and necessary, the ones which are least likely to cause fetal masculinization should be used. There is no excuse for giving a known androgenic steroid, such as methyltestosterone, even in small doses. There is no valid reason to blame the administration of progesterone, the natural hormone of pregnancy, for the masculinization of female infants, although occasionally there may be a mother who metabolizes progesterone abnormally. On the other hand, the synthetic progestins given orally are not natural hormones of the body and have weakly androgenic as well as progestational action. During the past year or two, Norlutin has caused fetal masculinization with sufficient frequency to preclude its use or advertisement as a safe hormone to be taken during pregnancy. Although the older compound 17-α-ethinyltestosterone has caused masculinization comparatively infrequently, it should also be considered potentially hazardous to the fetus.

It is most important for the obstetrician, pediatrician, and family physician to recognize that nonadrenal female pseudohermaphroditism does occur, especially when motners have been treated with the orally given synthetic progestins under discussion. These infants can readily be mistaken for males. If they are raised as males, the physician will be greatly embarrassed when they feminize and menstruate at puberty. Whenever the external genitalia have an ambiguous appearance or when an infant appears to be a hypospadic male or even a normal male with impalpable testes, the possibility of female pseudohermaphroditism should be considered and excluded. The nuclear chromatin pattern of the buccal smear should be studied.[2a] If it is chromatin-positive, the urinary 17-ketosteroid levels should be measured, to determine whether or not virilizing adrenal hyperplasia is present. Nonadrenal female pseudohermaphrodites should always be raised as girls. One can reassure the parents that they will develop as normal girls and mature into normal, fertile women. No hormonal therapy is required. If there is no labioscrotal fusion, no surgical correction is necessary unless the phallus is so large that its removal seems advisable for cosmetic or psychological reasons. Labioscrotal fusion, when present, should be corrected by an operation such as that described by Jones[15] in early infancy or certainly before the age of 2 or 3 years.

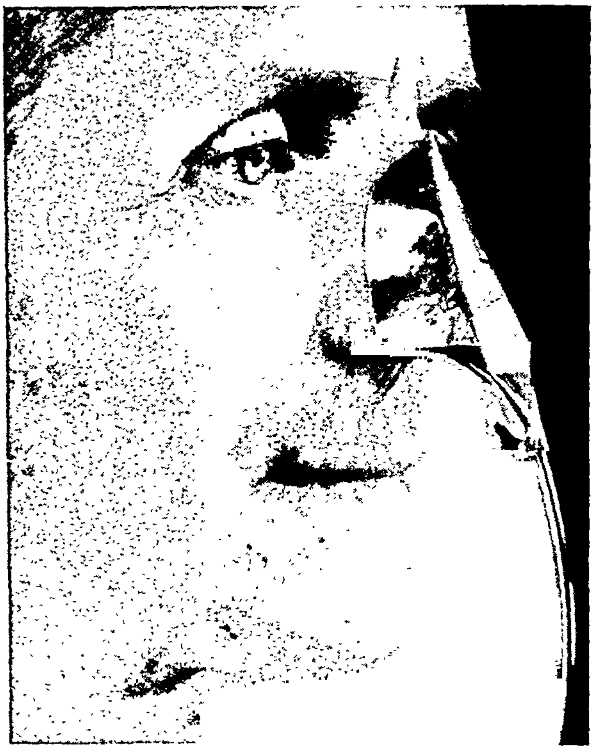
CLINICAL NOTES

NEW METHOD FOR HOLDING NASAL TUBES IN POSITION

Edward J. Hill, M.D., Detroit

A problem common to most patients subjected to nasal intubation for the purpose of either suction or long-time feeding is the difficulty involved in maintaining the tube in a fixed position. The usual method of fixation is the use of adhesive tape for adhering the tube to the nose, the cheek, or the forehead. This method is far from ideal, because adhesive tape quickly loses its effectiveness, becoming stretched or loosened by perspiration, thereby allowing the tube to move in and out as the patient swallows. This motion and the obvious pressure against the alar rim of the nose creates an unpleasant irritation or cellulitis which eventually leads to ulceration if the condition is not corrected.



Holder for nasal tube of thin malleable aluminum, approximately 0.005 mm. in thickness, molded to nose by digital pressure.

A new tube holder has been developed which is easily affixed to the nose, with no discomfort to the patient. It is constructed of a thin malleable aluminum, approximately 0.005 mm. in thickness, and is easily molded to the nose by digital pressure; it may be bent in any direction whatsoever. The holder projects below the tip of the nose to secure the nasal tube clear of the nasal rim, thereby eliminating the rubbing and irritation produced by the old method of securing the tube (see figure). The thinness and type of material allows it to be cut, if necessary, by the ordinary bandage scissors. The holder, or splint, has on one surface a nontoxic, nonirritative adhesive which keeps it firmly in position and allows the projection below the tip of the nose to grasp the nasal tube securely. This splint is designed to fit the nose snugly and is as easy to apply as ordinary adhesive tape. Its outstanding feature is that it may be firmly secured without rubbing or irritation to the nose. These splints have been designed to fit both adults and children.

1553 Woodward Ave. (26).

INTERNAL DRAINAGE OF ACUTE PSEUDOCYST OF THE PANCREAS

Capt. Wil B. Nelp
and
Lieut. Col. Strother B. Marshall, (MC), U. S. A. F.

Although pancreatitis is not an uncommon precursor of pancreatic pseudocyst, it is usually the chronic or relapsing form of the disease which gives rise to cyst formation. It is rare for an initial attack of acute necrotizing pancreatitis to lead to the development of pseudocyst. In the following case the rapid development of a large pseudocyst in the wake of an initial attack of severe necrotizing pancreatitis produced almost complete gastric obstruction and required early surgical intervention.

Report of a Case

A 21-year-old man was brought to the hospital by ambulance. Forty-eight hours prior to admission he had had sudden cramping epigastric pain and nausea, which soon subsided. Five hours prior to admission he again developed sudden severe epigastric pain and a burning sensation, with vomiting. There was radiation of the pain to the middle of the back.

His personal and family histories were unrevealing except for excellent general health. There was no history of gastrointestinal complaints, trauma, or operation. He did not drink alcoholic beverages.

Physical examination on admission revealed that the patient was well developed, well nourished, and in acute distress. He was pale, perspiring, and complaining of severe epigastric and back pain. His temperature was 97.4 F (36.3 C) pulse rate 92 per minute, blood pressure 124/80 mm. Hg, and respirations 16 per minute.

Skin and conjunctiva were clear. The abdomen was symmetrical and slightly distended. There were board-like rigidity and exquisite epigastric, flank, and middle back tenderness, and bowel sounds were absent.

Initial laboratory data showed a white blood cell count of 25,000 per cubic millimeter, with a marked shift to the left. The hemoglobin concentration was 18.4 Gm. per 100 cc., with results of urinalysis normal. A roentgenogram of the abdomen showed no free air, moderate distention of the large intestine, and a distended jejunal "sentinel loop" in the left upper quadrant. Serum amylase level was 546 Somogyi units (normal: 80-150 units).

A diagnosis of acute pancreatitis was made. Gastric suction was instituted and atropine, analgesics, and sedation were given, with fluids administered intravenously. Therapy with penicillin and streptomycin was started. There was some measure of relief, but pain was markedly increased by motion or when suction was discontinued for brief intervals. Oral feeding produced severe pain. During the first week the foregoing therapy was continued. His temperature intermittently rose to 101 F (38.3 C). The fever then abated and there was softening of the lower abdomen, but persistent epigastric guarding and tenderness remained. From the 7th to the 10th hospital day epigastric fulness became exaggerated and a rounded, smooth, tender mass could be outlined with some difficulty. On the 11th hospital day feedings were started orally but were poorly tolerated because of pain and vomiting.

On the 16th hospital day intravenous alimentation was resumed. The serum amylase level was still 312 units; the white blood cell count ranged between 10,000 and 20,000 per cubic millimeter. Serum protein, bilirubin, and electrolyte levels remained normal. There was a 20-lb. (9.1-kg.) weight loss. An obvious large, grapefruit-sized, smooth, tender, fixed mass was palpable in the middle of the upper part of the abdomen. At this juncture the patient became adept at removing and replacing his plastic nasogastric tube, leaving it out until vomiting became imminent or pain became too intense.

By the 28th hospital day operation seemed mandatory because of the nearly complete high intestinal obstruction and persistent pain. Gastric suction and parenteral alimentation were never effectively discontinued. An oral cholecystogram showed no filling of the biliary system and an upper gastrointestinal series (fig. 1) showed marked obstruction to flow of barium and the large mass displacing the stomach and duodenal loop anteriorly and superiorly.

On the 29th hospital day surgery was performed. A midline incision was made from xiphoid to umbilicus. Peripancreatic fat was hemorrhagic and edematous. The stomach was flattened and fixed anteriorly over a tense cystic mass occupying the whole lesser sac. The stomach was opened anteriorly and a trochar was inserted through the posterior wall into the mass; 1,650 cc. of pale green turbid fluid was removed. The amylase content was 486 units. The trochar opening was enlarged and the

Chief, Medical Service, 3902d USAF Hospital, and Clinical Assistant, Department of Internal Medicine, University of Nebraska School of Medicine (Captain Nelp), and Chief, Surgical Service, 3902d USAF Hospital, and Instructor in Surgery, University of Nebraska School of Medicine (Lieutenant Colonel Marshall). Captain Nelp is now assistant resident on the Osler Medical Service, Johns Hopkins Hospital, Baltimore 5, Md. Lieutenant Colonel Marshall is now at Mitchell Air Force Base, New York.

area of the pancreas was explored digitally. The gland was nodular and friable. Fat necrosis was present. The cyst wall was remarkably thick and a 2-cm. cystogastrostomy was performed with continuous 0.0 chromic catgut. The gallbladder was tense, but no stones were felt. Further exploration or surgery was deemed inadvisable.

Postoperatively, the patient did well. At the end of a week he was taking small bland feedings. There was occasional mild postprandial epigastric distress. A second gastrointestinal series performed on the 13th postoperative day was essentially normal. No communication between cyst and stomach could be demonstrated.

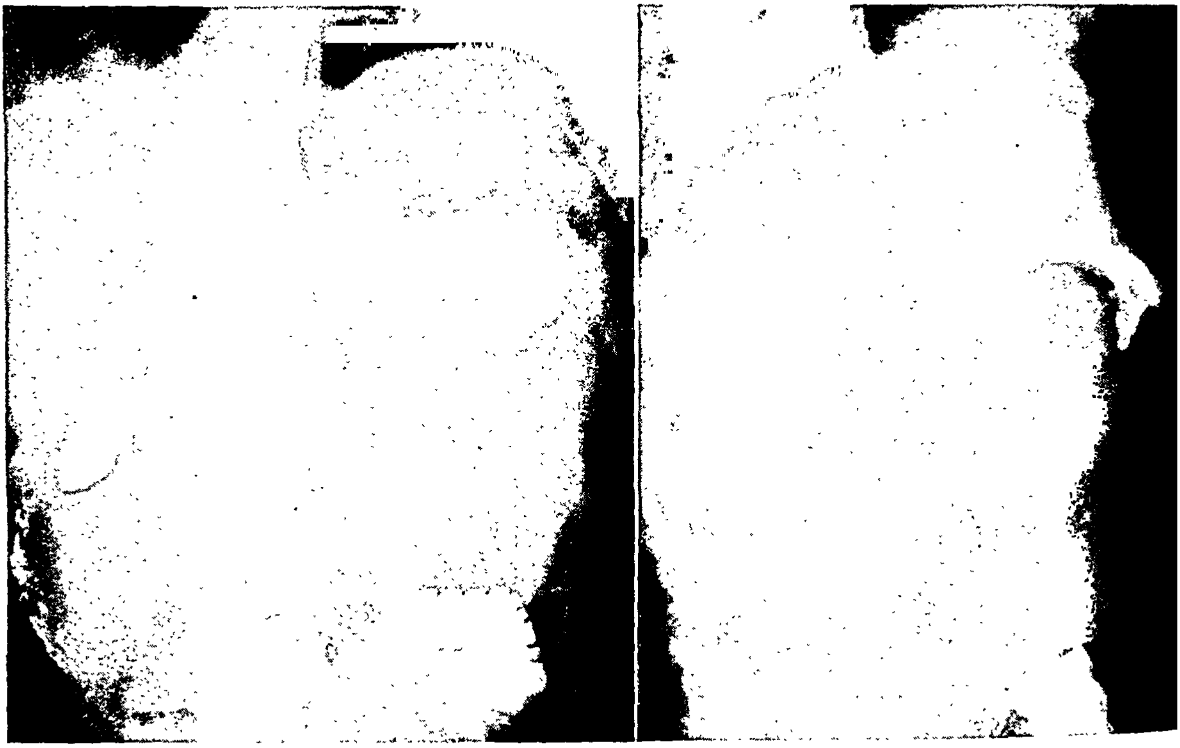

Fig. 1.—Gastrointestinal x-rays made on 28th day of illness, demonstrating large pseudocyst of pancreas. Barium w stilled with use of Levine tube.

A second cholecystogram showed filling of the gallbladder and multiple radiolucent stones. Two months after operation, the patient had regained his normal weight but had occasional postprandial burning. The serum amylase level had returned to normal and remained so.

The next week another operation was performed. The stomach appeared normal but was firmly affixed to the pancreas, obliterating the lesser sac. No evidence of pseudocyst was found. The cystic duct was thickened and dilated. The common duct appeared normal. Ten cubic centimeters of 35% iodopyracet (Diodrast) compound were injected by force of gravity into the isolated cystic duct segment. Retrograde filling of the pancreatic duct was seen (fig. 2). The common duct was explored and found free of stones. No larger than a no. 4 Ba
dilator could be made to pass through the sphin
of the ampulla. A transduodenal sphincteroto
was then performed, and afterward a no. 8 B
dilator could pass freely. Subsequent to sphincte
tomy the pancreatic duct was seen to enter the
tal third of the ampulla and was freely probed w
out obstruction. Cholecystectomy was then c
pleted and multiple small mixed bilirubin
cholesterol stones were found within the gallb
der. T-tube drainage was used. The patient's p
operative course was uneventful. Transient eleva
of the serum amylase level to 222 units was no
A cholangiogram made on the 12th postoper
day was normal and showed no evidence of
into the pancreatic duct (fig. 3).

The patient was last seen one year after
formance of the initial cystogastrostomy. He
maintained normal bowel function, he tolerate
foods well, and his physical findings were no

Comment

This patient presented several interesting
challenging features. The rapid development
pseudocyst was unsuspected, but its presence
be detected with some certainty 10 days
initial hospitalization. Its progressive enlarge
to the point of producing almost complete g
obstruction by the third hospital week made
gical intervention mandatory. Transgastric d

ge proved to be a relatively rapid, safe, and simple ethod in this case, in which the time and extent surgery needed to be minimized because of the tient's poor condition. His rapid recovery was deed gratifying; the gastrointestinal x-ray exami- tion on the 13th day postoperatively demonstrat- g no further evidence of the cyst and served to nphasize the effectiveness of this procedure. This nding was further verified at the subsequent opera- n two months after the initial procedure.

In 1923 Jedlicka successfully anastomosed a pan- eatic cyst remnant to the stomach after partial cision of a cyst, and Jurasz, in 1931, is credited ith the first transgastric cystogastrostomy.[1] The ocedure has since proved satisfactory in numer- s patients.[2] It has the obvious advantage of avoid- g an external drainage site, with the potential rbidity of chronic fistula formation and local in changes.

In a recent review Waugh and Lynn[2c] reported e course of 23 patients with pseudocyst treated by nple drainage and of 17 by marsupialization. ere was a mean drainage time of six and seven onths, respectively, in these two groups.

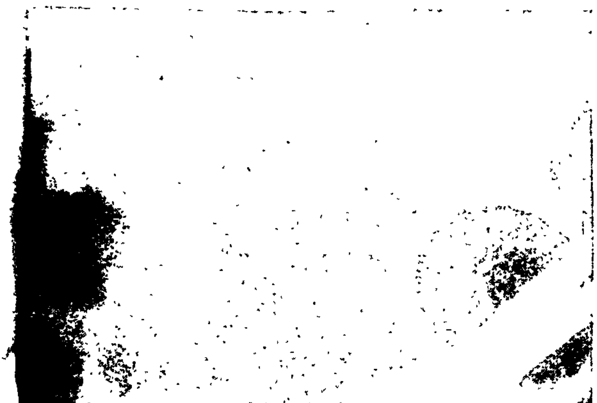

Fig. 2.—Operative cholangiogram made prior to sphinc- erotomy. Arrows point to reflux into pancreatic duct.

If drainage is adequate the granulation tissue ining of the cyst rapidly collapses and obliterates tself. Moreover, the stomach readily adapts in a hysiological manner to accepting pancreatic secre- ions directly—one need think only of the patient who takes his pancreatic secretion orally on a daily basis when plagued by a chronic draining external fistula.

Other surgeons[3] have been more restrictive in the use of internal drainage procedures for pancreatic cysts. The fear of overlooking a neoplastic lesion which may be curable by operation is a compelling reason for limiting such procedures. In such situations biopsy examination, with frozen section, would serve to clarify any question about the nature of the lesion. Recurrent cyst formation after cystojejunostomy or cystogastrostomy has also been cited as a significant deterrent. This, however, applies to all methods of pseudocyst drainage and only serves to emphasize that internal drainage alone is not a truly definitive procedure.

Fig. 3.—T-tube cholangiogram made on 12th day after performance of sphincterotomy, showing no pancreatic duct reflux—normal cholangiogram.

The omission of proper consideration of the biliary and sphincter components or other sites of obstruction in the pancreatic duct has been one of the major objections to pancreatic pseudocyst surgery consisting solely of internal drainage. In the present case, further definitive surgery was easily performed at the second operation. The patient did have cholelithiasis with small stones, an anatomically patent common biliary and pancreatic channel, and moderate stenosis of the sphincter of Oddi. Undoubtedly, the passage of one of the small calculi initiated his entire illness. The necessity for definitive correction of biliary and sphincter components in pancreatic cyst surgery has been strongly emphasized by Doubilet and Mulholland.[4] In less seriously ill patients internal drainage by cystogastrostomy and sphincterotomy with or without cholecystectomy could easily be combined.

Summary

A pancreatic pseudocyst developed rapidly and produced high intestinal obstruction after an initial attack of acute pancreatitis in a 21-year-old man who had cholelithiasis. Early internal drainage through cystogastrostomy followed in two months by cholecystectomy, choledochostomy, and sphincterotomy proved to be highly effective therapy. One year later, follow-up examination revealed apparently complete recovery.

NEW SUCTION-LAVAGE SIGMOIDOSCOPE

Isio F. Wasserman, M.D., Utica, N. Y.

The greatest obstacle to a successful sigmoidoscopy is the presence of intestinal contents which delay or interfere with the examination or surgical treatment. The problem of incomplete evacuation has been obviated by repeated enemas, liquid diet, evacuant suppositories, and the introduction of sodium phosphate solutions having detergent effect. However, none of these methods provides a guarantee to the physician that the examination will not be delayed because of improper preparation.

Proper biopsy, the most reliable procedure for the identification of malignancy, requires generous samples taken from different questionable areas. Bleeding of varying degrees may follow the first attempt, interfering with the taking of further samples. Electrofulguration of bleeding points, often imperative, becomes a hazardous procedure if the areas are not well visualized.

Massive bleeding from the upper gastrointestinal tract, regardless of preparation or method of counteracting this complication, is a major threat to complete examination. Until the present, these problems have been met by the insertion of a suction tube or swab in the lumen of the sigmoidoscope in order to cleanse the area. The examiner's visibility is impaired while these instruments are in use and often they provide only temporary relief, since, when they are removed, blood will again cover the area in question.

The sigmoidoscope with a suction tube attached laterally to its wall is usually inadequate because the tube is of small diameter and suction is effective only at the point of contact of the tube with the inner lumen of the intestine.

New Model Sigmoidoscope

To overcome these difficulties, a new model sigmoidoscope is proposed. Essentially it consists of two tubes, telescoped within each other, which form a double wall with an inner chamber between them. This chamber is open at the insertion end and closed at the proximal end, at which an extension neck with a stopcock enables the inner chamber to be connected to a suction or injection apparatus. The injection process introduces cleansing agents into the intestine and, alternately, the ejection process suctions off excess fluid and gas.

The proximal end of the sigmoidoscope contains a lateral type of illumination. Although distal lighting gives excellent illumination with no shadows, frequent soiling of the lamp by feces or blood and the inconvenience of cleaning the smeared bulb

---

Attending Surgeon, St. Luke's-Memorial Hospital Center, New Hartford; Attending Surgeon, St. Elizabeth's Hospital; and Attending Proctologist, Oneida County Tumor Clinic.

offset this advantage. With proximal lighting, visibility is diminished because the light source is set in the ocular system. Therefore, the lateral type of illumination, previously used by Yeomans,[1] has been improved on by use of a larger bulb, with increased wattage; burned-out bulbs can easily be removed and replaced since they are of the standard, screw-in type, costing about 15 cents apiece at any electrical supply store.

Method of Operation.—The instrument is introduced with the usual technique. When suction is indicated, the rubber tube of the suction machine is connected to the stopcock extension, enabling the chamber system to act as a constant or intermittent suction conductor at the distal end of the instrument. Any liquid in the intestinal lumen is channeled through the inner chamber and out to the container of the suction machine. Suction at the distal end is applied concentrically, thus keeping the area under observation clear of intestinal content (fig. 1). This is to be compared with the standard method of lateral suction tube drainage, in which only a small area is drained because of the limited size and suction power of the tube.

If examination is impeded by the patient's incomplete evacuation, an injection machine is attached to the stopcock of the sigmoidoscope; saline solution or sodium phosphate is introduced into the intestine and consequently withdrawn (by reversing the action to suction) to a separate container. This operation will effect a thorough washing and cleansing of the intestine. If an injector machine is not available, the detergent agent may be flushed directly through the inner lumen of the sigmoidoscope, to be retrieved by suction.

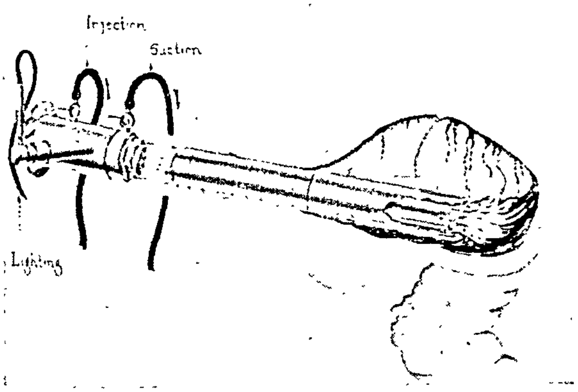

Fig. 1.—Continuous suction of intestinal content, achieving clear field.

Comment

If the patient is not properly prepared for examination, valuable time is lost for both physician and patient. The patient must be subjected to the undue stress of another sigmoidoscopy and the suction or swabbing has yet to be applied in order to remove intestinal contents. With this instrument, even if further cleansing is necessary, the sigmoidoscope need not necessarily be displaced, and the intestinal contents can be removed under direct visual control. The procedure of cleansing and suction can be repeated as many times as is required to be effective, and the examination can then continue. The same principle can be applied for diagnosis in a patient with massive bleeding. The bleeding of varying degrees which follows a first attempt at taking a biopsy specimen can easily be controlled, since the suction, concentrically applied, maintains a clear, dry area. Further samples can be taken under direct and constant visualization.

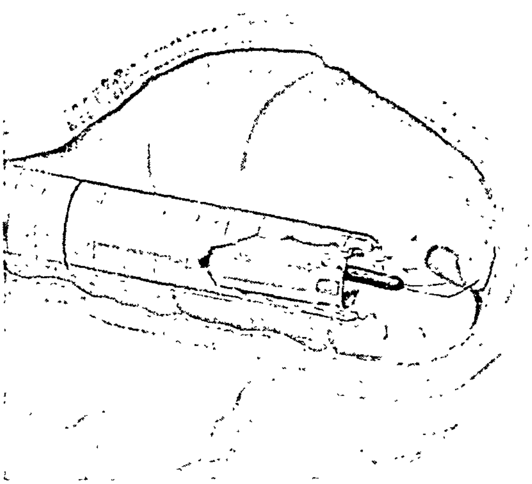

Fig. 2.—Prevention of explosion during fulguration by continuous suction of flammable gas. When necessary, inert gas is injected through suction chamber.

Surgical diathermy in the intestinal lumen, for the removal of polyps, hemostasis, or palliative treatment of carcinoma, is a surgical procedure which is extensively used. Arnous,[1A] Moutier,[2] Carter,[3] and Becker[4] reported cases of intestinal rupture due to gas explosion. Many such cases of explosion remain unreported, because of either lack of subsequent complications or poor understanding of the problem and the dangers involved. Explosion is caused by the effect of sparking on the high concentration of methane and oxygen in the intestine. Arnous[1] and Becker[4] suggested the use of a free tube which could carry carbon dioxide to the site while electrosurgery was performed, thus isolating the area by an atmosphere of inert gas. Another tube, either free-standing or attached to a sigmoidoscope, must be used to remove the resultant smoke. Obviously, the disadvantage of using an extra instrument in the inner lumen of the sigmoidoscope is the obstruction to visibility.

In my opinion, explosions will be prevented if there is sufficient suction to assure the complete expulsion of all potentially flammable gases. Carbon dioxide, when preferred, can be injected through the suction chamber and visibility is unimpaired (fig. 2).

Finally, it must be emphasized that, since suction in the proposed sigmoidoscope is applied in a constant manner, there is no need for superfluous instruments to be added. While the vision is kept free of any obstacle, the hands of the operator are available for further procedures.

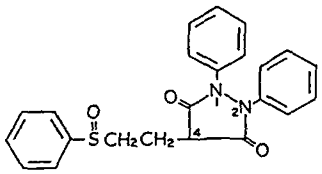
COUNCIL ON DRUGS

NEW AND NONOFFICIAL DRUGS

The following descriptions of drugs are based on available evidence and do not in any case imply endorsement by the Council.

H. D. Kautz, M.D., *Secretary.*

Sulfinpyrazone (Anturan).—1,2-Diphenyl-4-(2′-phenylsulfinethyl)-3,5-pyrazolidinedione.—The structural formula of sulfinpyrazone may be represented as follows:



Actions and Uses.—Sulfinpyrazone, a pyrazolone derivative chemically related to phenylbutazone, is a potent uricosuric agent employed in the management of gout. It is useful primarily in the prevention, rather than the treatment, of attacks of acute gouty arthritis. The severity and frequency of such attacks are reduced by continuous long-term administration of the drug, presumably by virtue of its ability to promote the renal excretion of uric acid. The maximal increase in uric acid excretion obtainable with sulfinpyrazone is comparable to that with probenecid, whereas the dose required for equivalent effects is smaller. Nevertheless, although most patients experience some reduction in the serum uric acid concentration, normal values cannot be achieved in all patients. Patients refractory to other uricosuric agents may respond to sulfinpyrazone.

In chronic gout, sulfinpyrazone suppresses formation of new tophi and may reduce the size of old tophaceous deposits and alleviate joint pain and stiffness. However, improvement usually becomes apparent only after several weeks or months of treatment. Most patients require the concomitant use of colchicine or of other drugs for adequate symptomatic relief, since sulfinpyrazone has only weak, if any, analgesic or anti-inflammatory action. For similar reasons, colchicine, phenylbutazone, and other analgesics are not replaced for the relief of pain and the other manifestations of acute gout.

Sulfinpyrazone is rapidly and completely absorbed from the gastrointestinal tract; about one-half of a single dose is excreted or metabolized within three hours. Experimental studies reveal that sulfinpyrazone increases the renal clearance of uric acid, depresses clearance of para-aminohippuric acid, and has little effect on the clearance of inulin. These observations suggest that, like probenecid, it produces its uricosuric effect by preventing tubular reabsorption of uric acid, without altering the rate of glomerular filtration.

Salicylates, which even in small doses strongly antagonize its uricosuric action, should not be administered with sulfinpyrazone. There is no known contraindication to the conjunctive use of phenylbutazone, probenecid, or zoxazolamine with sulfinpyrazone, however.

Side-Effects.—An acute attack of gouty arthritis is sometimes precipitated shortly after treatment with sulfinpyrazone is begun, and the frequency of acute attacks may be increased for several weeks thereafter. For this reason, the prophylactic administration of colchicine during the first few weeks of treatment has been recommended.

The marked increase in urate excretion induced by sulfinpyrazone sometimes provokes urolithiasis and renal colic. In order to minimize the incidence of this complication, eradication of preexisting urinary tract infections and administration of sufficient fluid and alkali to insure a large volume of alkaline urine are indicated. The drug should be used only with great caution, if at all, in patients with impaired renal function; in such cases, periodic tests of renal function should be performed.

Epigastric distress and other gastrointestinal symptoms are among the most frequent complications of treatment with sulfinpyrazone; activation of quiescent peptic ulcer has been reported. Hence, it is suggested that sulfinpyrazone be administered with food, milk, or alkali. The drug is contraindicated in patients who have, or who have recently had, an active peptic ulcer.

Leukopenia and thrombocytopenia have each been reported in a single patient taking the drug. In neither instance, however, was the effect definitely ascribable to the drug. Nevertheless, because of the known propensity of a number of other pyrazolone derivatives to depress hematopoietic function, all patients receiving sulfinpyrazone should have blood cell counts done at regular intervals. Experience with this agent has been relatively limited, and it is not yet possible to estimate the hazard of more serious toxic effects, such as those of the parent compound phenylbutazone, when sulfinpyrazone is given over protracted periods.

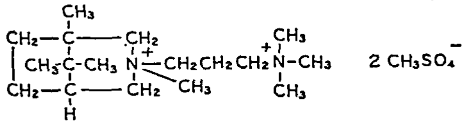
Dosage.—Sulfinpyrazone is administered orally, preferably with meals or with milk. The dose is 50 mg. four times daily, initially, and is gradually increased over a period of a week, until a total daily dosage of 400 to 800 mg. is reached. After a satisfactory reduction of the blood urate level has been achieved, somewhat lower doses, adjusted in accordance with the requirements of the individual patient, are often sufficient for maintenance. Treatment should be continued without interruption. Acute exacerbations of gout do not necessitate discontinuance, but, as previously mentioned, may require the concomitant use of colchicine, phenylbutazone, or other drugs.

Preparations.—tablets 100 mg.

Year of introduction: 1959.

Geigy Pharmaceuticals, Division of Geigy Chemical Corporation, cooperated by furnishing scientific data to aid in the evaluation of sulfinpyrazone.

Trimethidinium Methosulfate (Ostensin).—*d*-[N-Methyl-N-(γ-trimethylammoniumpropyl)]-1-methyl-8,8-dimethyl-3-azabicyclo[3.2.1]octane dimethosulfate.—The structural formula of trimethidinium methosulfate may be represented as follows:



Actions and Uses.—Trimethidinium methosulfate, a quaternary ammonium compound, is used in the treatment of hypertension. The principal pharmacological effects of the drug are referable to autonomic ganglionic blockade. In addition, trimethidinium also exerts some degree of centrally mediated activity. In terms of weight of drug required to produce comparable reductions in blood pressure, trimethidinium is more potent than hexamethonium but less so than mecamylamine. Its duration of action lasts about 7 to 12 hours after oral administration. The absorption of orally administered trimethidinium methosulfate is not complete, but it is reasonably regular and predictable when given to patients in a fasting or near-fasting state.

The clinical use of trimethidinium should be restricted to those patients with moderate to severe forms of diastolic hypertension who fail to respond adequately to therapy less drastic than ganglionic blockade. Ganglionic blocking agents should not be given for mild, labile hypertension. When indicated, orally administered trimethidinium will usually lower both systolic and diastolic blood pressure. The adjunctive use of chlorothiazide or reserpine may afford additional symptomatic relief and allow for reduction in the daily dose of trimethidinium. Tolerance to trimethidinium may occasionally develop after a stage of initial sensitivity; in such cases, however, if therapy is continued and the dose gradually increased, usually an antihypertensive effect can again be produced. Secondary tolerance has not been reported.

Therapy with trimethidinium should be undertaken cautiously, with the realization that the drug is capable of producing the full spectrum of pharmacological side-effects referable to ganglionic blockade. These include blurring of vision, postural hypotension, dryness of the mouth, constipation, interference with sex functions, weakness, nervousness, malaise, dizziness, and headache. Present evidence indicates that trimethidinium causes visual disturbances more often than do mecamylamine or hexamethonium. It shows a lower incidence and severity of certain other side-effects, such as constipation and paralytic ileus, common to other ganglionic blocking agents. The drug should be administered cautiously, if at all, in the presence of marked renal insufficiency, especially when there is elevation of blood nonprotein nitrogen levels. Patients with coronary insufficiency, recent myocardial infarction, cerebral thrombosis, and severe, generalized atherosclerosis should not be treated by ganglionic blockade. Other contraindications to the drug include glaucoma, organic pyloric stenosis, bleeding peptic ulcer, and uremia.

Dosage.—Trimethidininum methosulfate is administered orally. Dosage must be highly individualized according to the response of the particular patient and the appearance and severity of side-effects.

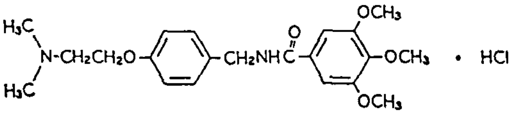
Oral therapy is initiated by the administration of 20 mg. before breakfast and again before the evening meal. Dosage is then increased by increments of 20 mg. every third day until a satisfactory response is obtained. The ultimate total daily dose may vary from 20 to 480 mg.

Preparations.—tablets 20 mg. and 40 mg.

Year of introduction: 1959.

Wyeth Laboratories, Division of American Home Products Corporation, cooperated by furnishing scientific data to aid in the evaluation of trimethidinium methosulfate.

Trimethobenzamide Hydrochloride (Tigan Hydrochloride).—N-(Dimethylaminoethoxybenzyl)-3,4,5-trimethoxybenzamide hydrochloride.—The structural formula of trimethobenzamide hydrochloride may be represented as follows:



Actions and Uses.—Trimethobenzamide hydrochloride, proposed for use as an antiemetic agent, is reported to be helpful in alleviating nausea and reducing the frequency of vomiting in the immediate postoperative period; in pregnancy; in motion sickness; in intoxication from digitalis, nitrogen mustard, and other drugs; and in such pathological conditions as malignancy, hepatitis, cholecystitis, uremia, alcoholic gastritis, labyrinthine disease, and radiation sickness. Although the early clinical reports are favorable, many are based on uncontrolled trials in which no comparisons with placebos or with other similar drugs were made, and the results obtained are difficult to appraise accurately. Nevertheless, the few comparative studies thus far reported suggest that trimethobenzamide hydrochloride has significant antiemetic activity. Effects appear within 20 to 40 minutes after either oral or intramuscular administration and persist for three to four hours.

Side-Effects.—No evidence of serious toxicity has accompanied the use of trimethobenzamide hydrochloride; adverse effects on the liver, kidney, or bone marrow have not been noted. However, most studies have been short-term trials, and further studies are greatly needed to establish definitely the safety of the drug for long-term use. Although the incidence of minor side-effects is not high, drowsiness, vertigo, diarrhea, exaggeration of preexisting nausea, pain at the site of injection, and local irritation after rectal administration have been reported. Administration prior to or during anesthesia apparently does not prolong awakening time. A sudden fall in blood pressure has been observed in one patient shortly after an injection of trimethobenzamide hydrochloride given during the postoperative period; however, it is questionable whether this complication was due to the action of the drug.

Experimental Pharmacology.—In animals, trimethobenzamide hydrochloride effectively inhibits apomorphine-induced vomiting, and is thus presumed to act primarily by depressing the chemoreceptor trigger zone; the possibility that depression of the medullary vomiting center may also contribute to its antiemetic effect has not been excluded, however. The antiemetic potency of trimethobenzamide hydrochloride is about one-tenth that of chlorpromazine when given subcutaneously and one-fourth that of the latter when given orally. When equieffective antiemetic doses of the two agents are compared, trimethobenzamide hydrochloride is the less active depressant of the central nervous system, as measured by degree of sedation, modification of behavior, prolongation of barbiturate sleeping time, and changes in the electroencephalogram.

Although trimethobenzamide resembles diphenhydramine and several other histamine-antagonizing agents in being an ether of dimethylaminoethanol, it seems to have only weak antihistaminic activity. Nor does it appear to antagonize the effects of epinephrine or of acetylcholine. An intravenous injection, in animals, produces a fall in blood pressure and an increase in bronchial tone.

Dosage.—Trimethobenzamide hydrochloride is administered orally, rectally, or intramuscularly. In adults, the recommended dose is 100 to 300 mg given orally or intramuscularly four times daily However, the effects of the larger doses within this range, when administered over prolonged periods have not been thoroughly explored. When given rectally, the dose is 200 mg. For the prevention o postoperative vomiting, a single dose of 200 mg. i given intramuscularly prior to or during surgery this dose may be repeated three hours after th termination of anesthesia, if necessary.

In children, the aforementioned doses are reduced, in proportion to their body weight. For th prevention of postanesthetic vomiting, the following single doses are given intramuscularly: in children weighing less than 30 lb. (13.6 kg.), 50 mg in those weighing 30 to 60 lb. (27.2 kg.), 100 mg 60 to 90 lb. (40.9 kg.), 150 mg.; and over 90 lb 200 mg.

Preparations.—capsules 100 mg.; solution (injection) 200 mg. in 2 cc.; suppositories 200 mg.

Year of introduction: 1959.

Roche Laboratories, Division of Hoffmann-LaRoche, Inc cooperated by furnishing scientific data to aid in the evaluation of trimethobenzamide hydrochloride.

Parenteral Use of Triamcinolone Acetonide (Kenalog)

Triamcinolone acetonide is a highly potent, synthetic gluco-corticoid, which was described previously for topical use in the treatment of certai acute or chronic dermatoses (*J. A. M. A.* 170:19 [May 9] 1959). The Council subsequently ha evaluated its usefulness and safety for parentera (intra-articular, intrasynovial, intrabursal) injectio in the treatment of painful and inflammatory cond tions of the joints, bursae, and tendon sheath When injected at these sites, the drug is usuall effective in relieving the joint pain, swelling, and stiffness associated with rheumatoid arthritis, osteoarthritis, bursitis, tendinitis, synovitis, and other conditions amenable to the anti-inflammatory action of locally injected gluco-corticoids. In responsive persons, beneficial effects generally appear within a few hours after injection and persist for periods of one to several weeks.

Systemic steroidal effects due to injection of triamcinolone acetonide are rare, if care is taken to guard against infiltration of the drug into soft tissues surrounding the joint. Painful local reactions at the site of injection have been reported only occasionally. Infrequently, dizziness and transient flushing may be encountered. Intra-articularly injected triamcinolone acetonide is contraindicated in patients with gonococcal or tuberculous arthritis or other infections in or near the joints.

The techniques of intra-articular injection of triamcinolone acetonide are the same as those ordinarily employed for other agents used by this route. If desired, a local anesthetic may be infiltrated into the surrounding soft tissues prior to the intra-articular injection. An aqueous suspension containing 10 mg. in 1 cc. is used. Dosage is variable and depends on the size of the joint and severity of symptoms. For small joints, amounts containing 2.5 to 5 mg. are generally used; for larger joints, the dose may range from 5 to 15 mg. Frequency of administration is determined by the duration of response.

The Council voted to amend the monograph on triamcinolone acetonide to describe its parenteral use.

E. R. Squibb & Sons, Division of Olin Mathieson Chemical Corporation, cooperated by furnishing scientific data to aid in the evaluation of the parenteral use of triamcinolone acetonide.

CLINICAL SCIENCE

NEWER APPROACHES TO ANTIHYPERTENSIVE THERAPY

Albert N. Brest, M.D.
and
John H. Moyer, M.D., Philadelphia

During the past decade a large number and variety of potent antihypertensive agents has been developed. These include Veratrum alkaloids, Rauwolfia compounds, hydralazine, ganglioplegic agents, and adrenergic-blocking drugs. The therapeutic actions of these compounds are directed primarily at the central mechanisms of sympathetic impulse formation or the peripheral sites of neurogenic transmission, or both (fig. 1). The more recent antihypertensive medicaments which are being developed, however, have much different mechanisms of action. It is the purpose of this report to discuss specifically those newer compounds which (1) affect catecholamine release, (2) alter fluid and electrolyte balance, and (3) interfere with enzymatic activity.

Antihypertensive Agents Which Affect Cathecholamine Release

Norepinephrine and epinephrine are catecholamines which are normally released by the postganglionic sympathetic fibers in response to sympathetic impulse transmission. These catecholamines, in turn, stimulate the peripheral neuroeffector site, thereby producing arteriolar vasoconstriction and a secondary increase in the arterial blood pressure.

The most important group of currently available antihypertensive drugs which affect catecholamine release is that of the Rauwolfia compounds. The earlier investigations into the mechanism of action of these compounds indicated that serotonin is released from binding sites within the brain. More recently it has been determined that Rauwolfia also releases catecholamines centrally from the hypothalamic centers, and in addition it has been found that catecholamines are released peripherally from the postganglionic sympathetic nerve fibers as well.[1] The latter effect depletes the sympathetic fiber of its catecholamine stores and thereby decreases the response to various pressor stimuli. These studies provide a better insight into the basic pharmacodynamic actions of this important group of antihypertensive agents.

Syrosingopine is a chemical modification of reserpine which exhibits predominantly hypotensive action with lesser central sedative effects. It appears that the hypotensive action of the latter compound is related primarily to its ability to release catecholamines from peripheral structures, whereas its reduced central effects are apparently due to a lesser capacity to liberate these amines from their central stores.[1] This type of pharmacological modification will undoubtedly continue and may eventually result in the development of even more potent hypotensive compounds.

Director, Hypertension Unit (Dr. Brest), and Professor of Medicine (Dr. Moyer), Hahnemann Medical College.

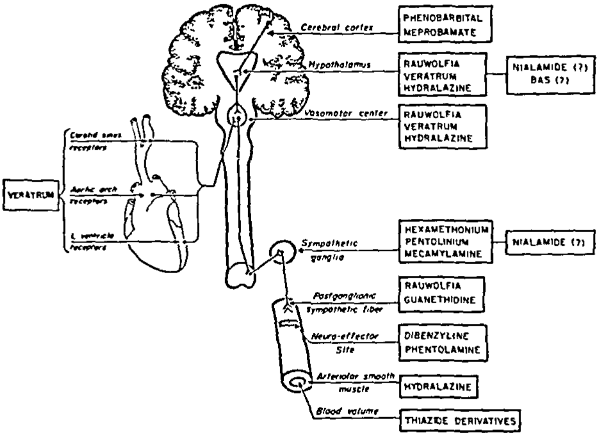


Fig. 1.—Diagrammatic illustration of various antihypertensive agents and their pharmacodynamic sites of action.

There is presently being developed a group of antihypertensive compounds, including guanethidine, whose mechanism of action appears to be an inhibition of the peripheral release of catecholamines from the postganglionic sympathetic nerve fibers. The activity of the sympathetic nervous system and the subsequent release of catecholamines is normally increased when the upright position is assumed. Guanethidine inhibits the usual response to this righting reflex, and blood pressure reduction thereby ensues. Preliminary studies by Page and Dustan[2] have suggested the marked hypotensive abilities of this compound, and subsequent studies[3] tend to confirm the effectiveness of this drug (fig. 2).

The blood pressure reduction obtained with guanethidine is predominantly a postural one and is therefore similar to that obtained with the ganglionic blocking compounds. However, in contrast to the ganglioplegic drugs, guanethidine produces a significant hypotensive response without the associated side-effects due to parasympathetic blockade. Side-effects encountered to date have indeed been minimal, with mild diarrhea as the only significant complaint even when large daily doses (450 mg.) of the drug are administered. No evidence of toxic action of the drug has been encountered thus far.

The dose of guanethidine needed to maintain a satisfactory hypotensive response has ranged from 25 to 450 mg. per day (average dose, 100 to 150 mg. daily). As with all of the other available antihypertensive agents, the concomitant administration of a thiazide derivative potentiates the blood pressure reduction obtained, thereby enhancing the therapeutic efficiency of the newer compound.

The blood pressure response to a single test dose of guanethidine given by mouth does not appear to be a reliable guide to the subsequent response. In fact, a significant blood pressure reduction may not be noted for 24 to 48 hours after the initiation of therapy. It is therefore recommended that at least 48 to 72 hours elapse before the daily dosage is increased. Also, since blood pressures fall more markedly in a patient who is standing than in one who is lying down, it would appear logical for the patient to sleep with the head of the bed elevated on 10-in. to 12-in. blocks in order to obtain the maximum therapeutic benefit from this drug.

The development of potent antihypertensive agents whose major effect is directed at peripheral catecholamine release promises to be an important contribution to the therapeutic armamentarium for diastolic hypertension.

Antihypertensive Agents Which Alter Fluid and Electrolyte Balance

The most important group of antihypertensive agents which has become available during recent years is that of the thiazide derivatives. The introduction of chlorothiazide as a hypotensive agent was followed by almost immediate clinical acceptance because of its potent antihypertensive qualities, its ability to potentiate the effectiveness of other hypotensive compounds, and the low incidence of associated side-effects and untoward reactions. Subsequently, several newer members of the benzothiadiazine family, including hydrochlorothiazide, flumethiazide, and hydroflumethiazide, have become available for clinical use.

A recent study[4] indicated that chlorothiazide, hydrochlorothiazide, and flumethiazide produce similar hypotensive responses when used in comparable (diuretic and natruretic) dosages. A significant hypotensive effect was obtained in about 40% of 121 hypertensive subjects, when they were in the supine position, and a slightly greater postural hypotensive response was induced (see table). The incidence of side-effects encountered was small with each of the drugs and, similarly, the incidence of beneficial effects obtained did not indicate an outstanding advantage for any one of the three compounds.

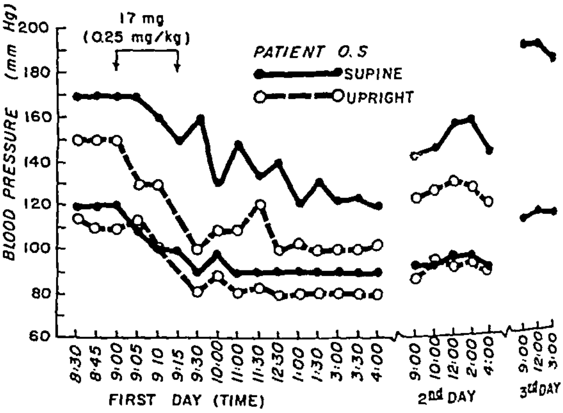

Fig. 2.—Blood pressure response to intravenously given guanethidine. Significant hypotensive response was obtained with single parenteral infusion of guanethidine, and blood pressure reduction was sustained for 48 hours.

The antihypertensive effect achieved with the thiazide derivatives is, of course, by no means unique. A similar hypotensive response can be obtained with the use of a rigid low-salt diet or the parenteral administration of mercurial diuretics. Unfortunately, in order to achieve a significant blood pressure reduction, the patient's dietary intake of salt must be reduced to 500 mg. per day or less, and there are few patients who will adhere to such a rigid dietary regimen for any significant period of time. Likewise the administration of daily injections of mercurial diuretics is obviously unsatisfactory from a practical standpoint. Thus the development of potent, well-tolerated diuretic substances which can be effectively administered orally must be considered a major contribution to the drug therapy of essential hypertension.

The antihypertensive mechanism of the thiazide derivatives is as yet undetermined. The initial pharmacodynamic studies[5] suggested that their hypotensive effect was related to a *reduction in plasma volume*, which resulted from the diuresis of sodium and chloride ions and the accompanying loss of water stores from the extracellular space. The subsequent decline in the cardiac output could thereby account for the ultimate reduction in the arterial blood pressure. However with the continued use of these drugs there is a reaccumulation of plasma volume[6] which is probably due to the migration of fluid from the extracellular space into the intravascular compartment. Thus, the original postulate appears to be an unlikely explanation.

Blood Pressure Response to Three Thiazide Derivatives

Drug*	Patients, No.	Supine, %			Upright, %		
		Normotensive†	Mean Blood Pressure Reduced >20 mm. Hg or Normotensive	Unresponsive	Normotensive†	Mean Blood Pressure reduced >20 mm. Hg or Normotensive	Unresponsive
Chlorothiazide	50	18	36	64	24	46	54
Hydrochlorothiazide	54	20	39	61	22	39	61
Flumethiazide	17	12	41	59	47	53	47

* The dose of chlorothiazide was 500 mg. b.i.d., hydrochlorothiazide 50 mg. b.i.d., and flumethiazide 500 mg. b.i.d.
† Blood pressure reduced to 150/90 mm. Hg or less.

One important facet about which we know little concerns the local effects which are induced within the intracellular compartment due to changes in electrolyte patterns. These effects might conceivably be the most important of all, and Preziosi and co-workers[7] reported some interesting experimental observations which did indeed suggest a local depressant action on the peripheral vascular smooth muscle. Further confirmation of these findings must be awaited.

Regardless of the precise mechanism of action of these compounds, it would appear that their antihypertensive abilities are related to their diuretic and natruretic effectiveness. Thus, when comparable doses of the various thiazide derivatives are administered, *similar hypotensive responses* are obtained.

Antihypertensive Agents Which Interfere with *Enzymatic Activity*

There is currently being developed another group of antihypertensive compounds whose major effect is apparently related to an interference with enzymatic (specifically, monoamine oxidase) activity. Monoamine oxidase (MAO) is an enzyme which actively destroys various monoamines including norepinephrine, epinephrine, and serotonin. It would therefore be anticipated that the MAO inhibitors would cause an accumulation of these hormones in muscle and nerve tissues, where they normally account for smooth muscle contraction and neurogenic transmission. Hence it seems rather paradoxical that hypotension should occur, since the expected result would be a hypertensive response secondary to the increased concentration of these pressor substances. It is of interest in this regard that many patients with norepinephrine-producing tumors (pheochromocytomas) may have a *supine elevation of blood pressure but a marked postural hypotensive effect*; and, similarly, hypotensive episodes may also occur in patients with hyperserotonemia due to malignant carcinoid tumors.

Any statement concerning the mechanism by which the monoamine oxidase inhibitors lower blood pressure is entirely speculative at this time. Some insight into their hypotensive abilities, however, may be obtained from a review of their clinical actions. The hypotensive response is mainly a postural one and the side-effects which have been reported (with iproniazid and other MAO inhibitors)[8] are similar to those encountered with the ganglionic blocking agents. These have included blurring of vision, dryness of the mouth, constipation, and urinary difficulty. The combination of these two clinical findings has therefore suggested that their mechanism of action may be due primarily to ganglionic blockade.

Brodie[9] has postulated that norepinephrine and serotonin act as neurohormones within the central nervous system to control and regulate the various autonomic, somatic, and psychogenic functions. Since the use of the MAO inhibitors can be expected to result in an increased concentration of these substances within the brain tissue, it is conceivable that the hypotensive abilities of these compounds may be intimately involved with this particular effect. However, much more investigative work needs to be accomplished in this regard.

In summary, the clinical actions of the monoamine oxidase inhibitors suggest that these compounds might be ganglionic blocking agents as well as monoamine oxidase inhibitors. Whether these two actions are separate or interrelated is uncertain at this time. However, regardless of the precise mechanism of action, continued study of these compounds in patients with hypertension is warranted and may, indeed, ultimately provide a clue to the pathogenesis of this important disease process. Finally, because of the additional beneficial effects of the monoamine oxidase inhibitors in the therapy of angina pectoris, it may well be that these drugs will be particularly indicated in the hypertensive subject with complicating coronary artery disease.

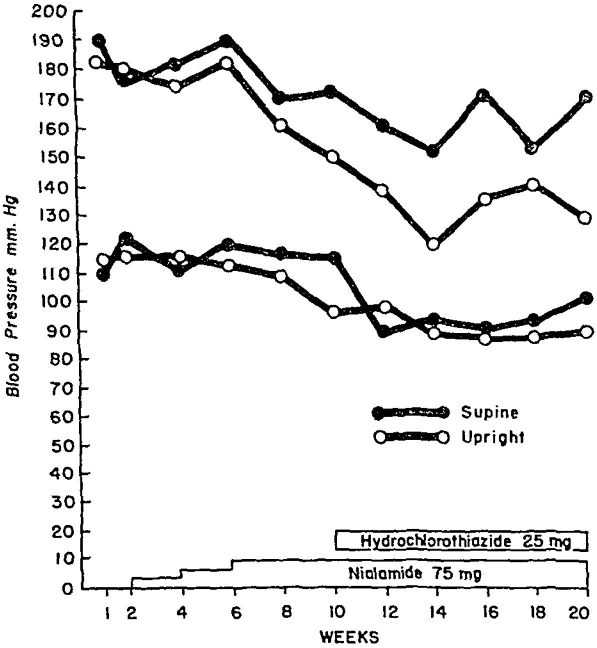

Fig. 3.—Response of patient to combined antihypertensive medication. Although significant postural hypotensive response was obtained with combination of nialamide (75 mg. t. i. d.) and hydrochlorothiazide (25 mg. b. i. d.), supine blood pressure remained elevated.

Our own experience[10] with the monoamine oxidase inhibitor nialamide, used alone and also in combination with hydrochlorothiazide, tends to confirm the clinical findings reported by other investigators; that is, although these compounds are indeed capable of effectively reducing blood pressure when used alone, they are considerably more effective when used in combination with the thiazide derivatives. It is also apparent that the hypotensive response which is obtained with these agents (whether used alone or in combination, or both) is most pronounced when the patient is in the upright position (fig. 3). The patient with moderate or severe hypertension should be started on therapy with hydrochlorothiazide, 50 mg. twice daily, and nialamide, 25 mg. three times daily. Thereafter the nialamide dosage can be doubled at 7-day to 14-day intervals, to a maximum of 100 mg. three times daily, unless an adequate response occurs at a lower dosage.

Summary

The therapeutic actions of most of the currently available antihypertensive agents are directed primarily at the central mechanisms for sympathetic impulse formation or at the peripheral sites of neurogenic transmission, or both. There are presently being developed a variety of newer compounds which affect other important pharmacodynamic sites. These include agents which affect the central or peripheral release of catecholamines, alter fluid and electrolyte balance, and interfere with enzymatic activity. The use of these newer agents provides a more diversified approach to the therapy of essential hypertension and possibly a better insight into the mechanisms involved.

SPECIAL CONTRIBUTION

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS POLICY FOR FOREIGN MEDICAL GRADUATES

"Regardless of the date of appointment, it is expected that all graduates of foreign medical schools serving as interns or residents in U. S. hospitals as of July 1, 1960, will have been certified by the Educational Council for Foreign Medical Graduates."

The above policy statement was sent to all hospitals conducting intern and resident programs and was published in The Journal of the American Medical Association, July 19, 1958. It does not apply to those foreign medical graduates who possess a full and unrestricted license to practice in the United States or its territories or possessions. Persons holding such licenses are advised, however, that ECFMG certification may be required when seeking reciprocity from other states.

The CMEAH was supported by the wholehearted reaffirmation of the July 1, 1960, cut-off date by the House of Delegates at its December, 1959, meeting. However, the House of Delegates directed that the above policy be implemented judiciously where local circumstances warrant. Accordingly, in implementing this policy, the following will pertain.

After July 1, 1960, no hospital should expect to maintain an approved internship or residency program unless its appointees who are graduates of foreign medical schools either (1) have a full and unrestricted state license to practice, (2) are in their final six months of training, (3) have secured a standard or temporary certificate from the ECFMG, or (4) have been given a contingent appointment for not more than six months based on their having been accepted for the September, 1960, American medical qualification examination of the ECFMG. Extension of the appointment beyond Dec. 31, 1960, will be dependent upon the appointee receiving temporary or standard certification from the ECFMG as a result of this examination.

It is a requirement of the law that institutions must notify the Immigration and Naturalization Service of changes in the appointments of those trainees who are in this country on temporary or student visas under the exchange-visitor program. This is not a requirement in the case of the permanent immigrant.

Each hospital making contingent appointments on or after July 1, 1960, should do the following:

a. Include in the contract or letter of agreement with the foreign medical graduate a statement that the appointment will be terminated on or before Dec. 31, 1960, and the Immigration and Naturalization Service notified if the candidate fails the September, 1960, AMQ examination. (It appears to the CMEAH that it is inappropriate to offer such an appointment to a foreign medical graduate who is not now in the U. S. In this event, it would seem morally indefensible to make such a contingent appointment with the result that the foreign graduate might spend only six months in this country.)

b. In all such instances of failure of the AMQ examination by a foreign medical graduate who is on the exchange-visitor program, address a letter promptly to the Immigration and Naturalization Service stating the date on which the individual's appointment will be terminated.

c. Forward a copy of the above letter to the CMEAH so the record of the hospital program can be cleared.

d. In the case of foreign medical graduates who have permanent immigrant or citizenship status, a similar letter should be addressed directly to this Council for action as stated in "c."

e. Check all other appointments to be certain that those noncertified foreign medical graduates are either in their final six months of training or have a license to practice in a state, territory, or possession of the United States.

Basis for Council on Medical Education and Hospitals Policy Implementing Certification by the Educational Council for Foreign Medical Graduates

"The Essentials of an Approved Internship and Essentials of Approved Residencies" state that "the development of a satisfactory program requires first of all, careful selection of applicants for appointment to the (intern or resident) staff. . . . The qualifications of the (intern or resident) staff should leave no doubt as to their competence to accept this assignment since the primary obligation of the hospital must be for the patients' welfare."

"The Essentials" further state: "The Council recommends that hospitals considering foreign medical school graduates for (internship or residency) positions acquire reasonable assurance in regard to their medical qualifications through utilization of the program of the Educational Council (or Foreign Medical Graduates)."

After July 1, 1960, the CMEAH will recommend to each review committee the disapproval of those training programs whose rosters contain graduates of foreign medical schools who do not satisfy requirements 1, 2, 3, or 4.

OPERATING ROOM INFECTION

IN THE latter half of the 19th century, Lord Joseph Lister,[1] on the basis of Pasteur's work and his own investigations, introduced, as part of his aseptic technique, the carbolic spray, in an attempt to free the air of the operative field of pathogenic bacteria. It was soon demonstrated, however, that contact contamination overshadowed any other source of inoculation of an open wound. As a result, aseptic technique was developed, with the principal objective of sterilizing, or, if unable to sterilize, of cleansing thoroughly everything except the air that came in contact with the wound. Contact inoculations have thus been controlled relatively satisfactorily. Masking, first of the mouth and later of the mouth and nose, by a technique inadequate at best, has long been advocated and widely adopted to prevent droplet contamination. The importance of "droplet nuclei" of bacteria, which will pass through most masks and lead to contamination of the air, is more generally recognized but has not been controlled. Bacteria in the air may float for varying periods of time and settle on the exposed "sterile field" and wound.

In the early days of "aseptic surgery" it was recognized that, despite the adoption of rigid precautions, some bacteria were present in every surgical wound, and a technique designed to leave the wound in the best condition for the body defenses to overcome this "irreducible minimum" of bacteria was developed. "Unexplained" infections were reduced and only occasionally were fatal. The "golden age of surgery" was ushered in, with more and more areas of the body becoming accessible to operations of greater and greater magnitude, duration, and trauma. No area of the body is inaccessible today to the trained surgeon. However, with these larger, more traumatizing, and longer procedures, "unexplained infections" have become progressively more common and more critical. In years past, infections associated with epidemics of respiratory tract contamination, particularly streptococcic, were critical in some instances. Postoperative infections after the widespread dissemination of hemolytic streptococci during and after the influenza epidemic of 1918-1919 became so frequent and so serious that some hospitals closed their operating rooms except to emergency cases. Staphylococci have now taken a front line stand and form a major group of respiratory tract contaminants. Dissemination of these pathogens may reach epidemic proportions during the colder months.

Despite this information and the studies that have related peaks of wound infections with epidemics of respiratory tract disease, the air as a route of spread of bacteria has been overlooked by some surgeons, except for "token masking" and restrictions at times on talking in the operating room. In contrast, attempts to control contact contamination have been continuous and have resulted in an ever-improving sterile technique which has been extended occasionally to produce such innovations as the "no-touch technique" for bone grafts. It should be evident that widespread epidemics of wound infections may be explained by a general and continuing distribution of the offending bacteria and cannot be explained always by incidental breaks in the aseptic technique routinely used. Frequently, when such an epidemic of wound infections has occurred, the aseptic ritual in the unfortunate hospital has been restudied and made more rigid, even when defects have not been demonstrated. During the time required for such a study, the epidemic of respiratory infections and the resultant air contamination may have subsided and the infection rate may have returned to the normally low level. Credit for control of the wound infections has then been attributed to the additional precautions instituted.

It is generally recognized that postoperative infections in clean wounds occur frequently, that they are caused predominantly by staphylococci, that the organisms are widely distributed, and that the respiratory tract is the usual reservoir. It is less generally recognized that these organisms can be recovered by sedimentation from the air of most closed areas that contain human beings. The effectiveness of ultraviolet radiation (2,537 A) in killing rapidly such bacteria either in the air or on exposed surfaces is pertinent. A communication by Hart in this issue of THE JOURNAL, page 1019, describes experience with ultraviolet radiation at Duke University over a period of three decades.

---

[1] Lister, J.: On Antiseptic Principle in Practice of Surgery, Lancet 2:353, 1867.

The control of epidemics of gastrointestinal infections by elimination of bacterial spread through contaminated water and food is recognized. In contrast to the intake of fluid and food, which is intermittent and can be deferred until rendered safe, the intake and exchange of air is a continuous process. Fortunately, the reservoir of air in which we live and breathe is relatively free of pathogenic bacteria, except in occupied closed areas. Here the degree and type of such contamination depend on the concentration of occupants who are carriers, the degree of their respiratory tract contamination, the propulsive forces that put the organisms into the air, the frequency of air changes, and the favorable or deleterious influences that affect the bacterial environment. The lethal value of ultraviolet sunlight against pathogenic bacteria and the purity of the air in the "wide open spaces" have long been recognized. It is not difficult to supply the operating rooms with air free of pathogenic bacteria. This is accomplished by taking in air that is relatively free of bacteria and removing the rest by washing and by mechanical and electrostatic filtration. However, subsequent pollution of this clean air in the occupied room with the pathogenic flora of the respiratory tracts of the occupants is difficult, if not impossible, to prevent. Such pollution can be held to a low level by limiting occupancy, by reducing propulsive forces, by more adequate masking, and by reduction of the bacterial build-up by frequent air changes. Even with these precautions, the organisms remaining in the air, if highly pathogenic, may cause wound infections of varying degrees of severity.

Continuous exposure of the operating room to an adequate intensity of ultraviolet radiation has been in daily use in the Duke Hospital for over 24 years and in as many as 15 operating rooms at a time. The viable bacteria on exposed surfaces and those settling from the air have been held to a low level. "Unexplained infections" in clean wounds have been reduced to a low percentage. This has been accomplished without serious or permanent injury to patient or personnel, even during the longest operations or after almost daily exposures of persons for more than two decades. The only protection used is shading of the skin and eyes, an insignificant handicap during an operative procedure. Although the source of the offending organisms is predominantly the respiratory tracts of the occupants of the operating room, control of the air route of spread is equally effective regardless of the source of the organisms, whether it is the respiratory tracts, air-conditioning system, blankets, linens, shoes, the floor of the operating room, or distant parts of the hospital. Consideration of this phase of bacterial control of the operating room seems pertinent.

COUNSEL TO AUTHORS

For many years the advertising pages have carried a column each week entitled "Suggestions for Contributors." Like a number of documents that appear unchanged decade after decade the suggestions were probably seldom read even by those who might have profited by doing so. A major revision has been made in the column in this issue. It is hoped that those who wish to prepare a manuscript for THE JOURNAL will take a moment to read what has been restyled as "Counsel to Authors." Special attention is directed to the paragraph beginning "Manuscripts . . ." which mentions the newly prepared pamphlet, "Suggestions for Authors of Articles Submitted to THE JOURNAL of the American Medical Association." A copy of the new suggestions may be obtained on request. It should prove helpful to the author.

THE DOCTOR ABROAD

At the turn of the century a significant number of physicians pursued postgraduate training in the medical centers of Europe, especially Austria and Germany. A smaller number of physicians visited the continent or other lands outside of America each year, attracted solely by the amenities of travel. In the second half of this century the reverse will most likely hold. The majority of physicians who travel abroad in 1960 will be pleasure-bound. Their activities will include a minimum of professional liaison. Only a smattering will undertake full-time postgraduate study. It is assumed that physicians in this category will do an excellent job of promoting understanding between other lands and the United States. It is to the traveling physician in the first category that a word of encouragement may be opportune.

The encouragement is to do more and not to do less while abroad. The opportunities to enrich one's experience as well as to foster better international relationships should not be overlooked. Behrman has emphasized in his letter to the editor, on page 1082, in this issue that physicians from the United States usually are welcome in any hospital, medical school, or doctor's office about the world. In most instances their presence is deeply appreciated, and, before many minutes have passed, the value of the exchange begins to be sensed. If one wishes to go further and initiate a one-way exchange, this also may prove to be highly enlightening as well as most self-satisfying.

Immediately after World War II, when critical drug items such as penicillin were short in supply, even small quantities of this drug were welcome abroad. The need for antibiotics, steroids, or other useful drugs probably is not critical in many areas at the present time. There are lands, however, particularly in the poorly developed areas of the world, where drugs still are critically short in supply and any quantity will be welcome. Another avenue for appreciation is the dispatch of books and periodicals. There are a number of areas in the world that are deficient in current monographs and textbooks as well as current periodicals. If contact is established with one or more physicians, most likely there are pieces of equipment, books, or periodicals in your office that might be sent abroad on your return to the United States that would be appreciated to the utmost and would strengthen mutual ties. The opportunity to support a one-man Marshall plan, patterned after the experience of Dr. Behrman, should not be overlooked. Areas that are in need of medical strength, spiritually and substance-wise, include most of the communities outside of the large population centers of the free world.

THE FOREIGN-SCHOOLED INTERN

The progressive increase each year in the number of interns who have received their formal professional education in a foreign land is of great general concern. The acceptance on the house staff of an intern educated outside of North America places responsibility on those who are answerable for the training program that is not appreciated universally. Newsworthy examples of substandard performance which expose our vulnerability to criticism of the current system of exploiting the outlander in many of our hospitals are featured in the public press from time to time. The unfortunate experience in New York City last fall which involved an intern from India and a British actor may be cited.

Whatever the goal of the intern, the hospital needs him and is dependent on the service he renders and is happiest when he is a graduate of an American medical school. Great effort is expended ordinarily by the medical staff in the education of the intern in the teaching hospital allied with a medical school. This effort is not as predictable in the nonaffiliated hospital. It is generally agreed, however, that the greater the industry of the visiting staff directed toward the intern training program the better the program and the better the patient care. One might speculate that an approximate correlation exists between the hours of thought and guidance of the internship by the professional staff and the number of fourth-year students who apply for that internship.

The distribution of foreign-born interns in American hospitals does not follow such a predictable pattern. The internships most highly desired by American graduates usually enroll the smallest number of foreign graduates. Hospitals with inferior or mediocre intern training programs enroll the largest number of foreign-born interns. The situation is truly deplorable in some hospitals. The responsibility for this state of affairs can be assigned only to a disinterested visiting staff. Instead of enlarging his professional experience, the foreign-born intern in such a situation may be assigned duties commensurate with a medical technologist. Even more frightening, he may be assigned complete responsibility for the medical care of a large number of patients; a responsibility for which he is often totally unprepared.

It is only fair to note, however, that in unusual circumstances the foreign intern may be exposed to a planned program of learning under the careful supervision of a director of house staff education, complemented by the understanding instruction of an enlightened portion of the attending staff. The educational opportunities and the professional responsibilities in this instance approach those offered by a medical school affiliated hospital. But even in such an institution, a truly valuable experience depends on a fairly satisfactory reading, writing, and speaking knowledge of the English language. Without this, it will be virtually impossible for the intern to gain the necessary familiarity with American customs as well as the professional knowledge and professional techniques which are the principal goals of the experience. In the absence of communicative skills even intellectual proficiency, industry, and dedication are not adequate to carry the foreign graduate toward the goal.

What is the result of this broad deficiency and deep mediocrity? The foreign-born intern is often least aware of the shortcomings of the internship and may appear thoroughly satisfied. It is a new experience for him, and if he fails to gain professional attainments, at least he is rewarded by the opportunity to live in a prosperous land, to consume good food, to dress well, to attend the latest movies, and to watch television. Unfortunately these should not be the zenith of attainment in themselves. The foreign graduate should be accepted for the same purpose as our American interns. He should be qualified according to standards established by the Educational Council for Foreign Medical Graduates. The hospital that accepts him must provide the same educational experience offered his American counterpart. The hospital should not accept him as a servant. The visiting staff cannot be allowed to shirk its responsibility to him, nor can he be allowed to overlook the responsibility to his native land, the fulfillment of which was the basic purpose for his admission to America and to an American hospital. It is the breadth of clinical knowledge gained here that will permit him to serve his people better upon his return. This fact cannot be forgotten. Should he decide to remain in America and practice, undoubtedly we gain. But it is usually at the expense of his own people, who in the majority of instances need his medical skill desperately. The magnitude of this problem increases yearly. Organized medicine has given much thought to these matters. Some progress has been made; much more progress is imperative.

COMMITTEE ON MEDICAL RATING OF PHYSICAL IMPAIRMENT

GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT

THE CARDIOVASCULAR SYSTEM

Preface

Evaluation or rating of permanent disability has long been recognized as an important and complex subject. In the past much confusion has resulted from inadequate understanding by physicians and others of (*a*) the scope of medical responsibility in the evaluation of permanent disability; and (*b*) the difference between "permanent disability" and "permanent impairment."

It is vitally important for every physician to be aware of his proper role in the evaluation of permanent disability under any private or public program for the disabled. It is equally important for him to have the necessary authoritative material to assist him in competently fulfilling his particular responsibility—the evaluation of permanent impairment. It is the purpose of this and other reports of the Committee on Medical Rating of Physical Impairment to correct a past confusion of terms and to provide a series of practical guides to the evaluation of various types of permanent impairments.

The following explanations of generally used terms in programs for the disabled will suffice, for all practical purposes.

1. *Permanent Disability.*—This is not a purely medical condition. A patient is "permanently disabled" or "under a permanent disability" when his actual or presumed ability to engage in gainful activity is reduced or absent because of "impairment" and no fundamental or marked change can be expected in the future.

2. *Permanent Impairment.*—This is a purely medical condition. Permanent impairment is any anatomic or functional abnormality or loss after maximum medical rehabilitation has been achieved and which abnormality or loss the physician considers stable or nonprogressive at the time evaluation is made. It is always a basic consideration in the evaluation of permanent disability. It should be remembered, however, that permanent impairment is a contributing factor to, but not necessarily an indication of, the extent of a patient's permanent disability.

3. *Evaluation (Rating) of Permanent Disability.*—This is an administrative, not a medical, responsibility and function. Evaluation of permanent disability is an appraisal of the patient's present and probable future ability to engage in gainful activity as it is affected by nonmedical factors such as age, sex, education, and economic and social environment, and the medical factor—permanent impairment. Nonmedical factors have proved extremely difficult to measure. For this reason permanent impairment is, in fact, the sole or real criterion of permanent disability far more often than is readily acknowledged. A determination of permanent disability is an administrative decision about the patient's entitlement.

4. *Evaluation (Rating) of Permanent Impairment.*—This is a function that physicians alone are competent to perform. Evaluation of permanent impairment defines the scope of medical responsibility and therefore represents the physician's role in the evaluation of permanent disability. Evaluation of permanent impairment is an appraisal of the nature and extent of the patient's illness or injury as it affects his personal efficiency in the activities of daily living. These activities are self-care, communication, normal living postures, ambulation, elevation, traveling, and nonspecialized hand activities. It is not and never can be the duty of physicians to evaluate the social and economic effects of permanent impairment. These effects must be evaluated by administrators in making determinations of permanent disability.

Competent evaluation of permanent impairment requires adequate and complete medical examination, accurate objective measurement of function, and avoidance of subjective impressions and nonmedical factors such as the patient's age, sex, or employability.

The Committee on Medical Rating of Physical Impairment believes that permanent impairment cannot vary because of the circumstances of its occurrence or the geographical location of the patient at the time. Furthermore, unlike disability, permanent impairment can be measured with a reasonable degree of accuracy and uniformity on the basis of impaired function as evidenced by loss of structural integrity, pathological findings, or pain substantiated by clinical examination.

Members of the Committee on Medical Rating of Physical Impairment are Drs. Raymond M. McKeown, Coos Bay, Ore., Chairman; George F. Gsell, Wichita, Kan.; Henry H. Kessler, Newark, N. J.; Quenton W. Mack, Boise, Idaho; and O. A. Sander, Milwaukee. Mr. George W. Cooley of Chicago is secretary.

Consultants in the preparation of this guide were Drs. David I. Abramson, Chicago; Lewis H. Bronstein, New York City; Richard J. Clark, Winchester, Mass.; S. Charles Franco, New York City; Leonard J. Goldwater, New York City; Hugh Montgomery, Philadelphia; William A. Leff, Newark, N. J.; Thomas W. Parkin, Rochester, Minn.; Oglesby Paul, Chicago; Donal R. Sparkman, Seattle; William D. Stroud, Philadelphia (deceased); James V. Warren, Galveston, Texas; and J. Allen Yager, Paterson, N. J.; and Mrs. Marjorie W. Grigsby, Evanston, Ill.

The Committee is familiar with the various formulas developed in the past for use in evaluation of permanent disability. These formulas are usually administrative devices which equate specific medical criteria to specific percentages of permanent partial or total disability (loss of working or earning capacity). From the medical standpoint the medical criteria may undeniably represent various anatomic or functional impairments. However, it is unrealistic to presume that many of these impairments, especially those of a minor nature, will necessarily at some time result in disability. These administrative devices are not generally available to physicians and in any event would not be useful in making sound evaluations of permanent impairment. On the other hand, although a number of valuable contributions have been made in the past, the Committee found no comprehensive practical system of the type necessary for the evaluation of permanent impairment by individual body systems or of the whole man. For this reason the Committee has undertaken to prepare a series of guides. The Committee has been greatly assisted in its work by the outstanding consultants whose names appear in connection with the appropriate guides.

Three guides are now available. The first, dealing with the extremities and back, was published as a special edition of the Feb. 15, 1958, issue of The Journal; the second, concerned with the visual system, was published as a special article in the Sept. 27, 1958, issue of The Journal. This third guide deals with the cardiovascular system.

All of the guides have been developed after careful study of the literature and of the views of recognized authorities and will be reviewed periodically to insure their continuing value as advances in medical knowledge and technique occur.

Each guide contains recommended percentage values related to the criteria provided. The use of numerical values is preferred because of difficulty in communication and variability in interpretation of such terms as "slight," "marked," and "moderate." Such values provide a practical means of expressing and calculating the extent of permanent impairment and encourage accurate, equitable, and uniform evaluation. Methods of calculating impairment are uniform, explained in detail with examples, and require a minimum of computation. Generally, when a single impairment is involved, the percentage value may be read directly from the text or transposed to a relative value of a unit of the body or of the whole man by referring to appropriate tables.

When two or more impairments are involved, however, the value of each impairment must be ascertained and transposed to a common denominator, such as the whole man. Thereafter these values must be combined. A combined values table is provided by which any combination of impairments may be easily found. The method generally used to combine various impairments is based on the principle that each impairment acts not on the whole part but on the portion which remains after the preceding impairment has acted. For purposes of computation, the source and chronology of the impairment values are immaterial.

After the values of all impairments involved have been computed and transposed to a common denominator, the final impairment value, whether the result of single or of combined impairments, is expressed in terms of the nearest 5%.

Introduction

Permanent impairment in varying degrees may result from any anatomic or functional deviation from normal in the cardiovascular system. The purpose of this guide is to assist physicians by providing criteria and methods for determining the degree of such impairment in terms of the whole man.

Evaluation of cardiovascular impairment involves special considerations and poses certain problems which are not generally encountered in evaluating other impairments. For these reasons the criteria provided in this guide must be general, yet reasonably specific, and withal not so complex as to discourage general use.

Special Considerations.—Permanent impairment in a cardiovascular context may be described as that condition which persists after maximum medical and surgical therapeusis and rehabilitation, and after a reasonable period has elapsed to permit maximum development of collateral circulation and other adjustments of nature after an acute insult. For example, a period of not less than six months should elapse before determination of permanent impairment after an acute myocardial infarction. In case of operation for rheumatic or congenital heart disease, the period should be at least one year after operation.

Furthermore, it must be recognized that the degree of permanent cardiovascular impairment is not static. Unlike certain other types of impairments, a constantly changing process is usually involved. For this reason all findings should be subject to review and the patient reevaluated for possible deterioration or improvement at intervals of six months to one year, depending on circumstances. This is also necessary because of the potential benefits to patients from newer therapeutic methods as they are developed in this rapidly changing field.

One of the problems in the evaluation of cardiovascular impairment is the frequent disparity between objective findings and subjective symptoms. For instance, a patient with coronary artery disease may appear completely normal on examination, including electrocardiogram and x-ray, yet he may be severely impaired by angina pectoris. At the other extreme is the patient with a loud murmur, moderately severe cardiac enlargement, and a bizarrely abnormal electrocardiogram; yet this patient may be able to perform his accustomed activities in comfort despite these apparently unfavorable findings.

It must be emphasized that the presence of symptoms or even signs suggesting heart disease does not necessarily indicate a pathological process of that organ. These manifestations may be purely psychological in origin. Moreover the presence of organic heart disease may render a patient more susceptible to the development of symptoms of a psychological nature. In view of these considerations, the paramount importance of a detailed and critical history is clear since it may serve as the principal or even the only basis for the evaluation of permanent impairment.

Method of Evaluation.—Evaluation of cardiovascular impairment is usually possible through sound clinical judgment based on a history, examination, and a minimum of laboratory aids.

It would be highly desirable if specific objective tests of cardiovascular function were available, from which relative impairment could be directly determined. If, for example, a test of a patient's physiological capacity could be matched with the energy requirements of various activities, a decision regarding his abilities might be easily reached. Unfortunately, the available tests do not provide such a simple solution. The performance of exercise tests provides an excellent opportunity for the physician to observe his patient under the stress of physical activity and may aid in diagnosis. In some instances, such tests lead to the discovery of excessive restriction of the patient's activity. It should be remembered, however, that the patient's performance may be importantly modified by his emotional approach and that evaluation of the test result is made difficult by considerable individual variations in training and physical ability. Physiological function tests, although of limited value at present, offer a fertile field for research and development. They supplement but do not substitute for the physician's clinical evaluation.

Classification.—Before classifying any patient, the physician must establish as accurately as possible a firm etiological,anatomic, and physiological diagnosis, supported by appropriate signs and symptoms as set forth in accepted criteria. As a result of a carefully obtained history, a thorough physical examination, and the use of appropriate laboratory aids, the physician should be able to classify a patient within the categories listed below and thereafter determine the percentage of impairment of the whole man.

For practical purposes, three categories have been established: (*a*) heart disease, (*b*) hypertensive vascular disease, and (*c*) vascular diseases affecting the extremities.

Each category is divided into a series of classes, each with its respective subjective and objective clinical findings and corresponding percentages of impairment.

When the clinical findings are such that a patient may not be classified in a single one of the above categories, evaluation of impairment in accordance with each of the appropriate categories should be made and the corresponding percentages of impairment noted. These values are then combined to obtain the percentage of impairment of the whole man contributed by the cardiovascular system.

Reports.—When making oral or written reports, the physician should explain and substantiate his conclusions about the patient's status. He should also clearly indicate that this information represents his findings and conclusions as of the date evaluation is made. A detailed history, complete physical examination findings, laboratory examination and reports, diagnoses, classification, and the resulting impairment value should be reported.

HEART DISEASE

Permanent impairment due to heart disease most commonly results from (1) failure of myocardial function leading to congestive heart failure; (2) impairment of coronary circulatory function resulting in angina pectoris, coronary insufficiency, coronary occlusion, or myocardial infarction and its complications; or (3) a combination of these.

The etiological diagnoses most commonly encountered are congenital, rheumatic, arteriosclerotic (coronary), hypertensive, syphilitic, and pulmonic (cor pulmonale) heart disease. In addition, it is recognized that in rare instances neurocirculatory asthenia (effort syndrome) and arrhythmias, occurring without demonstrable organic disease, may produce permanent impairment.

This category is divided into five classes, each with percentage values representing the impairment of the patient as a whole man. Classes 1 through 4 apply to patients with organic heart disease ranging from the asymptomatic (class 1) to the severely impaired (class 4). These four classes are adapted from the functional and therapeutic classifications of the American Heart Association. The fifth class, class 0, applies to patients with nonorganic heart disturbances.

Class 1—Impairment of Whole Man, 0-15%.—A patient belongs in class 1 when (*a*) organic heart disease exists but without resulting symptoms; (*b*) walking, climbing stairs freely, and the performance of the usual activities of daily living do not produce symptoms; (*c*) prolonged exertion, emotional stress, hurrying, hill-climbing, recreation (prophylactic restriction of activity such as strenuous competitive sport does not exclude a patient from this class), or similar activities do not produce symptoms; and (*d*) signs of congestive heart failure are not present.

Example 1: On routine chest survey, calcification was found in the patient's pericardium. Clinical examination revealed no evidence of other cardiac impairment and the patient was asymptomatic.

Diagnoses: Etiological: Unknown.
Anatomic: Calcified pericardium.
Physiological: Normal sinus rhythm; no cardiac insufficiency.
Impairment: 0% impairment of the whole man.

Example 2: A 25-year-old man has a definite history of rheumatic fever, presenting a grade 3 apical systolic murmur. Despite these findings he is asymptomatic and leads a normal life without limitation of activity.

Diagnoses: Etiological: Rheumatic fever, inactive.
Anatomic: Mitral insufficiency; no cardiac enlargement.
Physiological: Normal sinus rhythm; no cardiac insufficiency.
Impairment: 5% impairment of the whole man.

Example 3: The patient is a 50-year-old man who sustained a confirmed posterior myocardial infarction one year ago and made a good recovery. He has continued to show a fixed electrocardiographic pattern of the old infarct but has had no further angina, dyspnea, or other symptoms. He is able to carry on normal life activities, although he avoids excesses of exertion on the advice of his physician.

Diagnoses: Etiological: Atherosclerosis of the coronary arteries.
Anatomic: Healed myocardial infarction.
Physiological: Normal sinus rhythm; no cardiac insufficiency.
Impairment: 15% impairment of the whole man.

Class 2—Impairment of Whole Man, 20-40%.—A patient belongs in class 2 when (*a*) organic heart disease exists, but without resulting symptoms at rest; (*b*) walking freely on the level, climbing at least one flight of stairs, and the performance of the usual activities of daily living do not produce symptoms; (*c*) prolonged exertion, emotional stress, hurrying, hill-climbing, recreation, or similar activities produce symptoms; and (*d*) signs of congestive heart failure are not present.

Example 1: A 40-year-old man has clear evidence of rheumatic heart disease and mitral stenosis, with slight cardiac enlargement and atrial fibrillation. Two years ago he developed increasing dyspnea on exertion and had several episodes of paroxysmal nocturnal dyspnea. One year ago a mitral valvuloplasty was performed with highly successful results and marked improvement. There has been no further nocturnal dyspnea. Dyspnea on exertion has decreased until it occurs only with hurrying up two flights of stairs, hill-climbing, or fast walking of distances over a mile. He is continuing on a maintenance dose of digitalis.

Diagnoses: Etiological: Rheumatic fever, inactive.
Anatomic: Mitral stenosis, enlargement of heart; mitral valvuloplasty, postoperative.
Physiological: Atrial fibrillation; no cardiac insufficiency.
Impairment: 25% impairment of the whole man.

Example 2: A 54-year-old man two years ago experienced episodes of recurrent chest pain due to severe coronary insufficiency. After a three-month period of hospitalization and rest the symptoms largely abated and he was able to resume most of his usual activities. For the next six months typical angina occurred with walking more than a quarter of a mile and with stair climbing. Conditions improved, however, and for the past year he has been able to lead a normal life and to play golf. In this latter period typical angina and dyspnea have occurred only occasionally with emotional stress or hurrying.

Diagnoses: Etiological: Arteriosclerosis of coronary arteries.
Anatomic: Coronary sclerosis.
Physiological: Angina syndrome; normal sinus rhythm; no cardiac insufficiency.
Impairment: 35% impairment of the whole man.

Class 3—Impairment of Whole Man, 50-70%.—A patient belongs in class 3 when (*a*) organic heart disease exists but without resulting symptoms at rest; (*b*) walking more than one or two blocks on the level, climbing one flight of ordinary stairs, or the performance of the usual activities of daily living produce symptoms; (*c*) emotional stress, hurrying, hill-climbing, recreation, or similar activities produce symptoms; and (*d*) signs of congestive heart failure, if present, are usually relieved by therapy.

Example 1: A 50-year-old man has evidence of free aortic regurgitation and moderate cardiac enlargement. There was a history of syphilis for which full penicillin therapy had been given two years ago. He had past episodes of nocturnal dyspnea and intermittent ankle edema, but these had been held in abeyance during the past year since the institution of digitalis therapy, a low-sodium regimen, and occasional diuretics. Despite this he continues to have dyspnea on climbing one flight of stairs or on walking two blocks on the level.

Diagnoses: Etiological: Syphilis—inactive.
Anatomic: Enlarged heart, aortic insufficiency.
Physiological: Normal sinus rhythm, cardiac insufficiency.
Impairment: 60% impairment of the whole man.

Example 2: A 60-year-old man sustained attacks of myocardial infarction five years ago and again two years ago. Since the latter he has developed increasing dyspnea on exertion and typical angina on any special activity. Because of difficulties in stair climbing he has moved to a first-floor apartment. He is unable to walk more than one or two blocks slowly without dyspnea or chest pain despite fully adequate treatment including diuretic and digitalis therapy.

Diagnoses: Etiological: Arteriosclerosis of the coronary arteries.
Anatomic: Sclerosis of the coronary arteries, infarction of the myocardium.
Physiological: Anginal syndrome, normal sinus rhythm, cardiac insufficiency.

Impairment: 70% impairment of the whole man.

Class 4—Impairment of Whole Man, 80-95%.—A patient belongs in class 4 when (*a*) organic heart disease exists with symptoms even at rest; (*b*) the performance of any of the activities of daily living beyond the personal toilet or its equivalent produces increased discomfort; (*c*) symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest; and (*d*) signs of congestive heart failure, if present, are usually resistant to therapy.

Example 1: A 42-year-old man has had rheumatic heart disease since the age of 12 years. He was excluded from competitive sports in high school and college because of mitral stenosis and insufficiency. He had no symptoms until three years ago, when he noted dyspnea on exertion, palpitation, and periodic edema of the ankles. Physical examination revealed atrial fibrillation, cardiac enlargement, double mitral valve murmurs, and congestion of the lungs. He responded well to therapy with digitalis, diuretics, and a salt-free diet. Two years ago he developed numerous episodes of nocturnal dyspnea and hemoptysis. The congestive failure became more difficult to control. In addition to maintenance therapy with digitalis, he required parenteral administration of mercurials two or three times weekly. For the past 10 months his activities about the house have been limited to those of personal care and walking only from one room to the next.

Diagnoses: Etiological: Rheumatic fever, inactive.
Anatomic: Mitral stenosis, mitral insufficiency, enlarged heart.
Physiological: Atrial fibrillation, cardiac insufficiency.

Impairment: 95% impairment of the whole man.

This classification (classes 1-4), without examples, is shown in table 1.

Table 1.—*Classes of Organic Heart Disease*

Class 1 (0-15% Impairment)	Class 2 (20-40% Impairment)	Class 3 (50-70% Impairment)	Class 4 (80-95% Impairment)
Organic heart disease exists, but without resulting symptoms	Organic heart disease exists, but without resulting symptoms at rest	Organic heart disease exists, but without resulting symptoms at rest	Organic heart disease exists with symptoms even at rest
Walking, climbing stairs freely, and the performance of the usual activities of daily living do not produce symptoms	Walking freely on the level, climbing at least one flight of stairs, and the performance of the usual activities of daily living do not produce symptoms	Walking more than one or two blocks on the level, climbing one flight of ordinary stairs, or the performance of the usual activities of daily living produce symptoms	The performance of any of the activities of daily living beyond the personal toilet or its equivalent produces increased discomfort
Prolonged exertion, emotional stress, hurrying, hill-climbing, recreation,* or similar activities do not produce symptoms	Prolonged exertion, emotional stress, hurrying, hill-climbing, recreation, or similar activities produce symptoms	Emotional stress, hurrying, hill-climbing, recreation, or similar activities produce symptoms	Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest
Signs of congestive heart failure are not present	Signs of congestive heart failure are not present	Signs of congestive heart failure may be present, and if so, are usually relieved by therapy	Signs of congestive heart failure, if present, are usually resistant to therapy

* Prophylactic restriction of activity such as strenuous competitive sports does not exclude a patient from class 1.

Class 0—Nonorganic Heart Disturbances, Impairment of Whole Man, 0-10%.—Depending on their duration and frequency, arrythmias such as (1) paroxysmal atrial (auricular) flutter or fibrillation or (2) paroxysmal supraventricular tachycardia may produce impairment, but persons with these types must be placed in class 0. Premature beats of various types or sinoauricular tachycardia are considered nonimpairing when found alone.

Note: Neurocirculatory asthenia, cardiac anxiety neurosis, or effort syndrome, characterized by a group of symptoms including dyspnea, palpitation, chest pains, dizziness, exhaustion, and nervousness aggravated by mental or physical strain are recognized as significant entities which may, although rarely, cause impairment. When the symptoms are of sufficient severity to interfere with the activities of daily living, the problem is neuropsychiatric and for this reason no rating is given here.

HYPERTENSIVE VASCULAR DISEASE

Before classifying a patient in the category of hypertensive vascular disease, the physician should make every effort to avoid variables of measurement, by repeated examinations of arterial pressure, and to ascertain the etiological type of hypertension present.

Hypertensive vascular disease does not necessarily exist or develop when a patient exhibits transient or irregular episodes of elevated arterial pressure; these frequently are associated with increased heart rate, with some obvious emotional stimulus or environmental factor, or with signs or symptoms of hyperactivity.

Hypertensive vascular disease is assumed to be present when diastolic pressure is repeatedly in excess of 100 mm. Hg. Diastolic blood pressure readings less than 100 mm. Hg occurring as the result of therapy or intercurrent complications do not exclude a patient from this category.

Class 1—Impairment of Whole Man, 0-15%.—A patient with hypertensive vascular disease belongs in class 1 when diastolic pressure readings are repeatedly in excess of 100 mm. Hg and examination reveals none of the following findings: (*a*) abnormalities of urinalysis and urinary function tests, (*b*) history of hypertensive cerebrovascular damage, (*c*) evidence of left ventricular hypertrophy, or (*d*) hypertensive abnormalities of the optic fundus (except minimal narrowing or sclerosis of arterioles).

Class 2—Impairment of Whole Man, 20-40%.—A patient with hypertensive vascular disease belongs in class 2 when diastolic pressure readings are or have been regularly in excess of 100 mm. Hg and examination reveals any one of the following findings: (*a*) proteinuria and abnormalities in the urinary sediment but no impairment of renal function, (*b*) history of hypertensive cerebrovascular damage without residuals, (*c*) evidence of left ventricular hypertrophy, or (*d*) definite hypertensive changes in the retinal arterioles, with or without hemorrhages and exudates.

Class 3—Impairment of Whole Man, 50-70%.—A patient with hypertensive vascular disease belongs in class 3 when diastolic pressure readings are consistently in excess of 100 mm. Hg and examination reveals any two of the following findings: (*a*) diastolic pressure readings usually in excess of 120 mm. Hg, (*b*) proteinuria and abnormalities in the urinary sediment, with evidence of impaired renal function, (*c*) hypertensive cerebrovascular damage with permanent neurological residuals, (*d*) left ventricular hypertrophy but no congestive heart failure, or (*e*) retinopathy with definite hypertensive changes in the arterioles, with or without hemorrhages and exudates.

Class 4—Impairment of Whole Man, 80-95%.—A patient with hypertensive vascular disease belongs in class 4 when diastolic pressure readings are consistently in excess of 100 mm. Hg and examination reveals any two of the following findings: (*a*) diastolic pressure readings usually in the range of 140 mm. Hg or more, (*b*) proteinuria and abnormalities in the urinary sediment, with impaired renal function and evidence of nitrogen retention, (*c*) hypertensive cerebrovascular damage with permanent neurological residuals, (*d*) left ventricular hypertrophy with or without congestive heart failure, or (*e*) retinopathy as manifested by hypertensive changes in the arterioles, retina, or optic nerve.

This classification is shown in table 2.

VASCULAR DISEASES AFFECTING THE EXTREMITIES

Permanent impairment due to peripheral vascular disorders most commonly results from (1) diseases of the arteries that reduce blood flow and lead to one or more of the following: intermittent claudication, pain at rest, minor trophic changes, ulceration, gangrene, or loss of extremity; (2) diseases of the veins, resulting in one or more of the following: pain, edema, induration, stasis dermatitis, or ulceration; or (3) disorders of the lymphatics, leading to chronic lymphedema or elephantiasis.

The etiological factors most commonly encountered in patients with the arterial disorders are arteriosclerosis, trauma, and inflammatory lesions such as thromboangiitis obliterans. The venous system is most frequently affected by varicosities and thrombotic states. Diseases of the lymphatic system most frequently causing impairment are obstructive lesions of an inflammatory or neoplastic origin.

This category is divided into five classes, from the minimal nonimpairing (class 1) to the most severely impairing (class 5). Percentage values representing the impairment of the patient as a whole man are assigned to each class.

It is assumed that prior to classification a specific diagnosis of vascular disease has been established according to conventional criteria. The use of special and frequently simple tests of vascular function is often necessary, and the physician is referred to the standard texts for a discussion of these methods.

Since the classification of the patient depends on the severity and extent of the lesions, only those factors indicating these are used in the classification which follows.

The percentage of permanent impairment of any patient in this category should be ascertained by placing him in the appropriate class and determining the corresponding percentage of permanent impairment of the whole man. This also applies to those rare cases in which vascular disease may restrict joint motion.

An exception is made, however, when amputation due to peripheral vascular disease is involved. In these cases an additional percentage of permanent impairment is to be allowed. The percentage of permanent impairment due to amputation is determined in accordance with the amputation schedule shown in table 4, which has been taken from "A Guide to the Evaluation of Permanent Impairment of the Back and Extremities." The amputation percentage value and the classification percentage value are then combined, by means of the combined values table.

Class 1–Impairment of Whole Man, 0%.—A patient with vascular disease (or diseases) belongs in class 1 if (*a*) he experiences neither intermittent claudication nor pain at rest and (*b*) he experiences only transient edema.

Note: It is understood that the disease is not considered impairing if only the following findings are present: (*a*) loss of pulses; (*b*) minimal loss of subcutaneous tissue of fingertips; (*c*) calcification of arteries as detected by x-ray examination; and (*d*) asymptomatic dilatation of arteries (including painless aneurysms not amenable to surgery) or of veins, resulting in no curtailment of activity.

TABLE 2.—*Classes of Hypertensive Vascular Disease*

Class 1 (0-15% Impairment)	Class 2 (20-40% Impairment)	Class 3 (50-70% Impairment)	Class 4 (80-95% Impairment)
Hypertensive vascular disease exists, diastolic pressure readings are repeatedly in excess of 100 mm. Hg, and examination reveals none of the following findings	Hypertensive vascular disease exists, diastolic pressure readings are or have been repeatedly in excess of 100 mm. Hg, and examination reveals any one of the following findings	Hypertensive vascular disease exists, diastolic pressure readings are consistently in excess of 100 mm. Hg, and examination reveals any two of the following findings	Hypertensive vascular disease exists, diastolic pressure readings are consistently in excess of 100 mm. Hg, and examination reveals any two of the following findings
		Diastolic pressure readings usually in excess of 120 mm. Hg	Diastolic pressure readings usually in excess of 140 mm. Hg
Abnormalities of urinalysis and urinary function tests	Proteinuria and abnormalities in the urinary sediment and no impairment of renal function	Proteinuria and abnormalities in the urinary sediment with evidence of impaired renal function	Proteinuria and abnormalities in the urinary sediment with impaired renal function and evidence of nitrogen retention
History of hypertensive cerebrovascular damage	History of hypertensive cerebrovascular damage without residuals	Hypertensive cerebrovascular damage with permanent neurological residuals	Hypertensive cerebrovascular damage with permanent neurological residuals
Evidence of left ventricular hypertrophy	Evidence of left ventricular hypertrophy	Left ventricular hypertrophy but no congestive heart failure	Left ventricular hypertrophy, with or without congestive heart failure
Hypertensive abnormalities of the optic fundus (except minimal narrowing or sclerosis of arterioles)	Definite hypertensive changes in the retinal arterioles, with or without hemorrhages and exudates	Retinopathy with definite hypertensive changes in arterioles, with or without hemorrhages and exudates	Retinopathy as manifested by hypertensive changes in the arterioles, retina, or optic nerve

EXAMPLE 1: A 27-year-old woman had ileofemoral phlebitis after childbirth. The leg became painful on a regimen including anticoagulants, and for several months she had to wear an elastic stocking to prevent moderate edema. Now she notices a little swelling of the ankle at the end of the day. This disappears by morning. She no longer uses the elastic support.

Impairment: 0% impairment of the whole man.

Class 2–Impairment of Whole Man, 5-25%.—A patient with vascular disease (or diseases) belongs in class 2 when any one of the following findings exists: (*a*) intermittent claudication occurring on walking at least 100 yd. at an average pace, (*b*) vascular damage as evidenced by physical signs such as healed painless stump of an amputated single digit with evidence of persistent vascular disease or healed ulcer, or (*c*) persistent edema of a moderate degree, incompletely controlled by elastic supports.

EXAMPLE 1: Two years ago a 53-year-old man experienced sudden pain in the left calf while walking. For several months the left leg was cooler than the right. The left superficial femoral artery was found to be occluded. For the past year he has been able to walk only 200 yd. before pain occurs. As soon as the patient stops walking, relief is obtained. There are no other symptoms.

Impairment: 15% impairment of the whole man.

EXAMPLE 2: Several years ago three fingers of a woman's left hand became painful, cool, and alternately blanched and cyanotic. The middle finger was then injured and became infected and painful. The tip of the finger became necrotic and therefore the distal phalanx was amputated. Her recovery was uneventful and there has been no progression in the symptoms.

Impairment: 19% impairment of the whole man; 15% contributed by class 2 vascular disease and 5% contributed by amputation of distal phalanx of middle finger (15 combined with 5 is 19).

Class 3–Impairment of Whole Man, 25-50%.—A patient with vascular disease (or diseases) belongs in class 3 when any one of the following findings exists: (*a*) intermittent claudication occurring on walking as little as 25 yd. and no more than 100 yd. at an average pace, (*b*) vascular damage as evidenced by physical signs such as healed amputation of two or more digits of one extremity with evidence of persistent vascular disease or persistent superficial ulceration, or (*c*) marked edema which is only partially controlled by elastic supports.

EXAMPLE 1: Eight months ago a 45-year-old man with known diabetes mellitus of five years' duration developed a painful inflamed callus under the first metatarsophalangeal joint of the right foot. Purulent material was removed from under the callus and the pain was relieved. A sinus formed, however, and is only slowly improving. No pulse can be felt at the ankle. A vasodilation test shows that the arteries to the toes of this foot have a poor capacity for blood flow.

Impairment: 30% impairment of whole man.

Class 4—Impairment of Whole Man, 50-75%.—A patient with vascular disease (or diseases) belongs in this class when any one of the following findings exists: (*a*) intermittent claudication occurring on walking less than 25 yd. or pain at rest occurring at intervals, (*b*) vascular damage as evidenced by physical signs such as amputation at or above the wrist or ankle of one extremity or amputation of two or more digits of two extremities, with evidence of persistent vascular disease, or persistent widespread or deep ulceration involving one extremity, or (*c*) marked edema which cannot be controlled by elastic supports.

Example 1: A 48-year-old man has had recurrent thrombophlebitis in both legs for a number of years. The left leg has been especially affected. A year ago he had to reduce the length of time spent standing in order to lessen the swelling and the pain of a persistent deep ulcer. When he is on his feet he wears heavy elastic stockings, full-length and made to order. Despite these supports there is still extensive edema of the ankles and calves.

Impairment: 50% impairment of the whole man.

Class 5—Impairment of Whole Man, 75-90%.—A patient with vascular disease (or diseases) belongs in this class when any one of the following findings exists: (*a*) severe and constant pain at rest, or (*b*) vascular damage as evidenced by physical signs such as amputation at or above the wrist or ankle of two extremities or amputation of all digits of two or more extremities, with evidence of persistent vascular disease, or persistent widespread or deep ulceration involving two or more extremities.

Note: Edema alone cannot be the basis for classification in class 5.

Example 1: A 54-year-old man was shown to have thromboangiitis obliterans (Buerger's disease) when he lost the great and second toes of the left foot 10 years ago. Bilateral lumbar sympathectomy was performed. He continued to smoke against advice, and two years ago the left leg was amputated 3 in. below the knee. Since then the index and middle fingers of the right hand have been amputated. All sites of amputation healed. There is, however, infection deep in the right foot, and there are signs of severe ischemia nearly to the knee, but further surgery is not deemed necessary at this time.

Impairment: 93% impairment of the whole man; 85% contributed by class 5 peripheral vascular diesase and 52% contributed by amputations (85 combined with 52 is 93).

This classification, without examples, is shown in table 3.

Table 3.—*Classes of Vascular Diseases Affecting the Extremities*

Class 1 (0% Impairment)	Class 2 (5-25% Impairment)	Class 3 (25-50% Impairment)	Class 4 (50-75% Impairment)	Class 5 (75-90% Impairment)
Vascular disease (or diseases) exists	Vascular disease (or diseases) and one or more of the following findings exist	Vascular disease (or diseases) and one or more of the following findings exist	Vascular disease (or diseases) and one or more of the following findings exist	Vascular disease (or diseases) and one or more of the following findings exist
Neither intermittent claudication nor pain at rest is experienced	Intermittent claudication occurring on walking at least 100 yd. at an average pace	Intermittent claudication occurring on walking as little as 25 yd. and no more than 100 yd. at an average pace	Intermittent claudication occurring on walking less than 25 yd. or pain at rest occurring at intervals	Severe and constant pain at rest
	Vascular damage, as evidenced by physical signs such as (*a*) healed painless stump of an amputated single digit, with evidence of persistent vascular disease, or (*b*) healed ulcer	Vascular damage, as evidenced by physical signs such as (*a*) healed amputation of two or more digits of one extremity, with evidence of persistent vascular disease, or (*b*) persistent superficial ulceration	Vascular damage, as evidenced by physical signs such as (*a*) amputation at or above the wrist or ankle of one extremity or amputation of two or more digits of two extremities, with evidence of persistent vascular disease, or (*b*) persistent widespread or deep ulceration involving one extremity	Vascular damage, as evidenced by physical signs such as (*a*) amputation at or above the wrist or ankle of two extremities or amputation of all digits of two or more extremities, with evidence of persistent vascular disease, or (*b*) persistent widespread or deep ulceration involving two or more extremities
Only transient edema is experienced	Persistent edema of a moderate degree incompletely controlled by elastic supports	Marked edema, which is only partially controlled by elastic supports	Marked edema which cannot be controlled by elastic supports	Edema alone cannot be the basis for classification in this class

COMBINED VALUES TABLE

These combined values are based on the formula $A\% + B\%\,(100\% - A\%)$ =combined value of A% and B%. *The guides to the table* are percentages ranging from 1 to 100 printed down the side of the page and across the bottom. To combine any two values, locate the larger of the two on the side of the page and read along that row until you come to the column indicated by the second value at the bottom of the page. At the intersection of this row and column is printed the combined value. For example, to combine 35% and 20% read down the side of the page until you come to the larger value, 35%. Then read across the row you have located until you come to the column indicated by 20% at the bottom of the page. At the intersection of this row and column is the number 48. We say that 35% and 20% combine to 48%. Due to the construction of this table, the larger value must be read at the side of the page.

If three or more values are to be combined, select any two and find their combined value as above. Take this combined value and the third value and find their combined value. This process can be repeated indefinitely, with the value obtained in each case being the combination of all the previous values.

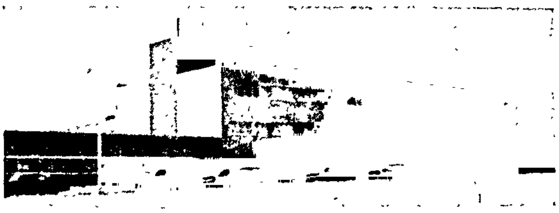
TABLE 4.—*Schedule of Amputations*

Upper Extremity, Type	Impairment of Whole Man, %
Forequarter amputation	70
Disarticulation at shoulder joint	60
Amputation of arm above deltoid insertion	60
Amputation of arm between deltoid insertion and elbow joint	57
Disarticulation at elbow joint	57
Amputation of forearm below elbow joint proximal to insertion of biceps tendon	57
Amputation of forearm below elbow joint distal to insertion of biceps tendon	54
Disarticulation at wrist joint	54
Midcarpal or midmetacarpal amputation of hand	54
Amputation of all fingers except thumb at metacarpophalangeal joints	32
Amputation of thumb	
At metacarpophalangeal joint or with resection of carpometacarpal bone	22
At interphalangeal joint	16
Amputation of index finger	
At metacarpophalangeal joint or with resection of metacarpal bone	14
At proximal interphalangeal joint	11
At distal interphalangeal joint	6
Amputation of middle finger	
At metacarpophalangeal joint or with resection of metacarpal bone	11
At proximal interphalangeal joint	8
At distal interphalangeal joint	5
Amputation of ring finger	
At metacarpophalangeal joint or with resection of metacarpal bone	5
At proximal interphalangeal joint	4
At distal interphalangeal joint	3
Amputation of little finger	
At metacarpophalangeal joint or with resection of metacarpal bone	3
At proximal interphalangeal joint	2
At distal interphalangeal joint	1
Lower Extremity, Type	
Hemipelvectomy	50
Disarticulation at hip joint	40
Amputation above knee joint with short thigh stump (3 in. or less below tuberosity of ischium)	40
Amputation above knee joint with functional stump	36
Disarticulation at knee joint	36
Gritti-Stokes amputation	36
Amputation below knee joint with short stump (3 in. or less below intercondylar notch)	36
Amputation below knee joint with functional stump	28
Amputation at ankle (Syme's)	28
Partial amputation of foot (Chopart's)	21
Midmetatarsal amputation	14
Amputation of all toes	
At metatarsophalangeal joints	8
Amputation of great toe	
With resection of metatarsal bone	8
At metatarsophalangeal joint	5
At interphalangeal joint	4
Amputation of lesser toe (2nd to 5th)	
With resection of metatarsal bone	2
At metatarsophalangeal joint	1
At proximal interphalangeal joint	0
At distal interphalangeal joint	0

GOVERNMENT SERVICES

AIR FORCE

New Hospital.—The USAF Hospital at Tinker Air Force Base, Oklahoma, was formally dedicated in January. This hospital has 75 beds for general medical and surgical inpatients and a comprehensive outpatient service. The 11 acres on which it stands was donated by the Oklahoma City Chamber of Commerce. Lt. Col. Herbert T. Clough Jr. is in command.



Personal.—Colonel Don S. Wenger was named chief professional consultant to the surgeon general. Prior to this appointment Colonel Wenger served as deputy commander and chief of the department of surgery at the U. S. A. F. Hospital, Lackland Air Force Base, Texas.

NAVY

Retirements.—The following medical officers were placed on the retired list: Capt. Ralph K. Hoch after more than 29 years service. His last assignment was as a permanent member of the physical evaluation board, Potomac River Naval Command. ——Capt. Hugh V. O'Connell after more than 21 years service. At the time of his retirement he was assigned at the U. S. Naval Hospital, Oakland, Calif.——Capt. Edward H. Taylor after more than 17 years service. His last assignment was at the Naval Air Station, North Island, San Diego, Calif. ——Capt. Harry G. Beck was retired after 18 years' service by reasons of temporary disability. His last assignment was at the U. S. Naval Shipyard, San Francisco.——Capt. Jarold E. List was retired after 20 years' service. His last assignment was at the Naval Air Station, Memphis, Tenn.——Capt. Walter H. Schwartz was retired after more than 29 years' service. His last assignment was as commanding officer of the U. S. Naval Hospital, Portsmouth, Va.

VETERANS ADMINISTRATION

Personal.—Dr. Oscar Auerbach of the East Orange, N. J., Veterans Administration Hospital and Dr. Ludwik Gross of the Bronx, N. Y., VA hospital were named as senior medical investigators; as such they will engage in full-time medical research. Only four such investigators have been named since the position was created in January, 1959.

PUBLIC HEALTH SERVICE

Fewer Patients in Mental Hospitals.—Again in 1959, for the fourth consecutive year, there was a drop in the number of inpatients in public mental hospitals in the United States. At the end of 1959 there were 542,721 patients in 277 such hospitals or 2,142 fewer than at the end of 1958. While the decline each year was slight, it reversed a decided upward trend that had prevailed until 1956. Between 1903 and 1951, the public mental hospital population quadrupled while the general population only doubled. Commenting on the current trend Dr. Robert H. Felix, director of the National Institute of Mental Health, said that so many factors were involved in these figures that it is unsafe to draw specific conclusions from them, but they undoubtedly reflect a prevailing improvement in the care and treatment of the mentally ill both in and out of mental hospitals.

Dr. Felix attributed this improvement, in part, to a basic change in the philosophy governing mental hospital administration and treatment in the past few years and in the public attitude toward mental illness. No longer is the hospital viewed as a custodial institution. It should function like other hospitals to rehabilitate the patient so that he can return to community living. Dr. Felix also credited new and improved treatment methods, including the wide use of psychoactive drugs, to the increased use of psychiatric beds in general hospitals, and to outpatient psychiatric clinics and other community facilities such as nursing homes, half-way houses, and sheltered workshops. He noted that 20 years ago, only 48 general hospitals treated psychiatric patients. Today there are about 500 such hospitals with psychiatric units and many others that accept mentally ill persons for short-term treatment. About 1,400 outpatient clinics offer psychiatric service.

Influenza Research.—Increased support for influenza research to permit investigators to take advantage of the study opportunities afforded by current influenza outbreaks was announced by the surgeon general. Methods to stimulate such research and to encourage long-range research in influenza and related diseases were developed in January when Dr. Burney called together the service's committee of investigators which is composed of some of the nation's leading authorities on influenza and related diseases. The meeting was held at the National Institutes of Health. Members of the committee agreed to accelerate their own research during this influenza season and to encourage other investigators to conduct influenza studies. The types of problems cited by the committee as needing study are: (1) assessment of the value of the vaccine given in the 1957 epidemic, (2) the present degree of immunity of unvaccinated persons who had influenza in the 1957 epidemic, (3) the physiological effects of influenza on the cardiovascular and respiratory systems, and (4) the neuromuscular effects of influenza.

Members of the committee of investigators are Drs. Robert Wagner, University of Pennsylvania, chairman; George Burch, Tulane University; Fred M. Davenport and Thomas Francis, University of Michigan; Ivan Bennett, Johns Hopkins University; George Hirst, Public Health Research Institute of the City of New York, Inc.; Maxwell Finland, Boston City Hospital; and Roderick Murray, National Institutes of Health.

Training in Microbiology.—The National Institutes of Health has established a new graduate training program in microbiology. A Microbiology Training Committee was appointed by the surgeon general and it held its first meeting at the National Institutes of Health in January. Under the chairmanship of Dr. Morris F. Shaffer, chairman, department of microbiology, Tulane University School of Medicine, the committee will review training grant applications in microbiology and related fields. It will function under Dr. G. Halsey Hunt, chief of the division of general medical sciences, and Dr. Frederick L. Stone, assistant division chief and chief of the research training branch.

This program is designed to support training at predoctoral and postdoctoral levels in medical schools, schools of public health, veterinary schools, other recognized graduate schools, and research institutions in the basic aspects of microbiology, bacteriology, and virology. Microbial genetics, cellular physiology, and cellular metabolism will also be included. The program seeks to provide a basis for the development of senior members of departments in various fields of academic medicine who will teach or perform research work in health-oriented fields. Members of the committee include Drs. George W. Kidder, of Amherst College, Amherst, Mass.; Charles L. Wisseman Jr., of the University of Maryland, Baltimore; Orville Wyss, of the University of Texas, Austin, Texas; Alan W. Bernheimer, of New York University College of Medicine, New York City; S. Edward Sulkin, of the University of Texas, Southwestern Medical School, Dallas, Texas; Ralph Emerson, of the University of California, Berkeley, Calif.; A. F. Rasmussen Jr., of the University of California Medical Center, Los Angeles; and P. W. Wilson, of the University of Wisconsin, College of Agriculture, Madison, Wis.

MEDICAL NEWS

CALIFORNIA

Dr. Pressman Receives Award for Research.—The International Committee for the Gould Award announced the selection of the recipient for 1959—Dr. Joel J. Pressman, University of California at Los Angeles—for his anatomic and radioisotope studies of laryngeal compartments. The Gould Award is presented annually for basic research in laryngology to encourage and reward fundamental investigations in this field. The International Committee for the Gould Award for the year 1960 includes: Sir Victor Negus, London, England; Dr. Cotoji Satta, Tokyo, Japan; Prof. Dr. Luzius Ruedi, Zurich, Switzerland; and Dr. Hans V. Von Leden, medical director, The William and Harriet Gould Foundation, 30 N. Michigan Ave., Chicago 2. The Gould Award consists of a plaque and an honorarium of $300.

Plan Hospital in La Jolla.—Plans for a new Scripps Memorial Hospital in La Jolla, construction of which is estimated to cost 4 million dollars, are being prepared. According to Mr. Fred W. Trader, hospital administrator, construction of the seven-story, 250-bed facility is expected to start in the fall of this year and will be completed about 18 months later. Plans call for 40 beds in the maternity section, with the remaining 210 allocated to medical and surgical cases. There will also be pediatrics, x-ray section, clinical laboratory, physical medicine, and dietary facilities. The seven-story nursing unit will be serviced by a free-standing elevator tower. The hospital will have a central nursing station to care for patients in rooms arranged around the perimeter of the building. All surgical, adjunct, and administration facilities are located on the ground level. Service facilities are grouped in the lower level, with the central medical supply for the entire building located under the elevator wing. Located on a 40-acre site on Torrey Pines Mesa, the hospital's patient rooms will have cantilevered balconies in the main tower. The hospital is designed for future expansion with the addition of another nursing unit on the opposite side of the elevator tower.

COLORADO

Dr. Longmire Gives Annual Lecture.—Dr. William P. Longmire Jr., head, department of surgery, University of California at Los Angeles School of Medicine, delivered the annual Clagett Lecture at t University of Colorado Medical Center, Denve March 2. He presented "Current Surgical Probler in the Treatment of Angina Pectoris." The lectu is sponsored by the C. U. department of surger and was endowed by Dr. Oscar T. Clagett, Ma Clinic surgeon, in memory of his father, the la Dr. O. F. Clagett, who was in practice for ma years at Rifle, Colo.

KENTUCKY

Program for Postgraduate Education.—The Ke tucky State Medical Association is working clos with the University of Louisville and the Univ sity of Kentucky Medical Schools in sponsoring active program of postgraduate education. It appropriated $10,000 for this purpose. Friedri Hertle, Ph.D., a native of Germany, has been e ployed as full-time director of the program. Hertle received his Ph.D. in economics and bu ness administration from the University of Bas He came to the United States in 1956. The Univ sity of Louisville has provided a furnished office a building directly across the street from the me cal school, formerly housing the School of Ph macy of the University of Kentucky, which moved to the Lexington campus. The U. of L. leased the building from the U. of K., and locati the postgraduate headquarters in that buildi "serve to emphasize the cooperative nature of program." Dr. Hertle will work under the directi of the state association's committee on postgradu education, headed by Dr. Walter S. Coe, Louisvil

LOUISIANA

Medical Assembly in New Orleans.—The 23 annual meeting of the New Orleans Graduate Me cal Assembly will be held March 7-10 at The Roo velt Hotel, New Orleans. Twenty-one guest spe ers will participate in the program and present talks. A clinical pathological conference is sche uled for March 7, 8:30 p. m. Round-table luncheo are scheduled for specialty groups March 8 and and for the general assembly, March 9. A panel d cussion, "The Recognition and Management Metabolic Alterations Resulting from Trauma," w be held March 9, 8:30 p. m. Films covering rece advances and semantic considerations in surge medicine, and allied specialties will be shown dai Technical exhibits are planned. The program is a ceptable for 28 hours category I credit by t American Academy of General Practice. The reg tration fee of $20 covers all aspects of the assemb

---

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education, and public health. Programs should be received at least three weeks before the date of meeting.

For information, write Miss Irma B. Sherwood, 1430 Tulane Ave., New Orleans 12, Executive Secretary.

MASSACHUSETTS

British Zoologist to Lecture.—Dr. Peter B. Medawar, Jodrell Professor of Zoology at the University College, University of London, will deliver the annual Dunham Lectures at the Harvard Medical School, Boston, on March 21, 23, and 25. His general topic for the three lectures will be "The Immunology of Transplantation." The lectures will be given at 5 p. m. each day in Amphitheatre D at the medical school. Dr. Bernard D. Davis, professor of bacteriology and immunology at Harvard and chairman of the Dunham Lecture Committee, will preside.

Plan Expansion of Nutrition Research Facilities.—A gift of $100,000 a year for 10 years from General Foods Corporation will provide for expansion of the nutritional research laboratories of the Harvard School of Public Health. President Nathan M. Pusey of Harvard, announcing the General Foods gift for construction of the laboratory unit, said it is the largest gift ever made by any business corporation for the capital purposes of Harvard University. The new four-story nutrition laboratory will be part of a projected research structure for the School of Public Health in Boston. The nutrition laboratory will occupy the top of an 11-story research building of the Harvard School of Public Health (with two research floors below ground) to be started this spring. Four additional floors will be added later. The 11-story structure will be financed in part by a grant of $1,450,000 from the National Institutes of Health (U. S. Department of Health, Education and Welfare) through its Health Research Facilities Branch, and in part by gifts of individuals, corporations, and foundations.

MICHIGAN

Research Forum for Students.—Twelve undergraduate medical students presented formal papers on their own medical research in the University of Michigan Medical School, Ann Arbor, on Feb. 16. The 12 were selected for the annual Student Research Forum sponsored by the medical students' honorary society, Alpha Omega Alpha. The program was held in University Hospital. Dr. William N. Hubbard, dean of the Medical School, opened the forum with an address. Dr. John W. Henderson, associate professor of ophthalmology, and Keith S. Henley, M.B., assistant professor of internal medicine, presided over the formal presentations.

Report on Rabies.—Confirmed rabies cases in skunks numbered an all-time high of 19 in Michigan during 1959, the state health department announced. Previous high for skunk rabies cases was 10, reported in both 1958 and 1957. Rabies cases from all types of animals totaled 52 in Michigan last year. This was the highest total since 117 cases were reported in 1954. Contributing to last year's 52 cases were 20 dogs, 5 cats, 4 cows, 2 foxes, 1 horse, and 1 bat. Six counties in central Michigan accounted for 13 of the 19 skunk cases. Last year rabid skunks are known to have attacked two humans, 29 dogs, and 6 cats in Michigan. The two persons bitten by the skunks received antirabies treatment and neither contracted rabies. Michigan also recorded 30 other human exposures to rabies last year, 20 of them from dogs, but these persons also were treated and none died. It was the 11th straight year in which Michigan was free from human rabies deaths.

Nutrition Conference in Detroit.—The sixth annual nutrition conference sponsored by Wayne State University College of Medicine will be held Friday, March 18, 1960. Speakers on the general subject "Prospects in Nutrition" will include Drs. Paul L. Day, Ph.D., of the U. S. Food and Drug Administration; Howard A. Schneider of the Rockefeller Institute; Philip L. White, Sc.D., of the American Medical Association; and James L. Wilson, of the University of Michigan. Members of the American Medical Association are invited. For information, write Mr. James M. Orten, chairman, Publicity Committee, Wayne State University, 1401 Rivard St., Detroit 7.

Nobel Prize Winners to Lecture.—British and American Nobel Prize winners are among the 13 biological scientists who are listed as speakers in a public lecture series sponsored by the Institute of Science and Technology at the University of Michigan. Sir Hans Krebs, of Oxford University, and Dr. Arthur Kornberg, of Stanford, won Nobel Prizes in physiology and medicine in 1953 and 1959, respectively. Sir Hans will lecture March 8, and Dr. Kornberg April 8, in the series titled "The Molecular Control of Cellular Activity." The series is focused on areas of biology basic to understanding how living organisms may be affected by space phenomena. Such studies have since last year been referred to as "exobiology." The studies are also referred to as "space biology." Dr. Paul A. Weiss, of the Rockefeller Institute, opened the series March 1, presenting "From Cell to Molecule." Each lecture will be at 4 p. m. in the third level amphitheater, Medical Science Building, admission-free and open to the public. Hewson H. Swift, Ph.D., of the University of Chicago, spoke March 3, and Dr. Torbjorn Caspersson, director of the Karolinska Institute, Stockholm, Sweden, spoke March 4. The series will continue through April.

Grant to Aid Research Project.—The University of Michigan announced that General Motors Corporation will donate half a million dollars to the university over the next five years for research into industrial health and the peaceful uses of atomic energy. Terms of the grant provide $350,000 for the Institute of Industrial Health which was created in 1950 when GM donated 1.5 million dollars to the university's Memorial–Phoenix Project for atomic research. The Institute of Industrial Health does research in the prevention, diagnosis, and treatment of occupational diseases. Results are available to American industry. The Phoenix project is the university's memorial to its dead in World War II. It is devoted to the peaceful uses of atomic energy and has received 8 million dollars in gifts since its creation. The university is conducting a drive to raise 2 million dollars for the Phoenix Project and has accumulated $760,000, including the General Motors gift.

NEW YORK

Dr. Handy Receives Cancer Medal.—The New York State Division of the American Cancer Society recently awarded a gold medal to Dr. Vincent H. Handy, assistant director of the Bureau of Cancer Control, New York State Health Department. The award was given to Dr. Handy in recognition of his "distinguished service in the field of cancer control." Dr. Handy is chairman of the professional information committee of the New York State division.

New York City

Faculty Appointments.—Four faculty members were appointed at the State University of New York Downstate Medical Center in Brooklyn. Dr. David L. Benninghoff, formerly instructor in radiology at Temple University Medical School, Philadelphia, was named assistant professor of radiology. Named assistant professor of environmental medicine and community health was Dr. David Hewitt, of Oxford, England. Dr. Daniel S. Feldman, director of the neurological division of Maimonides Hospital, Brooklyn, was named assistant professor of neurology. The final appointment went to Dr. Norman S. Blackman, cardiac consultant to the New York City Department of Health, who was named clinical assistant professor of medicine.

Program for Training in Orthotics.—New York University's School of Education will offer, beginning next fall, a four-year undergraduate curriculum in prosthetics and orthotics—the design, fabrication, and fitting of artificial limbs and braces. The program, developed in conjunction with the university's postgraduate medical school and college of engineering, is intended primarily for persons interested in the clinical practice of prosthetics and orthotics. The curriculum includes courses in English and speech; mathematics; the physical, biological, and chemical sciences; basic engineering; psychology; sociology and social studies; and shop methods. Students in the program, who will number no more than 15 each year, also will take specialized professional courses in upper and lower extremity prosthetics and orthotics, as well as in orthotics for the trunk. These will be supplemented by a clinical training program developed in cooperation with the American Orthotic and Prosthetic Association and a number of certified limb- and brace-making facilities throughout the country. Information may be obtained by writing Sidney Fishman, Ph.D., Prosthetics Education, New York University, 342 E. 26th St., New York 10.

PENNSYLVANIA

Forum on Radiation Effects.—Woman's Medical College of Pennsylvania, Philadelphia, has scheduled its annual forum celebrating Founders' Day for Wednesday, March 9, from 3 to 9 p. m. The subject, "Atoms, Rays and People—a Symposium on the Physiological Effects of Ionizing Radiation," was announced by Dr. Irwin J. Pincus, associate professor of medicine. The afternoon session, on the technical aspects of the subject, will be moderated by Dr. Harriet Hardy, assistant medical director, Massachusetts Institute of Technology. It will be held in the college auditorium at 3 p. m. The topics and speakers will be as follows:

Use of Isotopes in Medicine, Dr. Harvey D. Bruner, chief, medical research branch, Atomic Energy Commission.
Delayed Illness Resulting from Large Amounts of Ionizing Radiation, Robert A. Dudley, Ph.D., department of physics, M. I. T.
Biological Hazards of Ionizing Radiation, Max Zelle, Ph.D., chief, biology branch, Atomic Energy Commission.
The Establishment of a Health Physics Program, Elda Anderson, Ph.D., chief, health and training section, Oak Ridge National Laboratories.

The evening session at 8 p. m. is especially planned for the layman and will be held in the auditorium of the Eastern Pennsylvania Psychiatric Institute, adjacent to the college. Dr. Pincus will be the moderator and the speakers will be: W. H. Langham, Ph.D., biomedical research group leader, Los Alamos Scientific Laboratories, "Present Status of the World-Wide Fallout Problem," and Dr. Charles W. Shilling, deputy director, division of biology, Atomic Energy Commission, "The Effects of Radiation on the World's Most Precious Material." For information, write Dr. Pincus, Woman's Medical College of Pennsylvania, 3300 Henry Ave., Philadelphia 29.

TEXAS

Clinical Conference in Dallas.—The 29th annual spring clinical conference of the Dallas Southern Clinical Society will be held March 21-23 at the Statler Hilton Hotel, Dallas. The program includes the following guest speakers:

Drs. Douglas N. Buchman, Chicago; Edward L. Compere, Chicago; Robert E. Cooke, Baltimore; George Crile Jr., Cleveland; Arthur G. DeVoe, New York City; William Dock, Brooklyn; James E. Eckenhoff, Philadelphia; Herman Elwyn, New York City; Benjamin Felson, Cincinnati; Aram Glorig Jr., Los Angeles; Milton Helpern, New York City; Frank Hinman Jr., San Francisco; S. Leon Israel, Philadelphia; Charles G. Johnston, Detroit; Lawrence S. Kubie, New York City; Daniel G. Morton, Los Angeles; Robert E. Votaw, St. Louis; William M. M. Kirby, Seattle.

Round-table luncheons will consider medical, surgical, EENT, orthopedic, urological, pediatric, and obstetrics-gynecology problems. Postgraduate lectures, panel discussions, a clinical pathological conference, and technical exhibits are planned. The social program includes a dinner dance.

VERMONT

Drs. Raab and Pierce to Retire.—Dr. Wilhelm Raab will retire as professor and chairman, division of experimental medicine, University of Vermont College of Medicine, Burlington, effective June 30. Dr. Raab was born in Vienna, Austria. He received M.D. degrees from the University of Vienna and from the German University of Prague. He was appointed to the College of Medicine faculty in 1939 as associate professor. Harold B. Pierce, Ph.D., will retire as professor and chairman, department of biochemistry, effective June 30. Dr. Pierce received his Ph.D. from the University of Rochester, N. Y. He was appointed to the faculty in 1937 as associate professor.

WISCONSIN

Annual Lecture.—Dr. Thomas M. DuRant, professor of medicine, Temple University Medical Center, Philadelphia, will be the speaker at the annual Malcolm F. Rogers lecture sponsored by the Wisconsin Heart Association in cooperation with the University of Wisconsin School of Medicine on March 14. Dr. DuRant will present "Bedside Management of Cardiac Arrhythmias" at 8 p. m. in the medical school's Bardeen Auditorium in Madison.

GENERAL

Change Dates for Meeting of Maxillofacial Surgeons.—Dr. Edward C. Hinds, Secretary, American Society of Maxillofacial Surgeons, P. O. Box 20068, Houston 25, Texas, announced that because of a conflict with the meeting of the American Association of Plastic Surgeons, the meeting dates of the American Society of Maxillofacial Surgeons has been changed from May 15-18, 1960, to March 27-31, 1960.

Laryngologists Meeting in Florida.—The American Laryngological Association will meet at the Deauville Hotel, Miami Beach, Fla., March 18-19. Dr. William J. McNally, Montreal, Canada, president of the association, will open the meeting with an address. The program includes 18 scientific papers, and the following papers will include foreign authors:

Phonation: Clinical Testing versus Electromyography, Dr. David W. Brewer, Syracuse, N. Y., and Dr. K. Faa borg-Andersen, Falstar, Denmark.

The Sphenoidal Sinus in Its Relation to the Sellar Turcica, Dr. Gunnar Hammer, Goteborg, Sweden.

Trans-antro Sphenoidal Hypophysectomy, Dr. Carle-Axel Hamberger, Goteborg, Sweden.

Early Invasion of the Thyroid Gland in Carcinoma of the Larynx, Dr. Ricardo Tapia Aouna, Mexico.

For information, write Dr. Lyman G. Richards, Massachusetts Institute of Technology, Cambridge 39, Mass.

Triological Meeting in Miami Beach.—The 63rd annual meeting of the American Laryngological, Rhinological and Otological Society, Inc., the "Triological Society," will be held March 15-17 at the Deauville Hotel, Miami Beach, Fla. Following a business meeting the morning of March 15, Dr. Theodore E. Walsh, St. Louis, president of the society, will speak. Mr. Terence Cawthorne, London, England, guest of honor at the meeting, will present "The Influence of Deafness on the Creative Instincts." A panel discussion, "Tympanoplasty," will be moderated by Dr. Albert C. Furstenberg, Ann Arbor, Mich., and participants will include Dr. Harold F. Schuknecht, Detroit; Dr. Joseph E. Sullivan, Toronto, Canada; and Dr. Nils Richtner, Stockholm, Sweden. The following papers include invited authors:

Dysmetria in Post-Caloric Nystagmus: Its Clinical Significance, *Drs. Malcolm H. Stroud, St. Louis, and J. Santiago Riesco, Santiago, Chile.*

Aural Cholesteatoma: Experimental Observations, Drs. John R. Lindsay, and Caesar Fernandez, Chicago.

Tonsillectomy for Acute Peritonsillar Abcess, Drs. Benjamin M. Volk and Edward C. Brandow Jr., Albany, N. Y.

Method for the Identification and Localization of Cerebrospinal Fluid Rhinorrhea and Otorrhea, Drs. G. O'Neil Proud and Fernando R. Kirchner, Kansas City, Kan.

Isolated Keratosis of the Larynx: Its Relation to Carcinoma, Drs. Malcolm H. McGavran and Walter C. Bauer, St. Louis.

The Procurement and Processing of Endoscopic Biopsies, Drs. Paul H. Holinger, Kenneth C. Johnston, and Edwin F. Hirsch, Chicago.

A social program is planned. For information, write Dr. C. Stewart Nash, 708 Medical Arts Building, Rochester 7, N. Y., Secretary.

Appointments to Pharmaceutical Association.—Two appointments to the staff of the Pharmaceutical Manufacturers Association were announced Feb. 9 by Dr. Austin Smith, president. They are Dr. Robert J. Benford, former editor of the *U. S. Armed Forces Medical Journal* of Washington, D. C., to be director of medical relations for PMA; and Mr. Milton Golin, former editor of the "Medicine at Work" section of THE JOURNAL, to be assistant to the president of PMA for special projects. Both men have assumed their new duties.

Russian Scientists Tour U. S.—Four touring Soviet radiobiologists arrived in the U. S. in mid-December under the new U. S.-U. S. S. R. scientific and cultural exchange program and toured New York, Washington, D. C., Baltimore, Chicago, San Francisco, Los Angeles, and Portland, Ore. They were repaying a visit to Russia in October and November by a six-man American delegation. The Russian visitors were Dr. Mikhail Pobedinski, chairman of the group and director of the Central Scientific Research Institute for Roentgenology, Radiology, and Cancer in Leningrad; Dr. Georgie A. Zedgenidze, who occupies the chair of roentgenology at the Academy of Medical Sciences in Leningrad; Dr. Alexander Pavlov, lecturer on radiation medicine, roentgenology, and radiology at the Moscow Stomatology Institute; and Dr. Valerie Bochkarev, department chief of the Institute of Biophysics and Radiation Medicine at the U. S. S. R. Ministry of Health in Moscow.

Maxillofacial Surgeons Meeting in Los Angeles.—The annual meeting of the American Society of Maxillofacial Surgeons will be held at the Ambassador Hotel, Los Angeles, March 27-31. All members of the medical profession are invited. The program includes scientific and clinical sessions, and subjects will include the following: growth of jaws in relation to various deformities, diseases of the tongue and their treatment, and trauma of the face. A panel discussion, "Cleft Palate and Cleft Lip," is planned. A general discussion, "Geriatrics in Head and Neck Problems," is scheduled. Scientific exhibits have been arranged. The social program includes two dinners, at the first of which (March 28) Dr. Truman G. Blocker Jr., Galveston, Tex., will be presented the distinguished service award of the society. At the second dinner (March 30) officers will be elected and Dr. Casper M. Epsteen, Chicago, will give the presidential address. For information, write Dr. Edward C. Hinds, 1508 Medical Towers, Houston 25, Texas, Secretary.

Health Forum in Miami Beach.—New guidelines for programs to promote the health of older people are the goal of the 1960 National Health Forum at the Carillon Hotel, Miami Beach, Fla., March 14-17. Taking part in the sessions, sponsored by the National Health Council, will be invited authorities representing health and medicine, education, religion, government, social welfare, industry, and labor. They will discuss reports on current and contemplated research on the aging and exchange information on programs for the aging under way in this country and abroad. Chairman of the forum is Dr. Edward L. Bortz, of Philadelphia, president-elect of the American Geriatrics Society and a former president of the American Medical Association. Principal speakers at the 1960 forum will include Dr. Ali Berggren, governmental supervisor, Royal Board of Social Welfare, Stockholm, Sweden; Dr. Leroy E. Burney, Surgeon General, U. S. Public Health Service; G. Warfield Hobbs, New York City banker and chairman, National Committee on the Aging, National Social Welfare Assembly; and Francis H. Horn, Ph.D., president, University of Rhode Island. Group discussions are scheduled on problems which the increasing proportion of older people in the population pose for employers and workers, health care professions, public health, and public welfare. Other groups will discuss services for the aged at home, and psychiatry's role in healthy aging. The National Health Council will hold its annual meeting in conjunction with the forum. Member organizations of the council include 70 national health, professional, government, and other organizations with interests related to promotion of health. Headquarters of the council are at 1790 Broadway, New York 19. Philip E. Ryan is executive director.

CORRECTIONS

Seymour Blau.—In the item entitled "Counterfeiters of Tranquilizer Drugs Sentenced" in The Journal, Nov. 21, 1959, page 1709, one Seymour Blau was said to have pleaded guilty to five counts and testified for the government against Spandau. Dr. Seymour H. Blau of Jersey City, N. J. has requested The Journal to publish a statement that he has no connection whatsoever with the Seymour Blau mentioned in the item referred to above.

Sulfonamide Preparation C 17922 (Orisul): Clinical and Experimental Study of Its Use in Genitourinary Infections: Preliminary Report.—In the abstract entitled The Sulfonamide Preparation C 17922 (Orisul): Clinical and Experimental Study of Its Use in Genitourinary Infections: Preliminary Report, which appeared in The Journal, Dec. 19, 1959, page 2267, the dosage all through the abstract should have been in grams and not in milligrams.

EXAMINATIONS AND LICENSURE

EDUCATIONAL COUNCIL FOR FOREIGN MEDICAL GRADUATES, INC.

Educational Council for Foreign Medical Graduates: Stations around the world. March 16, 1960 and Sept. 21, 1960. Exec. Director, Dr. Dean F. Smiley, 1710 Orrington Ave., Evanston, Ill.

NATIONAL BOARD OF MEDICAL EXAMINERS

National Board of Medical Examiners: Part I, Various Cities. June 21-22 and Sept. 7-8. Part II, Various Cities, April 26-27. Applications must be received at least six weeks before the date of the examination. Exec. Sec., Dr. John P. Hubbard, 133 South 36th St., Philadelphia.

BOARDS OF MEDICAL EXAMINERS

Alabama: *Examination.* Montgomery, June 21-23. Sec., Dr. D. G. Gill, State Office Bldg., Montgomery.

Alaska:* On application in Anchorage or Fairbanks. Sec., Dr. W. M. Whitehead, 172 South Franklin St., Juneau.

Arkansas:* *Examination and Reciprocity.* Little Rock, June 9-10 Sec., Dr. Joe Verser, Harrisburg.

California: *Written.* Los Angeles, March 7-10; San Francisco, June 20-23; Los Angeles, Aug. 22-25 and Sacramento, Oct. 17-20. *Oral and Clinical.* Los Angeles, March 6; San Francisco, June 19; Los Angeles, Aug. 21, and Los Angeles, Nov. 29. *Oral for Reciprocity Applicants.* Los Angeles, Mar. 5; San Francisco, June 18; Los Angeles, Aug. 20 and Nov. 19. Sec., Dr. Louis E. Jones, Room 536, 1020 N Street, Sacramento.

Canal Zone: On Application. Acting Sec., Dr. B. K. Levin, Health Bureau, Balboa Heights.

Colorado:* *Reciprocity.* Denver, April 12. *Examination.* Denver, June 14-15. Sec., Dr. John B. Farley, 1612 Tremont Place, Denver 2.

Connecticut:* *Regular. Examination.* Hartford, Mar. 8-10. Sec., Dr. Stanley B. Weld, 160 St. Ronan St., New Haven. *Homeopathic. Examination.* Derby, Mar. 8. Sec., Dr. Ronald A. Davis, 38 Elizabeth St., Dover.

Delaware: *Examination and Endorsement.* Dover, June 12-14 and July 21. Sec., Dr. Joseph S. McDaniel, Professional Bldg., Dover.

District of Columbia:* *Reciprocity.* Washington, March 14. *Examination.* Washington, June 13-14. Deputy Director, Mr. Paul Foley, Department of Occupations and Professions, 1740 Massachusetts Ave., N.W., Washington 6.

Florida:* *Examination.* Miami Beach, June 19-21. Sec., Dr. Homer L. Pearson, 901 N.W. 17th St., Miami 36.

Georgia: *Examination and Reciprocity.* Atlanta, June. Sec., Mr. Cecil L. Clifton, 224 State Capitol, Atlanta 3.

Guam: *Subject to Call.* Act Sec., Dr. F. L. Conklin, Agana.

daho: *Examination and Endorsement.* Boise, July 11-13. Exec. Sec., Mr. Armand L. Bird, 304 Sonna Bldg., Boise.

ndiana: *Examination.* Indianapolis, June 22-24. *Reciprocity.* Indianapolis, fourth Wednesday of each month. Ex. Sec., Miss Ruth V. Kirk, 538 K. of P. Bldg., Indianapolis.

Maine: *Examination and Reciprocity.* Brunswick, March 8-10. Sec., Dr. Daniel F. Hanley, Box 637, Brunswick.

Maryland: *Examination.* Baltimore, June 15-18. Sec., Dr. Frank K. Morris, 1215 Cathedral St., Baltimore 1.

Michigan:* *Examination.* Ann Arbor and Detroit, June 6-8. Sec., Dr. E. C. Swanson, 118 Stevens T Mason Bldg., Lansing.

Mississippi: *Examination.* Jackson, June. Sec., Dr. A. L. Gray, Old Capitol, Jackson 13.

Montana: *Examination and Reciprocity.* Helena, April 5. Sec., Dr. Thomas L. Hawkins, 555 Fuller Ave., Helena.

Nebraska:* *Examination.* Omaha, June 13-15, 1960. Dir., Bureau of Examining Boards, Room 1009, State Capitol Bldg., Lincoln 9.

Nevada:* *Examination and Reciprocity and Endorsement.* Reno, March 8. Sec., Dr. G. H. Ross, 112 No. Cury St., Carson City.

New Hampshire: *Examination.* Concord. March 9-12. Sec., Dr. Edward W. Colby, 61 South Spring St., Concord.

New Mexico:* *Examination and Reciprocity.* Santa Fe, May 16-17. Sec., Dr. R. C. Derbyshire, 227 East Palace Ave., Santa Fe.

New York: *Examination.* Albany, Buffalo, New York City, Rochester and Syracuse, June 28-July 1. Sec., Dr. Stiles D. Ezell, 23 S. Pearl Street, Albany.

North Carolina: *Endorsement.* Raleigh, May 9. *Examination and Endorsement.* Raleigh, June 20-23. Sec., Dr. Joseph J. Combs, 716 Professional Bldg., Raleigh.

North Dakota: *Examination and Reciprocity.* Grand Forks, July 6-9. Sec., Dr. C. J. Glaspel, Grafton.

Ohio: *Reciprocity.* Columbus, April 5 and June 17. *Examination.* Columbus, June 16-18. Sec., Dr. H. M. Platter, 21 West Broad St., Columbus 15.

Oklahoma:* *Examination and Endorsement.* Oklahoma City, May 31-June 1. Sec., Dr. E. F. Lester, 813 Braniff Bldg., Oklahoma City.

Oregon:* *Reciprocity and Endorsement.* Portland, April 14-16. *Examination.* Portland, July. Exec. Sec., Mr. Howard I. Bobbitt, 609 Failing Bldg., Portland.

Pennsylvania: *Examination.* Philadelphia and Pittsburgh, July 5-7. Sec., Mrs. Margaret G. Steiner, Box 911, Harrisburg.

Rhode Island:* *Endorsement.* Providence, March 24. *Examination.* Providence, April 7-8. Administrator of Professional Regulations, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

Tennessee:* *Examination.* Memphis, March 23-24. Sec., Dr. H. W. Qualls, 1635 Exchange Bldg., Memphis 3.

Texas:* *Examination and Reciprocity.* Fort Worth, June 20-22. Sec., Dr. M. H. Crabb, 1714 Medical Arts Bldg., Fort Worth 2.

Utah: *Examination.* Salt Lake City, July 6-8. Director, Mr. Frank E. Lees, 324 State Office Bldg., Salt Lake City 1.

Virginia: *Examination and Reciprocity.* Richmond, June 13-17. Address: Board of Medical Examiners, 631 First St. S.W., Roanoke.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Arizona: *Examination.* Tucson, March 18. *Endorsement.* Tucson, March 15. Sec., Mr. Herman E. Bateman, University of Arizona, Tucson.

Arkansas: *Examination.* Little Rock, April 21-22. Sec., Dr. A. W. Ford, Department of Education, Education Bldg., Little Rock.

District of Columbia: *Examination.* Washington, May 23-24. Deputy Director, Mr. Paul Foley, Department of Occupations and Professions, 1740 Massachusetts Ave., Washington 6.

Florida: *Examination.* Miami, June 4. Sec., Mr. M. W. Emmel, Box 340, Gainesville.

Iowa: *Examination and Reciprocity.* Des Moines, April 12. Sec., Mr. Elmer W. Hertel, Wartburg College, Waverly.

Kansas: *Examination.* Kansas City, June 10-12. Sec., Dr. Leon C. Heckert, Kansas State College, Pittsburg.

Minnesota: *Examination.* Minneapolis, April 5-6. Sec., Dr. Raymond N. Bieter, 165 Millard Hall, University of Minnesota, Minneapolis.

Nebraska: *Examination.* Omaha, May 3-4. Sec., Mr. R. K. Kirkman, Room 1009, State Capitol Bldg., Lincoln 9.

Nevada: *Examination.* Reno, March. Sec., Dr. Kenneth C. Kemp, Box 9355, University of Nevada, Reno.

Oklahoma: *Examination.* Oklahoma City, April 15-16. Exec. Sec., Mrs. E. L. Haidek, 813 Braniff Bldg., Oklahoma City.

Tennessee: *Examination.* Memphis and Nashville, March 23-24. Sec., Dr. O. W. Hyman, 62 S. Dunlap St., Memphis.

Texas: *Examination.* Austin, Houston and Galveston. Sec., Dr. Cornelia M. Smith, State Office Bldg., 201 East 14th St., Austin.

Washington: *Examination.* Seattle, July 13-14. Administrator, Mr. Thomas A. Carter, Department of Licenses, Capitol Bldg., Olympia.

Wisconsin: *Examination.* Madison, April 9. Milwaukee, June 4. Sec., Dr. W. H. Barber, 621 Ransom St., Ripon.

Self, Thomas F., Roy, N. M.; Gate City Medical College, Dallas, Texas, 1907; died in the New Mexico Miners' Hospital, Raton, Nov. 25, aged 78.

Simms, Earlin Judson Ⓜ Columbus, Ohio; Ohio State University College of Medicine, Columbus, 1911; member of the Columbus Academy of Medicine; on the staff of Mercy Hospital, where he died Oct. 8, aged 72.

Sinclair, Jardine Frank Ⓜ Chicago; Dearborn Medical College, Chicago; 1907; past-chief of the medical staff of Medinah Temple; formerly on the staff of Alexian Brothers Hospital; died Oct. 20, aged 80.

Stabnick, Joseph Sigmund, Hartford, Conn.; Jefferson Medical College of Philadelphia, 1934; interned at the Reading (Pa.) Hospital and the New York Hospital, where he served a residency; served a residency at the John Gaston Hospital in Memphis, Tenn., and the Hartford (Conn.) Hospital; member of the American Society of Anesthesiologists; associated with the Veterans Administration Hospital in Newington and the Hartford Hospital, where he died Nov. 14, aged 49.

Stanton, Thomas Menees, High Point, N. C.; Medical College of Virginia, Richmond; 1916; during World War I served overseas with Base Hospital 65; died in the Veterans Administration Hospital, Salisbury, Oct. 7, aged 69.

Stofflet, Clinton F. Ⓜ Pen Argyl, Pa.; Medico-Chirurgical College of Philadelphia, 1898; past president and for many years treasurer of the Northampton County Medical Society; member of the board of health of Pen Argyl and public school examiner for many years; during World War II medical examiner for Northampton County Draft Board; on the auxiliary medical staff of Easton (Pa.) Hospital; served as vice-president and director of the First National Bank of Pen Argyl; died Nov. 28, aged 82.

Swierat, John Valentine, Depew, N. Y.; University of Buffalo School of Medicine, 1917; served in the Army Medical Corps; in 1942 was honored by the Medical Arts Society, of which he was a member, for twenty-five years of professional service; served as psychiatric consultant to various institutions in Cheektowaga and Amherst; on the staffs of Millard Fillmore, Mercy, and Sisters of Charity hospitals, Buffalo; died in Buffalo Oct. 8, aged 65.

Tackaberry, Arthur Lee Wilson Ⓜ Santa Monica, Calif.; Medical Department of Tulane University of Louisiana, New Orleans, 1896; formerly medical officer for the Ford Motor Company assembly plant in Houston, Texas; died Nov. 28, aged 85.

Tappan, Benjamin Ⓜ Baltimore; Johns Hopkins University School of Medicine, Baltimore, 1915; consulting physician at Johns Hopkins Hospital, Kernan Hospital, and St. Joseph's Hospital; visiting pediatrician at Union Memorial Hospital and Church Home and Hospital; died Dec. 30, aged 69.

Thieda, Arthur Alexander Ⓜ Cicero, Ill.; Rush Medical College, Chicago, 1930; interned at St. Mary of Nazareth Hospital, Chicago; member of the American Academy of General Practice and the Polish Medical Society; former medical director and health commissioner; on the staff of St. Mary of Nazareth Hospital, where he taught in the nurses training school and where he died Oct. 21, aged 54.

Toland, Joseph James Jr. Ⓜ Philadelphia; Medico-Chirurgical College of Philadelphia, 1912; interned at Frankford Hospital; fellow of the International College of Surgeons, the American College of Surgeons, and the College of Physicians of Philadelphia; served as chairman of the committee on legislation in the Philadelphia County Medical Society; served in the Navy Medical Corps during World War II; director of the Northeast National Bank; in November, 1958, received the first award of merit from the alumni association of his alma mater; received the nineteenth annual Signum Fidei Award from the Alumni Association of LaSalle College; in December, 1958, he was chosen outstanding Catholic physician of the year by the National Federation of Catholic Physicians Guilds, of which he was a past-president; also past-president of the Men of Medical Missions; surgeon and first commander of the Frankford American Legion Post; former medical director and chief of surgery at Nazareth Hospital; former chief surgeon at the Pennsylvania State Hospital, Byberry; died in the Temple University Hospital, Oct. 19, aged 72.

Veeder, Willard Hall Ⓜ Geneseo, N. Y.; University of Buffalo School of Medicine, 1903; specialist certified by the American Board of Psychiatry and Neurology; past-president of the Medical Society of the County of Monroe; past-vice-president of the Rochester Academy of Medicine; veteran of World War I; for many years on the staff of the Rochester State Hospital; retired superintendent of the Craig Colony at Sonyea; died in the Peterson Hospital at Sonyea Dec. 5, aged 80.

Vogelsang, Aaron Dewey Ⓜ Toledo, Ohio; Ohio State University College of Medicine, Columbus, 1922; specialist certified by the American Board of Urology; member of the American Urological Association; fellow of the American College of Surgeons; past-president of the Toledo Academy of Medicine; veteran of World War II; on the staffs of the St. Vincent's, Toledo, Flower, and Maumee Valley hospitals; died Nov. 29, aged 62.

Watson, Clyde Otis Ⓜ Corpus Christi, Texas; University of Louisville (Ky.) School of Medicine, 1908; twice served on the city council; member of the school board for ten years; on the staff of Spohn Hospital; died Oct. 6, aged 78.

Waugh, Henry Hartzell Ⓜ Dover Plaines, N. Y.; University of Wooster, Medical Department, Cleveland, 1891; specialist certified by the American Board of Ophthalmology; fellow of the American College of Surgeons; for many years practiced in Brooklyn, where he was a member of the board of trustees and senior surgeon of the Brooklyn Eye and Ear Hospital; died Oct. 5, aged 91.

West, Arthur Dudley Ⓜ Moline, Ill.; University of Vermont College of Medicine, Burlington, 1898; veteran of World War I; died Nov. 25, aged 86.

Wiginton, Marquis Claude Ⓜ Hammond, La.; Northwestern University Medical School, Chicago, 1924; member of the American Academy of General Practice; past-president of the Louisiana Academy of General Practice and the Tangipahoa Parish Medical Society; associated with the Wiginton Memorial Hospital; died in Indian River City, Fla., Nov. 25, aged 64.

Willcox, William David Ⓜ Fitzgerald, Ga.; Emory University School of Medicine, Emory University, Ga., 1937; veteran of World War II; formerly on the board of education; on the staffs of Ben Hill County Hospital; died Oct. 1, aged 47.

Woodcock, Charles Edwin Ⓜ Greenwood, Ind., Indiana University School of Medicine, Bloomington–Indianapolis, 1915; interned at Indianapolis City Hospital; for a time practiced in Zionsville; during World War I served with the Army Medical Corps and went to Siberia with Evacuation Hospital 17; member of the Chamber of Commerce; died Oct. 2, aged 72.

Wyatt, Kon Ⓜ Canon City, Colo.; University of Virginia School of Medicine, Charlottesville, 1920; past-president of the Fremont County Medical Society; veteran of World Wars I and II; bank president; associated with St. Joseph Hospital in Florence and St. Thomas More Hospital; served as county coroner; past-president of the Canon City Chamber of Commerce; died Nov. 28, aged 63.

Young, Armanus Hixon, Pomona, Calif.; born in Highland County, Ohio, Oct. 17, 1861; Iowa Eclectic Medical College, 1888; at one time practiced in Oklahoma; died in Ontario, Calif., Oct. 2, aged 97.

Young, Samuel A., Anaheim, Calif.; State University of Iowa College of Medicine, Iowa City, 1896; died Oct. 3, aged 89.

Zvaifler, Nathan Ⓜ Newark, N. J.; Jefferson Medical College of Philadelphia, 1917; interned at St. Michael's Hospital, Newark; specialist certified by the American Board of Ophthalmology and the American Board of Otolaryngology; past-president of the Newark Beth Israel Hospital staff and the Northern New Jersey Jefferson Medical College Alumni Association; member of the New Jersey Society of Surgeons and Phi Delta Epsilon; consultant to Martland Medical Center, Presbyterian Hospital, and Irvington General Hospital; died in East Orange Oct. 18, aged 65.

DENMARK

Spastic Paraplegia.—Pedersen and Schleisner (*Acta psychiat. et neurol. scandinav.* 34:342-353, 1959) reported that bis (4, 6 diethylamino-1,3,5-triazino-2-yl) hydrazine dihydrochloride (Ciba, 13,155), a new muscle relaxant, exerts its action by depressing the polysynaptic pathways. The effect of the drug was studied in 50 patients, most of whom had spastic paraplegia. It was effective when given orally and during an experimental period of seven months did not give rise to serious side-effects. The authors advised against a rigid dosage schedule but stated that the treatment might be started by giving a patient weighing 60 to 70 kg. (132 to 154 lb.) an initial dose of 50 mg. three times daily. The drug proved to have an excellent effect on difficulties in bladder control, especially in reducing pollakiuria and incontinence. In about one-half of the patients appreciable relaxation of muscular tone was obtained, with subsequent improvement of the gait.

Electroencephalography was performed before the institution of treatment with the drug and two or three times later, as far as possible when the patient was on the largest dosage schedule. Changes were observed in seven patients; slow activity was slightly increased in four, moderately increased in two, and returned to normal in one. The drug appeared to have certain features in common with zoxazolamine, but the latter does not improve volitional control, and its value has been further questioned in recent reports. Ciba 13,155 was undoubtedly superior both to mephenesin, which must be administered intravenously for maximum benefit, and to curare, which has a narrow margin of safety.

Imipramine for Endogenous Depressions.—Andersen and Kristiansen (*Acta psychiat. et neurol. scandinav.* 34:387-397, 1959) used imipramine to treat 85 patients who had endogenous depressions. The drug was given in 25-mg. tablets and intramuscularly. Both peroral and combined peroral and parenteral treatment were used, the latter in patients with severe depression. There was no appreciable difference between the effects of these two methods. Improvement commenced usually in the second or third week of treatment. The depressions were cured or ameliorated in 80% of the patients. There were no deaths, and no patient's condition deteriorated. Good results were obtained, and treatment could be terminated in about 50% of patients after four weeks or less of treatment. In most patients there was profuse perspiration, slight decrease in blood pressure, tremor, dry mouth, and disturbances of visual accommodation, but these disturbances were usually not serious. There were two cases of temporary icterus, three of short-lived delirium, and one of transient mania. Mild withdrawal symptoms were noted in 15 patients, but the authors did not observe euphoria or addiction. The authors concluded that imipramine is a promising antidepressive but that caution should be exercised when it is given to elderly patients or patients with increased blood pressure.

Therapeutic Use of Lithium.—Mogens Schou (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:51-55, 1959) gave lithium to 157 patients suffering from mania. Within two or three weeks after the start of the treatment, improvement or recovery was observed in 122 patients (about 80%). Doses of 1 to 2 Gm. per day were given to patients suffering from the manic phase of manic-depressive psychosis. Controlled studies indicated that, in at least 50% of these patients, the improvement was due to the lithium and not to spontaneous remission, suggestion, or inaccuracies of clinical observation. The author believed lithium treatment to be preferable to electric convulsive therapy and to other drug therapy in patients with protracted or frequently recurring mania. It was ineffective during depression. Lithium is potentially toxic, but the toxic effects may be checked and the drug used safely in controlled doses if the patients ingest a sufficient amount of sodium. Animal experiments have shown that the principal toxic action of lithium is on the kidney tubules. Sodium protects patients against toxic injury through a competition with lithium for entrance into and reabsorption through the tubule cells.

Perphenazine.—The results of nine months medication with perphenazine in a series of 309 patients with mental disease were analyzed by Gustav Hansen and co-workers (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:78-81, 1959). In this series 183 patients had previously had electroshock therapy, 108 had been treated with insulin coma, and 36 had each had a lobotomy. A total of 285 patients received no other treatment while the perphenazine was being given, and the rest had

supplementary treatment with electroshock, reserpine, or meprobamate. The series comprised 295 chronically and 14 acutely ill patients, 63% of whom were schizophrenic. Thus the majority were in the older age groups. Among the 285 who received perphenazine alone 16.1% were much improved, 29.5% were slightly improved, 49.5% showed little or no improvement, and 4.9% became worse. The results in the 24 patients who received supplementary treatment showed a similar distribution. Thus in the entire series 45.7% obtained improvement. One reason why the results were not better was probably that the series consisted of patients who had shown little response to other therapeutic measures. Side-effects occurred in 187 patients and consisted primarily of parkinsonism, fatigue, and drowsiness.

FINLAND

Contrast Examination of Lumbar Interspinous Ligaments.—Rolf Köhler (*Acta radiol.* 52:21-27, 1959) described a method for roentgenographic examination of the lumbar interspinous ligaments based on the injection of a contrast medium close to the ligaments on both sides. He examined a series of 100 patients with low backache or sciatica by this method. Bilateral injection of the contrast medium gave a more complete result than unilateral injection on the side of the patient's main symptoms. Because it is more concentrated than monoiodized water-soluble preparations (20%) a preparation such as 30% Urografin improved the quality of the film of the last 10 patients on whom it was used. In roentgenograms of normal persons the ligament appears as a flat spindle-shaped filling defect bounded by contrast medium. In pathological cases the contrast medium penetrates into the ligament through defects.

Of the 100 patients examined, 55 were operated on, the majority because of a diagnosis herniated nucleus. The roentgenographic findings corresponded well with the operative findings in patients in whom the contrast medium had been correctly deposited close to the ligamentous wall. Of the 55 surgically treated patients, 19 had normal ligaments in the L-3 to L-5 interspinous spaces. In 1 patient a herniation was seen in the L-3 to L-4 space, in 10 in the L-4 to L-5 space, and in 4 in the L-5 to S-1 space, while 3 had symptoms of sciatica without herniation.

Working Capacity of Uninsured Seriously Disabled Persons.—Kauko A. Solonen (*Ann. chir. et gynaec. Fenniae* 48:115-129, 1959) reported on a series of 17 uninsured patients who were able to work hard at jobs that often seemed especially strenuous in view of the patients' defects. The subjects included three with tuberculous spondylitis, three with arthrosis of the hip joint, two with pseudarthrosis of the olecranon, and one each with ankylosis of the wrist, destruction of the hip joint and marked shortening of the lower extremity, pseudarthrosis of the neck of the femur, pronounced traumatic deformation of the talocural joint and pseudarthrosis of the fibular malleolus, tuberculous coxitis, pseudarthrosis of the carpal navicular and carpal tunnel syndrome, osteosarcoma of the femur (this patient resumed his former occupation immediately on discharge from hospital three weeks after amputation), a malignant growth in the soft part of the ankle, and destruction of the hip joint as a result of a gunshot wound. Several of the patients were farmers who worked their own farms. All were engaged in heavy manual work and were well adapted to their environment. Their intelligence was average or above. They all had to work but appeared to enjoy their work.

The author observed that a young person adapts himself more easily to his trauma than an old person, but an intelligent old man or woman understands instinctively the naturalness of the limitations of age and is not depressed when they are felt. In the absence of insurance protection man makes the best possible use of his own physical and mental capabilities. The mobilization of these faculties is also affected by many other factors: individual characteristics; mode of life; social, economic, and home life; and emotional experience. The favorable effect of mental and physical activity and work was revealed by these patients. All these aspects should be considered. The patients should be treated as normal human beings.

Congenital Clubfoot.—Solonen and Parkkulainen (*Ann. chir. et gynaec. Fenniae* 48:130-140, 1959) reported that of the 134 patients with congenital clubfoot treated at the department of pediatrics of the Central University Hospital in 1947-1953, 74 were given a follow-up examination in 1957-1958. The final results were good in 51%, fair in 30%, and poor in 19%. In 34 patients with bilateral clubfoot the result recorded was that of the worse foot. The results were usually the same for both feet. Recurrences after inadequate primary treatment were seen in several patients. Insufficient or delayed primary therapy was the most important reason for the poor final result, although the results were also affected by the primary degree of difficulty of the deformity. Neglect of further therapy resulted in recurrences. The great number of recurrences was the reason for the exceptionally great number of operative measures (62% of the total number of patients).

The most troublesome of the residual deformities were talipes varus and talipes equinus, usually the most difficult components. The other components of the primary deformity were less troublesome. Treatment provoked such deformities as transversoplanus, rockerfoot, and planovalgus of the originally healthy foot. Early and intensive primary treatment and carefully supervised and controlled further treatment of long duration were the best guarantees of good results. The principal object of primary treatment must be correction of the most difficult deformity components, varus and equinus. If this treatment does not prove successful early achillotenotomy might be advisable.

Effect of Psychic Tension on Capillary Resistance.—The capillary resistance of 47 medical students was measured by Panu Hakola and co-workers during and after psychic tension due to a test (*Ann. med. exper. et biol. Fenniae* 37:314-319, 1959). That of 10 inmates of a mental hospital was also measured. Capillary resistance was observed to be higher when the subjects were under tension. The increase in capillary resistance was slightly greater in those who exhibited the lowest capillary resistance level when not excited. The increase was also found to be greatest in those with the quickest pulse during the tension. The average increase of capillary resistance during the tension was 2.23 cm. Hg, and there were differences between the student group and the inmate group, the average being 1.9 cm. Hg for the students and 3.8 cm. Hg for the inmates. Electric shock was the only other stimulus observed to produce an increase in capillary resistance in subjects in whom a decrease had been noticed when the general nervous system was stimulated mechanically, by means of x-rays, or after a concussion of the brain.

The authors concluded that it was possible that psychic tension influenced capillary tension through the increasing effect of the added epinephrine content of the tissues on the capillary resistance. This conclusion was supported by the fact that capillary resistance, increased by psychic tension, might decrease almost instantaneously. This phenomenon was observed when the tension was due to the subject's fear of the capillary resistance measurement, and it disappeared as soon as the measurement proved to be completely painless and harmless.

Delayed Effects of Brain Trauma.—Eero Hillbom examined a series of 3,552 patients with brain injury incurred in World War II (*Acta psychiat. et neurol. scandinav.* [supp. 137] 34:7-29, 1959). In 18.8% the injury was mild, in 59.3% it was moderate, and in 21.8% it was severe. Of the injuries 61.1% were caused by shell splinters, 22.7% by bullets, and 16.2% by other agents. The author made a detailed analysis of 415 of these patients. Frontal and facial injuries were comparatively frequent among the mildly injured, and the frontal injuries were fairly frequent among the severely injured. On the other hand sensorimotor injuries were very frequent among the severely injured. Pareses and disturbances of the tactile sense were most often the most serious symptoms causing disability. Disturbances of the tactile sense occurred in 109 patients. Ataxias and symptoms of metabolic and cardiovascular dysfunction were relatively frequent. Traumatic epilepsy was found in 41.5% of all the patients and in 70% of the severely injured patients. The more severe the injury the more diversified were the associated symptoms. Delayed psychotic complications were observed, particularly in those with temporal injuries. Severe changes of personality and epileptic attacks resembling hysteria were observed especially in those with frontal injuries.

Funnel Chest.—Tala and Laustela (*Ann. chir. et gynaec. Fenniae* 48:177-188, 1959) performed 18 operations on 16 patients for the correction of funnel chest. Their patients' ages ranged from 3 to 37 years. In all these patients the deformity was observed soon after birth. No subjective symptoms were attributable to the deformity in the children, but displacement of the heart to the left was found roentgenographically in two of them. On the other hand the adults had severe symptoms. Displacement of the heart to the left or compression was noted in all the adults. These patients also had a sternal depression of much greater degree than did the children, and it was asymmetric in most cases. Cardiorespiratory disturbances were frequent. Patients complained of palpitation, dyspnea on exertion, and precordial pain. Pulmonary insufficiency of a mild degree was noted in three patients.

The results of the operation were good in all patients, but the results were much better in the children than in the adults. The treatment was in part conservative and in part surgical. One of the most recent operative techniques consists of dividing the attachments of the xiphoid and osteotomy of the anterior cortex of the body of the sternum with elevation of the gladiolus. Several modifications of this procedure, such as fixation of the elevated sternum to an external splint or prosthesis or internal fixation with grafts of rib, cartilage, wires, or Steinman pins, were used.

Children were treated differently from adults. Correction of pectus excavatum of children required less effort, and the hazard was relatively negligible. The ideal age for operation is 4 years. The operation may then be performed by resecting the xiphoid cartilage and severing the fibrotic attachments between diaphragm and sternum. In the present series good cosmetic results were obtained in all patients below 15 years of age with the use of the above-mentioned operative technique, whereas in the group of adults the results were merely satisfactory in four of nine patients, whose sternum, which had a highly asymmetrical depression and rotation, could not satisfactorily be brought into the normal plane. However, these patients were satisfied with the results.

Staphylococci in Mother's Milk.—Rantasalo and Kauppinen (*Ann. chir. et gynaec. Fenniae* 48:246-258, 1959) subjected milk samples from mothers to bacteriological study. The series comprised 88 mothers delivered in hospital in 1951, 84 mothers delivered in hospital in 1957, and 36 mothers who gave birth at home in 1952. On the fifth postpartal day *Staphylococcus aureus* was found in the milk of about 50% of the parturients in institutions but in the milk of only 28% of mothers delivered at home. The incidence of mastitis was greater in parturients in institutions than in those at home (7% and 0%). The Staph. aureus strains found in the milk of mothers delivered at home were generally responsive to antibiotics. Staph. aureus strains resistant to antibiotics were much more common in institutional parturients, and this resistance became far more frequent during the six years of the investigation.

The prophylactic use of penicillin in institutions could not prevent the infection of mother's milk by Staph. aureus or decrease the incidence of mastitis. Other antibiotics would presumably also be ineffective, since resistant strains developed to all the antibiotics studied. This development was slowest with chloramphenicol but very rapid with streptomycin and the tetracyclines. The mothers generally contracted the Staph. aureus infection first and then transmitted it to their babies through milk. Although Staph. aureus strains resistant to various antibiotics developed more slowly at home than in hospital, it was advisable also in the home to avoid using rarer antibiotics in order to prevent the development of resistant strains, especially as staphylococcic infections in homes were generally sensitive to penicillin, streptomycin, and the tetracyclines.

Use of Hydroxydione in Cesarean Sections.—Kivalo and Tammisto (*Acta anaesth. scandinav.*, supp. 2, pp. 35-40, 1959) used hydroxydione as an anesthetic for cesarean section in a series of 65 mothers. The total dose for induction was 1.0 to 1.5 Gm. supplemented after the delivery by nitrous oxide and oxygen. In order to determine the most suitable application of the drug they used (1) hydroxydione alone, (2) hydroxydione with d-tubocurarine, and (3) hydroxydione with succinylcholine. The induction of the 11 patients in the first group took, on the average, nine and one-half minutes and proved entirely unsuitable, as patients responded violently to the incision. Of the babies 27.3% suffered from asphyxia immediately after birth but were cured with electric shock. In the 33 patients of the second group only 6 were adequately anesthetized, and in the remaining 27 patients movements of the body interfered with the operation. All 21 persons in the third group were successfully anesthetized. The authors concluded that the administration of the larger doses of hydroxydione resulted in a higher frequency of neonatal asphyxia and the slower recovery of the infants. The drug, however, may be recommended for preeclamptic and diabetic patients. In emergency sections necessitated by fetal asphyxia, premature separation, etc., when induction must be as rapid as possible, hydroxydione was inferior to other anesthetics.

New Steroid.—A new synthetic steroid, 6 α-chloroprednisolone, has a potent antirheumatic and antipyretic effect. Kalliomäki and Häkkinen (*Acta endocrinol.* 32:59-62, 1959) used it to treat a series of 15 hospitalized patients who had rheumatoid arthritis. It was found that the improvement in these patients which was obtained with 15 mg. of prednisolone a day could be maintained with 12 mg. of the new drug. During treatment with 6 α-chloro-prednisolone no tendency for sodium retention, potassium loss, hyperglycemia, changes in serum inorganic phosphorus, weight change, blood pressure elevation, and gastric or psychic disturbances were observed. The rebound phenomenon could also be observed after cessation of treatment with the new drug.

FRANCE

Vibration Therapy for Psychosomatic Disorders.—At the meeting of the French Society of Psychosomatic Medicine in October, P. Strouzer and A. Albert reported the results of treatment with vibrations in a series of 206 patients. The patients were placed in recumbent position on a vibrating table. The head rested on a platform that did not vibrate. The frequency of the vibrations ranged from 12 to 50 cycles per second. A definite improvement was recorded in 19 patients with post-traumatic sequelas of occupational accidents; in 17 patients with sequelas of cranial trauma with or without fracture, comprising such syndromes as right hemiplegia and facial paralysis; and in 22 of 44 women with cellulitis. In 13 of 42 psychotics with neuroses, an improvement was observed in the neuroses but not in the psychosis. In general, euphoria was observed, and, in particular, a transitory or definitive tendency to improvement of insomnia was noted in those patients in whom no improvement had resulted from other forms of treatment.

A similar effect was recorded in a group of 11 patients (including one with chronic chorea, one with paraplegia, one with a phantom limb, one with paralysis agitans, one with facial hemispasm, and one with epilepsy), but there was no improvement in the underlying disease. In certain hypotensive patients a mild increase in pressure was noted. In patients with mild hypertension a significant and permanent drop of the systolic and diastolic pressure was observed. The speakers gave 10 to 12 sessions of vibration therapy at a rate of 3 sessions per week.

Renal Diseases and Polyarthritis.—E. Berthoud (*Rev. rheumatisme,* no. 2, 1959) reported that in a series of 57 patients treated for chronic progressive polyarthritis 32, in whom the duration of the disease varied from 1 to 35 years, showed no renal lesions. In the remaining 25 patients, in whom the duration of the disease averaged 42 years, temporary or discrete renal changes such as insufficiency on functional tests, increased arterial tension, temporary proteinuria, leukocyturia, or cylindruria were observed. These were not believed to be due to the disease but to the use of acetophenetidin or to that of chrysotherapy with its renal toxicity, even in those who appeared to tolerate this treatment well.

INDIA

Health Priorities.—The Regional Director of WHO for South-East Asia reported (*Antiseptic,* vol. 58, Nov., 1959) that a stricter order of public health priorities should be followed by India and other countries in the southeastern part of Asia in the use of their limited supply of men and material. Because of a shortage of qualified doctors, new medical schools have been opened and the admissions to existing schools doubled, but adequate teaching staffs have not been provided. The result may be a vast number of inadequately trained doctors. One source of relief for the acute shortage of doctors and nurses would be greater use of auxiliary medical personnel. Domiciliary midwifery should be encouraged. The growing tendency for even normal deliveries to be made in hospital is most uneconomical. Rural health centers must devote more effort to preventive measures. Far too little has been done at these centers to improve sanitation or to provide health education, especially in nutrition.

Acetazolamide for Epilepsy.—K. Bhaskaran and co-workers gave acetazolamide to six patients with epilepsy who had proved refractory to the usual anticonvulsant treatment (*J. Indian M. A.,* vol. 33, Nov. 1, 1959). These patients had been suffering from fits for 2 to 36 years. Acetazolamide in doses of 250 mg. three times a day was added to the routine therapeutic regimen. The response was excellent in the four patients with idiopathic epilepsy. In one patient who had petit mal the total number of attacks, which was 540 in the three months preceding the trial, decreased to 4 in the next three months. In the three who had grand mal the number of fits before the trial was 34, 14, and 17, and after the addition of acetazolamide these decreased to 3, 3, and 6 respectively. In the patients with postencephalitic epilepsy and the one with posttraumatic epilepsy there was no appreciable improvement.

Tuberculous Meningitis.—Shah and Bhavsar (*J. Indian M. A.* 33:9 [Nov. 1] 1959) studied a series of 77 patients with tuberculous meningitis—10 in the early, 54 in the intermediate, and 13 in the advanced stages. All patients were given specific antituberculosis treatment in addition to supportive treatment with cod liver oil, vitamins, and symptomatic measures; 43 received streptomycin and isoniazid; 27 received streptomycin, isoniazid, and steroids; 2 received streptomycin intrathecally in addition to injections of streptomycin and isoniazid; and 5 received streptomycin with other antibiotics. In the latter patients the diagnosis was not proved, and these patients died or were taken out of the hospital against medical advice.

Of the 77 patients, 18 were moribund on admission and died. Of the remaining 59 patients, 56 responded well to treatment. The results of treatment were best in patients who came in the early stage. The mortality in those who came in the advanced stage was 54% and of those who came in the intermediate stage 23%. Of the patients who had meningitis alone 70% survived, but of those who also had associated tuberculous lesions 81% survived. If only the patients with advanced cases are considered, 47% of those with meningitis alone and 55% of those with associated lesions failed to respond to treatment. The addition of isoniazid to the therapeutic regimen of these patients changed the course of this grave disease. Most patients who come early enough for treatment can be expected to recover on therapy with streptomycin and isoniazid. In advanced cases, the failure of treatment was 52% in those to whom steroids were not given but only 42% in those to whom they were given. Thus corticosteroid therapy was of definite help in the treatment of patients with advanced cases.

Corneal Xerosis.—K. Bagchi and co-workers (*J. Indian M. A.,* vol. 33, Nov. 16, 1959) stated that xerosis of the cornea is usually believed to be a manifestation of vitamin A deficiency. More recently, protein malnutrition has been found to play some part in precipitating or aggravating vitamin A deficiency, especially in regard to ocular lesions. The authors studied 46 patients with corneal xerosis. They found that brown or muddy pigmentation of the sclera, whether generalized or patchy, has a close relation to nutritional deficiency and corneal xerosis. Thus in six patients xerosis was seen in only one eye, but the other eye had a comparable area with brown pigmentation. These triangular patches cleared with treatment even before improvement began in the xerosis. The latter usually took a long time to clear.

A number of children with protein deficiency were also found to have pigmented patches in both eyes in areas which were in many cases the site of xerosis. These patches cleared up after protein therapy, but in the children who did not receive such treatment the patches gradually became xerotic. If the xerosis was due only to vitamin A deficiency, the absence of other associated manifestations of this deficiency in most of these patients would be surprising, for only four showed night blindness while a large percentage showed evidence of protein deficiency. This finding suggested that protein deficiency played a part in the development of this lesion. One group of these patients received vitamin A by mouth in doses of 50,000 I. U. daily, and the rest received the vitamin in the same dosage and skimmed milk powder which supplied them with 30 Gm. of protein daily. The clinical response took about six months to appear when vitamin A was used alone, but when protein was supplied in addition the response was prompt. Rapid improvement occurred not only in the eye lesions but also in the patients' general condition.

Dacryocystography.—D. P. Aggarwal (*Indian J. M. & Surg.* 24:6 [June] 1959) stated that dacryocystography is useful mainly in determing stenosis or obstruction of the nasolacrimal duct. The exact site of obstruction and position of the lacrimal sac can thus be visualized and the correct line of treatment planned. It is also helpful in evaluating the results of operations. The author used neohydriol, a contrast medium containing 40% iodine. It was easy to inject because of its low viscosity. With its use even small irregularities in the outline of the lacrimal passage could be demonstrated. No undesirable side-effects were observed. Of the 25 patients treated by dacryocystorhinostomy after preliminary visualization by this method, 20 became symptom-free after the operation.

NORWAY

Fat Embolism.—Dr. E. Ofstad (*J. Oslo City Hosp.*, vol. 9, October, 1959) reported a series of 25 patients (21 men and 4 women) who had fat embolism after injury. In 14 the injury was due to a traffic accident. The interval between the injury and the onset of symptoms indicative of fat embolism varied from 20 minutes to seven days. In two patients, who died 45 minutes and 10 hours, respectively, after the injury, small amounts of fat were found post mortem in the cerebral vessels. This finding shows that fat emboli may occur in the systemic circulation soon after an injury. The length of survival of the patients after the injury was from 45 minutes to seven days. Though it is generally assumed that fat embolism usually follows fracture of the long bones, the present series showed that cancellous bones may also yield fat emboli in elderly persons. In three patients the major injury was pelvic fracture in addition to soft tissue injury. The author concluded that pulmonary fat embolism is probably of little clinical importance except in persons with impaired cardiorespiratory function. He also found that petechial hemorrhages provide an important clue to the diagnosis of this condition.

More Doctors Needed.—The dismal forecast of a glut of doctors in Norway in the near future was emphatically denied by Dr. H. Seyfarth (*Tidsskr. norske laegefor.*, Nov. 1, 1959), who believed that the concept of psychosomatic disease has done much to challenge the school of medicine which thinks and teaches exclusively in terms of morbid anatomy. The implications of this teaching led to an oversimplification of diagnosis which eased the task of the doctor. Now that he has learned to recognize psychosomatic disease he can no longer dismiss a headache as a nosological entity but must spend time unraveling the chain link by link. Unfortunately he is himself often the victim of overwork and not mentally fresh enough to tackle this problem well. If there were more physicians it would surely help him to lead a less hectic life and to give his patients better service.

Bromide Psychosis.—Although bromides have largely been replaced by modern sedatives, bromide psychoses still occur occasionally. Between 1951 and 1959 three patients with this psychosis were observed at the Gaustad Mental Hospital to which they had been admitted from other hospitals where it had not been properly diagnosed. K. Noreik (*Tidsskr. norske laegefor.*, Nov. 1, 1959) pointed out that the most conclusive diagnostic test in this ailment is the test for bromide in the serum. The findings were 302, 171, and 189.6 mg. per 100 ml., respectively, in these patients. All of them suffered from delirium and hallucinations, with disturbances of balance and dysarthria. All three had been addicted to alcohol and barbiturates, and all three recovered completely in a few weeks on the withdrawal of bromides and the regulation of fluid intake. Two of them were given sedative doses of insulin. Isotonic sodium chloride solution was given intravenously for four days to one patient.

SWEDEN

Hormone Production of the Placenta.—Under physiological conditions it is difficult to assess adequately the placental elaboration of estrogens and progesterone because of the existence of the fetus. However, a new method for the interruption of pregnancy through artificially induced fetal death (interruption of the connections between the fetus and placenta) offers a suitable means of studying the endocrine functions of the placenta isolated in situ. Ove Cassmer (*Acta endrocrinol.* [supp. 45] 32:7-82, 1959) reported hormone assays of 46 physically healthy patients before and after surgical interruption of their pregnancies. All but two were in the 17th to 21st week of gestation. One-stage and two-stage operations were performed. In the first type the placenta and fetus were completely removed after hysterotomy. In the second type fetal death was induced by interrupting the connections between the fetus and placenta, and the placenta was left in situ. The operation was completed after three days with removal of the placenta and macerated fetus. In a control group of 18 women only artificial rupture of the membranes was performed.

The human chorionic gonadotrophin (HCG) concentration in urine in three of the patients who had the two-stage operation indicated that the interruption of the connections between the fetus and placenta did not interfere with the placental elaboration of HCG. In 11 patients artificially induced fetal death resulted in a slight but significant drop of urinary pregnanediol excretion. On the subsequent three days the pregnanediol excretion remained unchanged, whereas after the complete removal of the placenta and macerated fetus a greatly diminished excretion was observed. In 10 patients the one-stage removal of the placenta and fetus resulted in an immediate marked decrease in the urinary pregnanediol excretion.

In 19 patients artificially induced fetal death resulted in a decrease in all estrogen fractions studied to 46% of the preoperative level. During the subsequent period with the placenta isolated in situ, the excretion further decreased although at a much slower rate. After complete removal of the placenta and macerated fetus the estrogen excretion showed a much more rapid elimination and dropped within three days to normal levels. The disappearance rate of total estrogens, which was estimated before and after complete removal of the products of conception, showed a significant increase.

In 18 patients who had the one-stage operation the estrogen excretion dropped to about 10% of the preoperative level after removal of the fetus and placenta and returned to the normal level within three days. The disappearance rate of total estrogens did not differ from that obtained by the two-stage operation. Statistical analysis of the control series revealed that rupture of the membranes did not interfere with the urinary estrogen excretion.

Allantoin and Psoriasis.—C.-G. Herdenstam (*Acta dermat.-venereol.* 39:216-224, 1959) conducted double-blind tests on 22 patients who had psoriasis with symmetrical bilateral skin lesions in order to study the topical effect of allantoin-petrolatum, allantoin-tar lotion, and allantoin-tar ointment. In six patients the effect of the allantoin-tar ointment was compared with the effect of a 0.25% anthralin ointment. The observed differences between the left and the right side in these patients were not significant, although a more rapid clearing of the skin was noticed on the side where the placebo was applied. The tar preparations were more effective than the petrolatum preparations.

Angiography of Cerebral Arteries.—Georg-Fredrik Saltzman (*Acta radiol.* 52:1-20, 1959) investigated the reason why the posterior communicating artery was visible by carotid angiography in only about one-third of the examinations in which the necessary anatomic conditions for the free passage of the contrast medium were present (354 times in 1,020 carotid angiographies). The posterior cerebral artery was visible less often in the youngest patients and most frequently in middle-aged patients. The incidence dropped again slightly in the higher age-groups. The author concluded by making the following suggestions as to how best to demonstrate the posterior cerebral artery. 1. An attempt should be made to puncture the internal carotid artery. 2. The examination should be in the form of a rapid serial angiography. 3. The contrast medium should be injected rapidly (a short needle might be used in order to reduce the resistance on injection). 4. Puncture complications should be avoided as far as possible (in practice this means that an experienced operator should perform the puncture if demonstration of the posterior cerebral artery is of special importance). 5. The vertebral artery might be compressed.

UNITED KINGDOM

Noise in the Hospital.—Dr. Cecily Statham at the Royal Northern Hospital in London, which is in an area of heavy traffic, questioned 114 patients on noise in the hospital and correlated these findings with a detailed picture of the background noise or quietness of their home and work. Half the patients did not complain of the noise at all. The other half said that certain hospital noises disturbed or worried them. In this group the sex distribution was equal. Patients with noisy surroundings, either in the home or at work, made fewer complaints than those with quiet backgrounds. Patients under 21 and over 65 years of age complained more than those in the intermediate age group, and those in single rooms complained more than those in large wards.

The hospital noises that disturbed patients most were made by other people talking, snoring, and calling out, particularly at night and early morning, and to a lesser extent by the voices of the nursing staff. About half the noise was made by people. The internal hospital noises that worried patients and accounted for 25% of the total noise were the banging of doors, clanking of bed pans, dropping of things on the floors in wards and corridors, the noise of carts, bells, buzzers, elevator gates, and the scraping of chairs, tables, and beds on the floor or wall. External noises, which caused about 25% of the complaints, were mainly due to traffic, in particular the sudden explosive acceleration of motorcycles. One patient used ear plugs at night to deaden the noise.

From these observations the following recommendations were made. When possible patients who are restless, talkative, senile, or disturbing to others should be placed in a single room or small ward. Single rooms should also be used for patients with headache or conditions which make them likely to be distressed by noise. Doors, carts, appliances, and elevator gates should be checked for quiet working. All movable furniture should be fitted with buffers and nurses should be instructed not to cause clatter with bed pans. Future hospitals should be located away from main roads. Wax ear plugs should be provided for those susceptible to noises at night.

Antibiotics and Hospital Infection.—An important contribution to the problem of antibiotic-resistant staphylococcic infections in hospitals was reported by Dr. Mary Barber and co-workers of the Hammersmith Hospital (*Brit. M. J.*, Jan. 2, 1960). An accompanying editorial stated that a series of preventive measures has helped to control these infections. A policy for the use of antibiotics was introduced, to be observed throughout the hospital. Prophylactic use was sharply restricted, the use of penicillin was abandoned except in specified wards, and when antibiotics were used two were given together or one was combined with a sulfonamide. K. Knorr and A. Wallner confined the use of antibiotics in a maternity unit as far as possible to tetracycline and oleandomycin, with the result that the frequency of staphylococcic resistance to some antibiotics decreased by about 50% although resistance to penicillin decreased only from 87 to 73%.

In the larger and more protracted study at Hammersmith Hospital, a similar effect was observed. Among strains isolated from patients, the frequency of penicillin resistance decreased from 74 to 52% and of resistance to both penicillin and tetracycline from 51 to 36%. Strains possessing multiple resistance were responsible for most of the more serious infections which occurred. The authors discussed the question of whether these strains are intrinsically more virulent, but it was difficult to distinguish such an intrinsic property from the consequences of simple resistance to therapy. However, the morbidity and mortality from these infections decreased during this period. There was also a diminution in the frequency of penicillin-resistant strains in nurses who were carriers. The results might have been better if repeated importation of resistant strains in patients transferred from other hospitals had not occurred.

Iron Deficiency Anemia.—Cox and co-workers reported subnormal serum concentrations of vitamin B_{12} in a number of patients with iron-deficiency anemia (*Lancet* 2:998, 1959). The marrow showed no evidence of megaloblastic erythropoiesis, and the hematological findings did not differ significantly from those of a group of patients with iron deficiency and normal serum vitamin B_{12} levels. All patients showed a return to a normal blood picture, including a normal serum vitamin B_{12} level, after treatment with iron only. Hitherto it was believed that B_{12} deficiency, as indicated by low serum levels is always associated with marrow changes. The observations of the authors indicate that this is not so. The finding of subnormal serum vitamin B_{12} levels in patients with iron-deficiency normoblastic anemia caused by repeated acute blood loss suggests that either the serum vitamin B_{12} level is not an accurate measure of the body stores or that a deficiency of vitamin B_{12} can occur without either neurological or hematopoietic abnormalities. In the patients in the present study the slow return of the serum vitamin B_{12} to normal, after hematological remission with iron therapy, suggests that a failure of absorption was corrected. This view was supported by the more rapid return of the serum vitamin B_{12} level to normal in patients with anemia due to blood loss, probably as a result of mobilization of vitamin B_{12} from the tissues.

Sedimentation Rate of Stored Blood.—Drs. Melville and Rifkind of Glasgow (*Brit. M. J.*, Jan. 9, 1960) reported that the need to set up sedimentation rate estimations immediately after withdrawal of blood samples was obviated by taking the blood into the anticoagulant, edathamil. When this was used there was no significant retardation of the sedimentation rate up to six hours after the blood was taken. It did not matter whether the blood stood undisturbed or was mixed at intervals, provided it was thoroughly mixed before the estimation was made. Storage for longer periods at room temperature was often accompanied by marked retardation of the sedimentation rate. Storage of edathamil-treated blood in the refrigerator for 24 hours did not affect the sedimentation rate, but storage for 48 hours was usually attended by marked slowing of the rate. It was recommended that edathamil-treated blood not be used for sedimentation rate estimations if it has been kept in the refrigerator longer than 24 hours.

CORRESPONDENCE

THE DOCTOR ABROAD

To the Editor:—When a physician plans a trip to some foreign country, he will miss a great deal if he overlooks the fact that he is a doctor. The purpose of this letter is to suggest that the physician use some of his vacation time for international good will, for the exchange of ideas with colleagues in other countries, and for the personal satisfaction of being a humanitarian. We may not turn out to be as selfless and effective as Albert Schweitzer, but we should carry out some of the traditions of the Hippocratic oath. I believe that members of the medical profession can create more international good will and help more to lessen international and interracial tension than all the millions of dollars our paternalistic government is pouring into dams, factories, and good-will missions. The reasons are self-evident. Official government missions, with the best of intentions and the most altruistic of motives, are often regarded with suspicion. This does not mean that we as a nation should stop giving and helping; on the contrary, we should do more and more, even if our motives are misunderstood. Some good must come of it. However, we as physicians can do a great deal on a personal and unofficial basis.

When a doctor visits a foreign country and seeks out a hospital, a local physician, a local health station, or whatever the unit of medical care happens to be, he may be performing a service for the United States. If he introduces himself and states that he has come to learn, to observe, to exchange ideas, and to be of some help if possible, he will be welcomed with open arms, with courtesy, and with respect. It is not only the personal contribution that counts but the desire to be friendly, to show interest, and to offer something of himself. I have seen, heard, and shared many experiences of this type and I believe that the physician who has not has missed some of the most rewarding experiences of his lifetime.

You may find out, to your surprise, that you learn more than you teach. You may see examples of diseases which are common locally and are treated successfully with local remedies, whereas these same disorders are rare in your practice or unresponsive to the measures you employ. You may make friends with whom to correspond over the years and whose friendship makes an average trip a fascinating vacation. You may end up by sending your colleagues medical supplies needed locally, hard-to-get journals, equipment easy for you but impossible for them to obtain, or you may merely continue a relationship based on common interests, a mutual desire to help the sick, and a sincere friendship. This same feeling may permeate the other people in the community, namely, of that nice American doctor who came in friendship and only wanted to be helpful.

In the summer of 1958 I visited Italy as an official representative of the United States Committee of the World Medical Association. I enjoyed several meetings with the president of the medical society of Rome, Dr. Carlo Prandi, and with other physicians. These conferences were in the nature of preliminary explorations in order to develop spheres of mutual understanding and to obtain information about problems of significance on both sides of the Atlantic. My primary interest in dermatology drew me to Dr. Ugo Granelli, one of the leaders of Italian dermatology and the director of the Ospedale San Gallicano in Rome. This hospital was built in the early 18th century and it is one of the largest institutions in Italy devoted entirely to the treatment of diseases of the skin. Despite the antiquity of the building, it is well equipped for the modern dermatological care of about 350 inpatients and many more clinic patients. Dr. Granelli has a large and competent staff of dermatologists and specialists in related fields. The institution services one of the largest and poorest districts of the oldest part of Rome, the Trastavere. During several of my visits with Dr. Granelli, it was my good fortune to examine patients with ordinary or rare skin diseases and to exchange information about recent developments in the field. Certain procedures and techniques were relatively new to both Italian and American dermatology, and I was asked many questions about skin planing or dermabrasion, with which they had then had little personal experience. As a result, I promised to equip their clinic with the items necessary for this procedure and to return the following summer to demonstrate the somewhat complicated technique.

I returned in the summer of 1959, after having shipped the necessary equipment to the hospital in the early months of that year. It is difficult to describe the pleasure of this reunion and the affection with which I was greeted by my many medical friends in Italy. A special surgical room had been set up in the Ospedale San Gallicano and many of the staff were on hand to observe several demonstrations of the new technique. I was gratified by the interest of the doctors and especially by the presence of the dean of the medical profession in Italy, Dr. Raffaele Chiarolanza, the president of the national federation of the medical societies of Italy.

If this letter has served to demonstrate some of the issues raised in its opening paragraphs, it will have served its purpose. Remember that it is not necessary to travel on an official mission in order to show interest in a country from a medical standpoint. It is only essential that you make an effort to show friendliness and human interest as a physician and include with it an offer of your own services as a humanitarian. You will never regret it.

Howard T. Behrman

Director of Dermatological Research
New York Medical College
New York.

HYPERSENSITIVITY TO IMMUNE SERUM GLOBULIN

To the Editor:—The clinical note in The Journal, Sept. 26, 1959, page 415, is a case report entitled "Hypersensitivity to Immune Serum Globulin." The publication of this seems unfortunate to me, since both diagnosis and treatment are open to question. The inaccuracies which it contains could lead to disaster in circumstances of a similar nature. The concept of spontaneous hypersensitivity to human immune serum globulin is hardly borne out by any of the evidence or comments printed. The fact that both parents had a strong allergic history scarcely gives any additional credibility to this diagnosis, in a 15-week-old child who has yet to manifest one symptom of an allergic nature despite the fact that it has met and apparently overcome successfully innumerable antigens.

Even the comments of the consultant which are included contain rather misleading statements; e. g., speaking of the possibility of allergy, "The mechanism is of some interest. The baby was only 15 weeks old at the time of the injection. This might mean that this baby still possessed atopic reagins from its mother." No one, not even the most enthusiastic supporter of a hereditary concept in allergy, has ever stated or shown that atopic reagins are transmitted from the mother through the placenta to the infant (Kuhns: *Am. J. Med.* 20:251 [Feb.] 1956).

The second suggestion, that of a vasomotor reaction, seems to me the more likely diagnosis. This has probably, in the past, been frequently accepted or misconstrued as an immediate anaphylactic type of reaction. I have seen a state of acute syncope, which resulted also in the onset of a grand mal seizure with complete evacuation of the bladder contents, frothing at the mouth, and holding of the breath, after a skin test in a 14-year-old girl. By the use of hypnotic suggestion, removing sensation from the arm that testing was performed in, this could be completely obviated or made to recur at will. Should this be called an anaphylactic reaction of an allergic nature?

Apparently this 15-week-old boy, who had never had an injection before, resented the intrusion of a 20-gauge needle into his buttock in such a manner that a deep, firm indurated area, 2 in. in diameter, remained for several days thereafter. This suggests a local hematoma.

As for the treatment described, it appears to me that most of what occurred to the child afterward was the result of overmedication, beginning with 1 cc. of epinephrine and its subsequent repetition, and of the other drugs used. The ferocity of the therapy may reflect the physician's acute distress. This apparently was the infant's first experience with an injection, because a statement is made that at the age of 7 months no other injections had been given. One would wonder why immunizations of the usual type were not begun earlier in a 15-week-old boy who appeared to be thriving.

This case report aptly ends with the statement that there are no other reported cases of sensitivity to gamma globulin, although perhaps 40 million cc. has been distributed and used. It fails to state also that many of these had been used in allergic children. Articles such as this should be more carefully screened, with an eye to their implications both in diagnosis and in treatment.

BREAST CANCER

To the Editor:—In The Journal, Oct. 31, 1959, two references to simple mastectomy for cancer require further comment. I refer to the article, "Survival Rate of Patients with Breast Cancer in a Small Community" (page 1180), and the filler on page 1220 entitled "Simple or Radical Mastectomy?" In the article, table 1 indicates that McWhirter's five-year operative survival rate was 58%. This is a pernicious figure which, in my estimation, should not be circulated without a full and complete analysis showing what McWhirter meant by "operable" and what virtually the rest of the surgical world means by "operable." McWhirter limited his "operable" group to only 56% of patients coming to him for treatment, whereas the Mayo Clinic finds 84% operable. (Berkson and others: *Proc. Staff Meet. Mayo Clin.* 32:645 [Nov. 13] 1957.)

The general findings in the treated patients reveal that McWhirter had a 48.1% and the Mayo Clinic a 59.3% five-year survival rate, based on treatment rendered in the period 1941-1947 by both. While the Mayo Clinic has shown consistent improvement over the years in the rate of five-year survival (65.1% of the operable patients in the period 1950-1954), we do not know whether McWhirter's figures bettered or worsened with the trial of time. Furthermore, while McWhirter has not revealed his 10-year survival figures, there is reason to suspect that radiation may not kill but may merely retard the growth of cancer cells in axillary nodes. Does axillary radiation, then, not cure but merely postpone regional recurrence? In contrast, of all patients treated in the most recent group at the Mayo Clinic, 45.9% survived death from all causes for 10 or more years after operation, while those with axillary metastases had a 29.5% 10-year survival rate.

The extract from Dr. Case's article on page 1220 reflects only therapeutic nihilism not substantiated by fact. He reasons as follows: Since cancer of the breast has so many pathways of spread, why attack only one, the axilla? We as physicians deal not *primarily in philosophy*, but *in facts*. Where is his evidence? The end-result of the controversy between proponents of simple and radical mastectomy is not simply a didactic one. The lives of many women hang on the decision made by their physicians. The responsibility of publishing full and complete findings rests with the editors of the various journals. The references cited in the two articles were misleading, potentially harmful, and undeserving of publication without comment.

REACTIONS TO POLIOMYELITIS VACCINE

To the Editor:—The article "Reactions to Poliomyelitis Vaccine" by Christensen in The Journal, Oct. 17, 1959, page 869, implies certain things about reactions to the penicillin contained in poliomyelitis vaccine which are not necessarily true. The statements that, "It seems likely that most of the severe reactions would have been reported," and that Eli Lilly & Co. has had only 284 complaints after 184 million ml. of the vaccine was distributed are illogical. Even if all reactions known were reported to the company, as noted by the A. M. A. Council on Drugs in discussing the similar problem of trace amounts of penicillin in milk (*J. A. M. A.* 171:49 [Sept. 5] 1959), such penicillin reactions "have gone unreported and unrecognized." I had a paper on penicillin reactions to poliomyelitis vaccine in The Journal, Aug. 9, 1958, page 1807, but I did not report to the company, although the first case reported in the paper was an allergic reaction to penicillin in Lilly vaccine.

The author's assumption that the *incidence* of reactions is one to 1,200,000 doses is at variance even with the sources quoted in his bibliography. Statistics in these vary from "allergic reactions in 110 out of 4,340 patients" to "major reactions in 1 out of 25,000 persons."

While his statement that "antibiotics cannot be omitted from the manufacturing process of poliomyelitis vaccine" is true, since May 26, 1955, other antibiotics have been used instead of penicillin. Wyeth vaccine, to which polymyxin B is added, is virtually penicillin free (less than 0.001 IU per milliliter).

It was pointed out by the A. M. A. Council on Drugs that "Antibiotics such as bacitracin, neomycin, polymyxin B, and the tetracyclines . . . do not pose a hazard to health. . . . On the other hand, even in small amounts, . . . penicillin, which is highly antigenic, is capable of causing allergic reactions in highly sensitive individuals." If the author is going to give a bibliography, it seems to me that he might include reference to such comments. In the United States we are now reaping the whirlwind of our profligate use of penicillin for the last 15 years.

Murray C. Zimmerman, M.D.
301 E. Hadley St.
Whittier, Calif.

This letter was referred to the author of the original article, whose reply follows.

To the Editor: My experience, the experience of my practicing physician friends, and the records at Eli Lilly and Company strongly suggest that allergic reactions to the penicillin in poliomyelitis vaccine are extremely infrequent. It was believed important to express this view in print because the contrary one has been published by certain authors, including Zimmerman (*J. A. M. A.* 167:1807 [Aug. 9] 1958).

Zimmerman is right when he says that, from the data available to the company, the incidence of reactions cannot be computed, and this point was stressed in the summary of my article: "Because of incomplete reporting, the data do not allow an estimate of the incidence of reactions." It may also be said that the data presented in Zimmerman's article *do not allow an estimate* of the incidence of reactions, yet he states that "six cases from private practice between May and November, 1957, indicate that penicillin reactions to poliomyelitis vaccine are *relatively* common."

Federal regulations do permit the use of antibiotics other than penicillin in the manufacture of poliomyelitis vaccine, but in the past all manufacturers used penicillin, and it is my understanding that they all continue to use penicillin, at least in *the initial tissue-culture phase* of manufacture. This last statement may no longer be true, because not all manufacturers have recently published details about this aspect of their production methods. If penicillin is used in the early tissue-culture stage (before the addition of seed virus), it does not have to be declared on the label of the product. Nevertheless, an unknown number of penicillin molecules could remain in the final product, but, even with the method of production which we use, most lots of the final product contain less than 0.001 unit of penicillin per milliliter (Thompson and others: *Proc. Soc. Exper. Biol. & Med.* 102:377 [Nov.]

1959). Although this amount of penicillin may represent a hazard to a few highly sensitive persons, the available data suggest that such persons are encountered extremely infrequently. I have not heard of a death due to anaphylaxis after the administration of poliomyelitis vaccine.

From a medical viewpoint, there has been good reason to be reluctant about changing to other antibiotics. During the field trials of 1954 (Francis and others: *Am. J. Pub. Health* 45:2 [May, part 2] 1955) allergic symptoms were recorded less often n children given vaccine than in those who were nerely observed (given neither vaccine nor penicillin-containing placebos). This suggests that the ncidence of allergic reactions reputedly due to poliomyelitis vaccine may approximate the prevaence of allergic symptoms occurring from multiple causes in large population groups at any one time. Under these circumstances, there is no reason to expect that a change in antibiotic would significanty alter the incidence or severity of allergic reactions.

Furthermore, many antibiotics are toxic to cells n tissue culture and will render the cells less able o support the growth of virus. If a "toxic" antibiotic were used in the vaccine, the antibiotic could damage the cells of tissue cultures used for safety testing, and, thus, live virus might not be detected n the finished vaccine. Until we at Eli Lilly and Company can complete our evaluation of all ramications of a change in our production methods, we are unwilling to make any change in the procss that might, even in theory, have an adverse earing on safety. Because this company has been he major producer of poliomyelitis vaccine, it has felt keenly the responsibility to avoid, if possible, ny interruption in supply and therefore has been onstrained not to tamper prematurely with a prouction process which we know results in a safe roduct.

Indianapolis.

THE CHRONIC ALCOHOLIC

To the Editor:—In The Journal, Dec. 26, 1959, page 299, there is an excellent article on the chronic lcoholic. Doctors Pannill and Smith pointed out he importance of providing these persons with eneral hospital care during the acute stages of heir disease and emphasized the importance of he family physician in their future care. They id not, however, emphasize one important point, which is a basic tenet of Alcoholics Anonymous. The chronic alcoholic cannot take even one drink. Some physicians and members of Alcoholics Anonymous realize this, but all physicians should be aware that chronic alcoholics should not drink any alcohol, nor should they take medicaments containing alcohol such as elixirs or tonics.

The authors mention the sober state which, in chronic alcoholism, depends on the patient's taking no alcohol whatsoever. While some chronic alcoholics can drink in moderation for a few weeks or even months, they usually lose control and revert to their former condition. Alcoholism is a disease, the cause of which is unknown, but it seems that chronic alcoholics are in some way sensitive to alcohol. It should be strongly emphasized to these patients that it is no more possible for them to drink alcohol than it is possible for a patient who is sensitive to penicillin to take that drug.

YOUNG TURKS

To the Editor:—Your editorial on "Young Turks—Old Turks" in The Journal, Dec. 12, 1959, page 2102, brings cheer to all those interested in clinical investigation, and for this we can be grateful. A couple of historical points can be questioned, however. I think it was to the Society for Experimental Biology and Medicine, and not the ASCI, that the term "Meltzer Verein" was applied—Meltzer was a founder of both. Also, I do not think the "Young Turks" revolted against the "Old." In fact, the latter encouraged the formation of the former. The term "Young Turks" was applied because at the time the newspapers were full of the so-called Young Turk movement in Turkey, and the name got to be used very loosely.

Thanks for the corrections.—Ed.

INTERMEDIUM

To the Editor—The title of an editorial in The Journal, Jan. 30, page 456, contains the word "intermedium." I am unable to find this word in my dictionary.

M. J.
New Jersey.

In my dictionary, published only a few days ago (1960), there are eight lines devoted to "intermedium." Zoologically speaking, this is "the bone or cartilage situated between the radiale and ulnare in the carpus. . . ." The definition applicable to the term in the title refers to an intervening agent or instrument, similar to the legal use of "instrument" as a document. Either you should procure a larger dictionary, or I should be content with a smaller one.—Ed.

MEDICAL FILM REVIEWS

Transperitoneal Bilateral Lymphadenectomy for Testis Tumor: 16 mm., color, sound, showing time 11 minutes. Produced in 1958 by and procurable on loan from Walter Reed Army Institute of Research, Walter Reed Army Medical Center, Washington 12, D. C.

After a discussion of various retroperitoneal approaches to this operation, the midline transperitoneal incision is demonstrated. The peritoneum is opened and organs and nodes are palpated. The transverse colon and small intestine are exteriorized and packed. Dissection is illustrated and described in detail and the nodes and spermatic vessels are removed. Closure and sutures are shown. A postoperative view of the incision shows no evidence of herniation or limitation of motion. Interest would have been added to the film if a discussion of the pathological findings on the dissected nodes had been included. This film makes good use of schematic drawings to introduce specifics of the following operation and to describe briefly the operative procedures used in surgical correction of testis tumors to this time. Close-up views during the operation permit good visualization of the procedure. The photographic quality is good except for the footage used in the introduction. It is primarily of interest to urologists and general surgeons and also recommended for residents and interns.

A New Transparent Plastic Surgical Drape: 16 mm., color, sound, showing time 17 minutes. Prepared in 1959 by William G. Pace, M.D., R. M. Zollinger, M.D., and Marjorie Reed, R.N., Columbus, Ohio. Procurable on loan from Aeroplast Corporation, 420 Dellrose Ave., Dayton 3, Ohio.

This film demonstrates and describes the use of this new type of drape for operative incisions of the abdomen, chest, extremities, and neck. The descriptions of the use of the material and the spray-on adhesive required for its application are adequate and understandable. The film illustrates and the narrator describes the various advantages obtained by the use of this material in operative surgery. One possible advantage that is not mentioned is its use to collect blood from the operative field in infants or very small children during open-heart or other types of surgery where, of necessity, a fair amount of blood loss is unavoidable. This would enable more accurate measurement and, therefore, replacement of blood loss in these patients. It would appear that this new type of drape will receive increasing usage as knowledge of its availability is increased. The exposure, illumination, and color are good to excellent at all times. The film will be of interest to interns, residents, and general surgeons.

Physical Diagnosis of the Ear, Nose and Throat: 16 mm., color, sound, showing time 28 minutes. Prepared in 1959 by William H. Saunders, M.D., Columbus, Ohio. Procurable on rental ($6) or purchase ($240.) from the Ohio State University, Department of Photography, Motion Picture Division, 1885 Neil Ave., Columbus 10.

This film shows exacting details of physical examinations of the ear, nose, and throat. There are three sections: first, the ear; second, the nose and paranasal sinuses; and third, the oral cavity, nasopharynx, larynx, and neck. At the end of the film is a short recapitulation. The film explains specific points and shows exactly how the various areas are examined. This film demonstrates procedures very well and the instrumentarium most frequently used in the examination of the ear, nose, and throat. It gives the student a view of the area examined. In general, the photography is excellent and the narration is good. Although areas and structures under examination are visible to the viewer, use of animated diagrams could have been employed to explain more fully the principles involved. Some schools may prefer minor variations in technique; however, this film will serve to give the necessary basic instruction. It is highly recommended for sophomore and junior medical students.

The Diagnosis and Treatment of Depressions in General Practice: 16 mm., black and white, sound, showing time 21 minutes. Prepared by S. Bernard Wortis, M.D., New York. Produced in 1959 by Medical Dynamics Inc., New York, for and procurable on loan from Wallace Laboratories, New Brunswick, N. J.

The author presents a clinical lecture on psychiatric depressive states interspersed with scenes purporting to show patients with various forms of these disorders. The validity of the differential diagnostic classifications may be questioned, and psychiatrists will readily detect that the rehearsed histrionics of the subjects used cannot accurately reproduce the variously strained, retarded, appealing, quasi-self-deprecating, demanding, or desperate sufferings of the truly melancholic patient. However, these minor defects do not seriously impair the usefulness of this film in reminding physicians in all specialties of the incidence and importance of depressive reactions in patients they may encounter in their daily practice. The author also furnishes good advice as to preventative measures and supplies excellent leads regarding balanced treatment by environmental support, drug administration, psychotherapy, or referral in appropriate cases. The photography and narration are good. The points are well made and the story moves on quickly. The film is recommended for teaching residents, medical students, and medical practitioners.

The Faces of Depression: A Phenomenological Approach to the Depressive Syndrome: 16 mm., black and white, sound, showing time 28 minutes. Prepared by Hans E. Lehmann, M.D., Montreal. Produced in 1959 by Robert Anderson Associates Ltd., Ottawa, for and procurable on loan from Geigy Pharmaceuticals, Professional Service Department, P. O. Box 430, Yonkers, New York.

This film presents a series of illustrations of depressed patients before, during, and after various forms of therapy. Among its merits are the following: each scene is manifestly genuine, there is no insistence on rigid classification, the author and his associates present a sympathetic mode of interviewing and a discerning commentary, and the closing scenes properly emphasize an optimistic approach to prognosis and treatment. The film may be used for psychiatric teaching, or, with appropriate explanations, for presentation to intelligent lay audiences, although here the possibility of someone recognizing the undisguised patients, though remote, would be a deterrent. The photographic quality is good. This film is recommended to general practitioners, psychiatrists, residents, and psychologists.

Vaginal Construction for Agenesis: 16 mm., color, sound, showing time 17 minutes. Produced in 1959 by and procurable on loan from Walter Reed Army Institute of Research, Walter Reed Army Medical Center, Washington 12, D. C.

The purpose of this film is to describe a technique by which a functional vagina may be constructed in a patient who has congenital absence of the vagina and uterus. It shows the preoperative studies, the plan of surgery, and the immediate and ultimate surgical result. The operation is straightforward and the technique is excellent. However, the graft is cut so thick that one year later the girl still has a noticeable scar on the inner aspect of her left thigh. The assumption can be made that a complete diagnosis of the patient's condition justified this operation. From the standpoint of technique of manufacture of an artificial vagina this film is excellent. The color is good and the sound is fair, but the photography does not have quite sufficient depth of field for adequate vaginal visualization. The film would be of primary interest to gynecologists and general surgeons and could be recommended for residents and interns.

NEW FILMS ADDED TO A. M. A. MOTION PICTURE LIBRARY

Bronchocinematography: 16 mm., black and white, sound, showing time 15 minutes. Prepared by Shogo Awataguchi, Sendai, Japan. Procurable on loan (service charge $3) from Motion Picture Library, American Medical Association, 535 N. Dearborn St., Chicago 10.

Fluorocinematography has been made a practical and valuable medical tool by the development of the image intensifier. Through its use, fluoroscopic images may be preserved for record and teaching. These points are particularly well illustrated in this film. It begins with an illustrated discussion of the instrumentarium and techniques of fluorocinematography. After this, the contrast media, equipment, and technique of bronchography are described and shown. The principle portion of the film, however, consists of bronchographic demonstrations, the recorded fluoroscopic image following the filling of various types of physiological and pathological bronchial patterns. Bronchial motility is well shown. Tubercular and bronchiectatic cavities are illustrated, and the effect of bronchial stenoses on the flow of the oily medium is shown. This type of film will certainly be improved technically as new equipment is developed. Yet the basic concepts of bronchial physiology and pathology are included. For this reason, it is of value to medical students as well as specialists in the fields of radiology and diseases of the chest.

Radiation: Physician and Patient: 16 mm., color, sound, showing time 45 minutes. Presented by the American College of Radiology in cooperation with the United States Public Health Service. Supported by a grant from the Rockefeller Foundation. Produced in 1959 by Medical Radio and Television Institute Productions, New York. Procurable on loan from Motion Picture Library, American Medical Association, 535 N. Dearborn St., Chicago 10.

This film brings together some of the nation's foremost authorities in radiation cell damage, genetics, carcinogenesis, and physics, with some well-known physicians shown in the process of referring their patients for x-ray examinations and consulting with the radiologist in a highly effective manner. The excellent photography of these authorities in their offices and laboratory environments is priceless as a record; however, at times there is too much emphasis on the individual person, which distracts from the information being conveyed. The concern and attitude of several referring physicians toward their patients present, answer, and clarify the major radiation questions of the day. Since the patients are chosen from such critical areas as pediatrics, orthopedics, and obstetrics, everyday problems are faced and analyzed. The presentation has a relaxed air which makes the patient consultations seem natural, and there is little hysteria. Anyone who uses fluoroscopy and who sees nothing wrong with the opening sequences should be compelled to see the whole film. The closing sequences will deliver a message to such a viewer which will either impress him enough to change his ways or encourage him to give up fluoroscopy. This is an important film for the nation's practicing physicians, medical teachers, and medical radiation research workers.

MEDICAL LITERATURE ABSTRACTS

INTERNAL MEDICINE

The Liver in Wilson's Disease. I. H. Scheinberg and I. Sternlieb. Gastroenterology 37:550-564 (Nov.) 1959 [Baltimore].

Confusion about the role of the liver in hepatolenticular degeneration (Wilson's disease) induced the authors to review the role of the liver in the light of recent investigations. On the basis of 74 published reports, they conclude that hepatolenticular degeneration is the result of an inherited defect in protein synthesis, which can be recognized by a deficiency of the plasma copper-protein, ceruloplasmin, and which is associated with disturbances of copper metabolism. A continued small positive copper balance apparently results in the deposition of excessive amounts of copper in the liver, brain, and other organs. Large amounts of copper can be present in the liver for a year, and probably considerably longer, without causing significant pathological changes or symptoms. Eventually, however, the liver seems to react to the deposited copper with degeneration and necrosis, which finally result in a typical clinical and pathological picture of postnecrotic cirrhosis.

Specific treatment of this hereditary hepatic disease can be directed only toward the environmental factor which probably makes it manifest—copper. A regimen may be used to prevent absorption and promote excretion of this metal. The results of such therapy in patients with already diseased livers have not been encouraging, although marked improvement in neurological symptomatology has been effected. Treatment of the postnecrotic cirrhosis itself differs little from the usual treatment of this condition. It is possible to detect asymptomatic and healthy children who will develop this disease. Treatment of such persons to prevent further copper deposition and to remove copper already deposited may be expected to prevent or delay onset of the disease.

Primary Biliary Cirrhosis (Chronic Intrahepatic Obstructive Jaundice). S. Sherlock. Gastroenterology 37:574-586 (Nov.) 1959 [Baltimore].

Sherlock points out that the association of the clinical picture of prolonged obstructive jaundice (cholestasis) without mechanical obstruction to major bile ducts is well known, having been described in 1851 by Addison and Gull and later by Hanot, Thannhauser, and Magendantz and many others. In 1950 Ahrens and co-workers reviewed the literature on the condition and described personally observed cases under the term "primary biliary cirrhosis," which Sherlock regards as an ambiguous term. The most important feature of this lesion is the disturbance of the zonal architecture of the liver by regeneration, so that each nodule is divided by short, wide venous channels (internal Eck fistulas). This is certainly not true of primary biliary cirrhosis, in which nodular regeneration is inconspicuous and disruption of the essential architecture is a very late feature. "Chronic intrahepatic obstructive jaundice" is a better term.

The author presents observations on 42 patients (36 women and 6 men, mostly middle aged or elderly), who were followed up between 1944 and 1959. The onset of the disorder was insidious, usually with pruritus coincident with, or followed by, jaundice and skin pigmentation. The liver was always enlarged; the spleen was palpable in 80% of the patients. Depth of jaundice was variable. In the most deeply jaundiced patients hepatocellular failure developed the soonest. Certain diagnosis is usually impossible without laparotomy, preferably with direct operative or postoperative cholangiography. The mean duration of the disease in 23 fatal cases was 5 years, 5 months. Hepatocellular failure was the commonest cause of death (15 patients). Xanthomas were seen in 20 patients, all of whom had high serum cholesterol values. Xanthelasma was noted in 6 patients, often with virtually normal serum cholesterol levels. Steatorrhea was in proportion to the serum bilirubin value. Bone thinning was noted in 21 of 34 patients investigated. Pain was relieved by vitamin D injections and oral administration of calcium, but bone thinning progressed.

Gastrointestinal hemorrhage occurred in 16 patients (in 9 from a peptic ulcer and in 7 from esophageal varices). In all, 13 patients had a peptic ulcer. Portal blood pressure was usually raised, but clinically significant portal hypertension was rare. The onset of hepatocellular failure was marked by deep-

The place of publication of the periodical appears in brackets preceding each abstract.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by persons in continental United States or Canada who subscribe to its scientific periodicals. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover 1956 to date for English language and 1958 to date for foreign language journals. No photoduplication services are available. No charge is made to members, but the fee for others is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

ening jaundice and falling serum albumin level with peripheral edema. Ascites was rare and terminal. Disappearance of pruritus and xanthomas and a fall in serum cholesterol and alkaline phosphatase levels foretold the end. Treatment was symptomatic. Intractable pruritus was relieved by methyltestosterone or norethandrolone, but jaundice deepened. Blood bile acid levels did not fall with relief of pruritus. Fat-soluble vitamins were given by injection, and calcium was given orally. Corticosteroid therapy proved ineffective. The etiology of the condition is obscure.

Pathogenesis of Myocardial Infarct. K. F. Feiks. Wien. Ztschr. inn. Med. 40:345-355 (Sept.) 1959 (In German) [Vienna].

The author analyzed the records of 513 patients who were admitted to a Vienna hospital on account f myocardial infarction between 1953 and 1958. There were 360 men and 153 women. The infarct vas new and extensive in 470 of the patients who vere admitted with severe symptoms during the irst 2 days of their illness. In the remaining 43 atients the infarct had been in existence for some ime, or was small. The mortality averaged 41% mong men and 49% among women. The death ate was especially high among those in whom he infarct involved the ventricular septum and n whom the electrocardiographic record indicated low healing. The mortality was also higher among atients with high blood sugar or leukocyte values; special sympathetic reactivity, rather than unusully large infarcts, seemed to be the cause of these leaths.

Autopsy was performed on all of the 224 patients vho died as the result of their infarcts. In 62 cases 28%) no thrombus could be found. While the cornary arteries of the large majority of the patients vithout thrombus showed severe atherosclerotic hanges, there were some in whom the coronary rteries were practically normal, and yet the myoardium showed large new areas of myomalacia. n this connection the author cites literature reports hich indicate that functional circulatory disturbnces may lead to the formation of areas of myoalacia. Furthermore, atherosclerotic vessels may e more sensitive to oxygen deficiency, and this reater sensitivity may be further increased by pasm.

In studying the case histories, the author oberved a high incidence of occupations of a sendenary nature. Many patients had a history of ypertension or of diabetes, but as regards cigarette moking there was no noticeable difference beween the patients with infarcts and the control roup. Few of the patients with infarcts (less than alf as many as the controls) were in the habit of aking small quantities of alcohol with their meals, ut many drank large quantities of coffee. Complete abstinence from alcohol was relatively frequent among infarct patients. Many had a second job, in addition to their main occupation. The author feels that the assumed vasodilator effects of the small amounts of alcohol are probably less important than the psychological differences between the infarct patients and controls, patients with infarcts being, on the whole, more tense than the controls. In the majority of patients the history revealed a preinfarction stage of subjective symptoms, but in about one-fourth of them the myocardial infarct occurred without any precursory symptoms of stenocardia. The patients reviewed in this group included 110 in whom the infarct was the second one, and 18 who had a third infarct. Of those with a second infarct, 58 died; thus, patients with a second infarct had a higher mortality rate. The interval between the first and second infarcts was, in most instances, less than 2 years.

The Use of a Vasopressor Agent as a Diagnostic Aid in Auscultation. L. Crevasse. Am. Heart J. 58:821-826 (Dec.) 1959 [St. Louis].

A vasopressor agent has been found useful in converting the late systolic or atypical murmur of patent ductus to the typical continuous murmur. Rapid changes in cardiac output and increases in aortic pressure can be useful in clarifying or intensifying certain murmurs. The studies aimed to determine the clinical usefulness of rapid changes in cardiac output and aortic pressure on the intensity and graphic form of the common congenital and acquired heart lesions. The following cases were included in this study: aortic stenosis (5); pulmonic stenosis (5); tetralogy of Fallot with Blalock shunt (2); atrial septal defect (4); aortic insufficiency (6); mitral stenosis (3); mitral stenosis and insufficiency (4); mitral regurgitation (8); ventricular septal defect with and without pulmonary hypertension (6); pulmonic insufficiency secondary to atrial and ventricular septal defects (5); and functional or contact murmurs (8). The changes in intensity and graphic form were recorded by a Sanborn Twin-Beam phonocardiogram before and during the height of the pressor response after the intravenous administration of 15 to 30 mg. of mephentermine (Wyamine) sulfate. This amine increases aortic pressure by increasing myocardial contractility, while exerting little influence on peripheral arteriolar resistance.

The author describes observations and graphs are reproduced which show how the equivocal or atypical murmur of mitral insufficiency becomes characteristic after the administration of Wyamine. The following points are stressed: 1. Wyamine will accentuate and bring out the graphic characteristi of the murmur of mitral insufficiency in st [illegible] in which the murmur is equivocal or aty [illegible] Increases in aortic pressure will striking [illegible] the intensity and duration of aortic insufficiency and verify its presence in suspected or atypical cases. 3. Pulmonary arterial pressure is altered only slightly in relation to increases in aortic pressure by Wyamine, and the murmur of pulmonic insufficiency remains essentially unchanged, an important feature of differentiation from aortic regurgitation. 4. By raising aortic pressure and widening the aortic-pulmonic pressure gradient, the patency of a Blalock shunt can be determined because the continuous murmur will appear. 5. Functional murmurs or contact sounds are usually unaffected in duration or graphic characteristics. 6. The systolic murmurs of aortic and pulmonic stenosis, and atrial and ventricular septal defects, were all increased in intensity because of the ionotrophic action of Wyamine, and thus provided no useful differential feature.

Study of Intestinal Involvement in Patients with Pulmonary Tuberculosis. A. B. de Pablo. Rev. clín. españ. 74:312-320 (Sept. 15) 1959 (In Spanish) [Madrid].

Two groups of tuberculous patients were studied clinically and roentgenologically in an investigation of the frequency of intestinal involvement in pulmonary tuberculosis. The first group was composed of 400 patients who had not received any streptomycin, animosalicylic acid, or isoniazid. The second group was composed of 250 patients who had previously been treated with at least 2 of these drugs. Three diagnostic categories were established: (1) intestinal tuberculosis, the patient presenting subjective intestinal symptoms together with roentgenologic signs; (2) tuberculous dyspepsia, with subjective intestinal symptoms without roentgenologic confirmation and (3) asymptomatic or silent intestinal tuberculosis, with roentgenologic manifestations but without subjective symptoms.

Roentgenologic signs of intestinal tuberculosis were found in 182 patients (45.5%) of the first group, while subjective symptoms were present in 240 (60%). According to the categories established, 116 patients received a diagnosis of intestinal tuberculosis; 124, a diagnosis of tuberculous dyspepsia; and 15, a diagnosis of asymptomatic or silent intestinal tuberculosis. One hundred forty-five patients (approximately 36%) were free from intestinal involvement. The relationship between pulmonary cavitation and intestinal involvement was studied in 235 patients. Positive roentgenologic signs were found in 159 (85%) of the 188 patients with cavitation and in only 20 (42.5%) of those without cavitation. In the second group of tuberculous patients only 7 (2.8%) presented roentgenologic signs of intestinal tuberculosis. With the exception of a girl who had a primary infection, all presented subjective symptoms, with the clinical picture of chronic tuberculosis and positive sputum culture. The author recommends that every tuberculous patient be subjected to intestinal roentgenologic study. Although the roentgenologic data cannot clarify the etiology of the involvement, they provide valuable elements for the diagnosis and consequent treatment of intestinal complications.

The Marfan Syndrome: A Study of Five Generations in a Kentucky Family. A. M. Gordon. J. Kentucky M. A. 57:1511-1517 (Dec.) 1959 [Louisville].

Marfan's syndrome, which is a rare hereditary disorder of connective tissue, was found in 6 members of a 5-generation Kentucky family. The affected members included the propositus, his father, an uncle, a brother, a cousin, and a niece. The father died at the age of 44 years of "dropsy." The uncle died at the age of 54 years of heart disease. The uncle's daughter died at the age of 32 years of heart disease. Both the father and the uncle were longilineal. The father, the uncle, and the cousin had eye discomfort all their lives.

The propositus, his brother, and the brother's daughter were examined for Marfan's syndrome. All 3 were longilineal. The brother died at the age of 37 years of dissecting aneurysm; he had ectopia lentis and severe pectus excavatum. One of his 3 daughters, aged 14 years, who is still living, has Marfan's syndrome. She is dolichocephalic, has scoliosis of the spine, and has a dislocated lens of one eye. The author believes that this girl and the propositus had the typical Marfan syndrome. The propositus died at the age of 24 years of intractable heart failure. Final anatomic diagnosis after autopsy stated: "Marfan's syndrome, chronic mitral endocarditis with calcification, hypoplasia of the ascending aorta, cardiac hypertrophy and dilatation, bilateral hydrothorax, ascites, chronic passive congestion of liver, pulmonary infarction, pleural adhesion, and phthisis bulbi, right."

North American Blastomycosis. G. L. Baum and J. Schwartz. Am. J. M. Sc. 238:661-684 (Dec.) 1959 [Philadelphia].

The pathogenesis, the clinical picture, and the treatment of North American blastomycosis, a pulmonary disease caused by Blastomyces dermatitidis, which is restricted mostly to the North American continent and which was first described by Gilchrist in 1896, are discussed. Conclusions are drawn from a review of the literature and from the authors' observations of some patients with the disease. Blastomycosis is primarily a chronic indolent active infection which rarely becomes acute and rapidly progressive. The most commonly observed clinical manifestation is the skin lesion; it may appear as a single focus of the disease or may be accompanied by many sister skin lesions in various stages of development. Finally, the skin lesions may be a part of an active disseminated disease, with simultaneous lesions of many internal organs. The one common factor in all variations of the skin manifestations of blastomycosis is that the primary lesion is in the lung and that all the lesions seen, whether localized to the skin or spread throughout the body, are metastatic. Usually, however, no involvement of the gastrointestinal tract is seen in North American blastomycosis. Pulmonary blastomycosis, despite being the primary lesion in all types of blastomycosis, is often clinically silent. There may be no obvious pulmonary focus on clinical or roentgenographic examination, or the roentgenogram may reveal a nondescript scar or thickening. The chronic form of pulmonary blastomycosis is nonspecific in clinical or roentgenographic appearance.

The pathological picture of blastomycosis combines an acute purulent reaction with a chronic granulomatous one in most of the organs in which the disease is observed. In the lung this produces a reaction which, in part, is similar to tuberculosis and the other deep fungous diseases; it also produces a response which is different from any of them. The former is the development of epithelioid-cell granulomas which, except for the presence of the specific organism, are similar in other fungous diseases. The latter is microabscess formation which is commonly found in blastomycosis but not in the other entities. This is seen in all organs and has particular expression in the skin, where the abscesses are visible and serve as sources for diagnostic material, and in the prostate, where abscess formation may lead to urinary obstruction. Caseation necrosis is a reaction not prominent in blastomycosis.

The excellent response of North American blastomycosis to amphotericin B and, in many cases, to stilbamidine and its derivatives has removed the fear of diagnosis of this disease. There is no proof of transmission of this form of blastomycosis from man to man or animal to man. In North America the disease should be suspected in all chronic pulmonary disorders of granulomatous character which are not tuberculous, histoplasmic, or of other mycotic origin. Even when tumor is suspected from roentgenograms, blastomycosis should not be counted out.

The Milk Alkali Syndrome: Case Report of Reversible Hypercalcemia, Alkalosis and Renal Insufficiency. J. F. Crenshaw and L. L. Campbell, J. M. A. Alabama 29:189-193 (Dec.) 1959 [Montgomery].

Although until 1955 only 21 cases of the syndrome of hypercalcemia and renal insufficiency secondary to prolonged excessive milk and absorbable alkali intake had been reported in the literature, more recent reports seem to indicate that this syndrome is more common than is ordinarily suspected. The authors cite the history of a 63-year-old man with a gastric ulcer, who, while ingesting standard amounts of milk and the alkali, calcium carbonate, developed the milk-alkali syndrome, characterized by hypercalcemia, alkalosis, and renal insufficiency without hypercalciuria or hypophosphatemia. There was no evidence of ocular changes or other calcinosis. After a low-calcium diet and withdrawal of the alkali, improvement was rapid and apparently complete. The intake of alkali and milk by this patient did not seem excessive, relative to the usual standards of peptic ulcer therapy. It is believed that the preexistent mild renal impairment exhibited by this patient before being placed on a strict milk-alkali program possibly influenced the development of this syndrome. The diagnosis of hyperparathyroidism was entertained, but appears untenable in view of the disappearance of the chemical abnormalities and the general well-being of the patient.

Primary Aldosteronism: A Review of Medical Literature from 1955 to June, 1958. P. Delorme and J. Genest. Canad. M. A. J. 81:893-902 (Dec. 1) 1959 [Toronto].

The authors analyze the etiological, pathological, clinical, and biochemical aspects, and the postoperative follow-up, of 31 patients with primary aldosteronism, who have been reported since Conn's first description of this condition in 1954. There were 12 men and 19 women, with ages ranging from 11 to 63 years and a peak incidence (16 patients) in the 30-to-45 age group. Pathological adrenal changes were observed in 28 patients, while renal changes were present in 16. The renal conditions were "vacuolar nephropathy" in 8 patients, arteriolar lesions in 10, nonspecific tubular lesions in 3, and pyelonephritis in 3. Arterial hypertension, headache, polyuria, polydipsia, and/or nocturia were the most frequent symptoms at the onset of the disease. Thirteen patients also had muscular weakness when admitted to the hospital. Seven developed tetany during the course of their illness. Hypopotassemia was present in all the patients. Different effects of corticotropin (ACTH) on the urinary excretion of sodium and potassium in patients with aldosteronism have been reported. Dietary changes and administration of specific drugs produce effects which have received different interpretations from different authors.

The characteristic of aldosteronism are summarized. The main cause is adrenal adenoma, although adrenal hyperplasia is more frequent in young patients. Arterial hypertension, polyuria, polydipsia, nocturia, episodes of muscular weakness or of paralysis, and, less often, tetanic crises are the main clinical features. Hypopotassemia, sometimes accompanied by hypernatremia and alkalosis, is a constant finding. Surgery is the only definitive treatment. As arterial hypertension, clinically indistinguishable from essential hypertension, may be the sole manifestation of this condition, plasma potassium determinations should be carried out in every hypertensive patient of any age. The primary importance of recognizing aldosteronism is that it belongs to the small group of causes of hypertension for which a permanent cure may be achieved by operation.

Evaluation of the Pharmacologic and Chemical Tests as an Aid to Diagnosis of Pheochromocytoma. G. M. Roth, E. V. Flock, J. L. Bollman and W. F. Kvale. Angiology 10:426-430 (Dec.) 1959 [Baltimore].

The article deals with the required precautions and encountered difficulties with the pharmacological and chemical tests for the diagnosis of pheochromocytoma. The greatest obstacle to the successful diagnosis of pheochromocytoma is previous medication. The pharmacological test for pheochromocytoma at the Mayo Clinic consists of performing the cold pressor test, followed by administration of either histamine or phentolamine (Regitine) hydrochloride. Histamine stimulates the adrenal tumor to produce the rise in blood pressure and the characteristic attacks. The histamine test is employed in patients with paroxysmal hypertension, and the Regitine test in patients with sustained hypertension. A basal blood pressure, obtained while the patient is lying comfortably for at least half an hour, is important in the interpretation of the results after the administration of histamine or Regitine. Pharmacological tests may yield false-positive results if sedatives, narcotics, and self-medication drugs are not prohibited for at least 48 hours before any test is given. Antihypertensive drugs should be withdrawn for 8 to 10 days. Regitine tests on 3 patients gave negative results while these patients were receiving antihypertensive drugs, but positive results after use of these drugs was discontinued for 8 to 10 days.

In the series studied, administration of histamine also produced increased pressor amines in the plasma and increased catecholamines in the urine. The values for pressor amines in 29 patients with pheochromocytoma ranged from 6.9 to 360 mcg. per liter of plasma. The levels of urinary catecholamines ranged from 42 to 493 mcg. per 100 ml. in 4 patients with pheochromocytoma. Vasoconstrictors, which are used locally for nasal stuffiness, produced false-positive results from chemical tests. The authors carried out 13,117 pharmacological tests on 12,007 patients, 557 tests for pressor amines on 417 patients, and tests for catecholamines on 504 patients during the past 15 years. Seventy-one pheochromocytomas have been diagnosed in 61 patients and have been successfully removed. No untoward effects have developed in connection with the pharmacological tests. The combination of pharmacological and chemical tests offers a high degree of accuracy for the diagnosis of pheochromocytoma.

Treatment of Ulcerative Colitis with Retention Enema of Prednisolone and Phthalylsulfathiazole: Preliminary Report. H. G. Mitchell. Prensa méd. argent. 46:1577-1579 (June 19) 1959. (In Spanish) [Buenos Aires].

Five patients with ulcerative colitis were treated with prednisolone tributylacetate and phthalylsulfathiazole, in the form of retention enema, for periods of 4 to 6 weeks. Two of the patients were men, and 3 were women. Symptoms common in the 5 patients were diarrhea with liquid bloody feces, abdominal pain, and loss of weight. One of the male patients and one of the female (a 26-year-old woman who was pregnant) had undergone temporary transverse colostomy and had obtained temporary relief. The enema mixture was composed of 125 mg. of prednisolone tributylacetate, 16 Gm. of phthalylsulfathiazole, and 2.40 Gm. of carboxymethylcellulose, to which 240 cc. of distilled water was added. Each patient used 30 cc. of this mixture daily, in 60 cc. of lukewarm water, for a retention enema at bedtime. By adding barium to the mixture, it was possible to ascertain radioscopically that the preparation reached the ascending colon in a variable period of time. No toxic or secondary effects were observed. Clinical improvement in 4 patients was confirmed by radiology and endoscopy. The pregnant patient was delivered at term of a healthy fetus. Only a 70-year-old woman, whose condition was critical, failed to respond to the treatment, which was interrupted at the end of 4 weeks.

SURGERY

Results of Decompression Operation for Trigeminal Neuralgia Four Years Plus After Operation. H. J. Svien and J. G. Love. J. Neurosurg. 16:653-655 (Nov.) 1959 [Chicago].

Decompression of the posterior root and gasserian ganglion of the 5th cranial nerve by the extradural procedure (Love's modification of Taarnøhj's original procedure) was performed on 100 patients at the Mayo Clinic between June, 1952, and March, 1954. The authors evaluated the results 4 years or more after the operation in 91 of the 100 patients. Of the 91 patients, 65 did not experience sensory loss after the operation, 15 had experienced subjective sensory loss after the operation, and 11 had experienced objective sensory loss after the operation. Of the 65 patients, 55 (84.6%) had recurrences of trigeminal neuralgia. Ten (66.7%) of the 15 patients in whom subjective sensory loss only was sustained had recurrences. Four (36.4%) of the 11 patients in whom objective sensory loss was present as a result of the operation had recurrences. The significantly better results obtained in the patients who sustained sensory loss because of the operation lend credence to the view that worthwhile results are obtained by means of this procedure only if the nerve is systematically traumatized to a degree sufficient to produce mild to moderate postoperative sensory loss.

Occult Cancer of Breast: Review with Special Attention to Form Primarily Manifested by Metastases to Axillary Nodes. A. Johnsen. Ugesk. læger 121:1681-1686 (Oct. 29) 1959 (In Danish) [Copenhagen].

By occult cancer of the breast the author designates histologically verified cancer of the breast which had not at any time caused manifest symptoms in the mammary gland, and he refers especially to the form primarily manifesting itself by metastases in the axilla, where the enlarged lymph nodes in the axilla are the only signs of the disease. The affected lymph nodes vary in size from small nodules to large adherent masses. If there is a lymph node tumor or other tumor in the axilla, biopsy should be performed, and if pathological examination shows cancer, the patient should be treated as one with cancer of the breast, unless primary tumors elsewhere are known. A woman is never adequately examined for cancer of the breast without thorough palpation of both axillas. The 54 cases of occult cancer of the breast reported in the literature, including the author's case, occurred in 53 women and 1 man, aged from 30 to 71 years. With 3 exceptions, the patients themselves became aware of the axillary tumor, and they came under surgical treatment relatively soon. All 54 were operated on, in practically all cases with radical mastectomy. On the whole, latent cancer of the breast has a somewhat better prognosis than the usual cancer of the mammary gland with axillary metastases.

Stroke Associated with Elongation and Kinking of the Internal Carotid Artery: Report of Three Cases Treated by Segmental Resection of the Carotid Artery. J. K. Quattlebaum Jr., E. T. Upson and R. L. Neville. Ann. Surg. 150:824-832 (Nov.) 1959 [Philadelphia].

As far as the authors could ascertain, all reported instances of obstruction to the carotid circulation have been on the basis of intimal thickening due to atherosclerotic deposits at or near the carotid bifurcation, with or without secondary thrombosis. Their 3 patients, however, had internal carotid occlusion, not secondary to intrinsic narrowing of the lumen, but due to elongation of the vessel of sufficient degree to produce narrowing by way of kinking with associated transient hemiparesis. The patients were a 69-year-old woman and 2 men, aged 75 and 68 years, respectively. One patient was treated by segmental resection of the common carotid artery with end-to-end anastomosis with a good result. The other 2 patients, because of the presence of a partially stenosing atheromatous plaque in the carotid bifurcation, were treated by resection of the carotid bifurcation with end-to-end anastomosis of the common carotid to the internal carotid artery. A fourth case of similar elongation of the carotid artery without symptoms from kinking is reported. It is felt that more cases will be forthcoming as the result of increasing angiographic investigation of the carotid artery currently in vogue. Occlusion times of 13½ minutes of the common carotid artery and of 8½ minutes and 17 minutes of the internal carotid artery were tolerated without serious ill-effects.

In each of these patients the authors were impressed with the flexibility of the arteries. Aside from the localized plaque in the carotid bifurcation in 2 cases, there was no significant sclerosis of the vessels. Obviously the process is one of elongation due to loss of elasticity. As the vessel elongates, it bends on the fixed points at the base of the skull and thoracic inlet. The ending is limited by the resistance of the fascia of the carotid sheath. It was demonstrated on the operating table in these patients that there is a much greater tendency to kinking as the head is turned toward the side of the vessel in question. This has been confirmed by arteriograms. The authors recommend local anesthesia for preliminary exploration and test periods of occlusion before proceeding to general anesthesia, with hypothermia when necessary.

Case of Conn's Syndrome. P. K. M. Barrett, J. R. Rees and D. Marrack. Brit. M. J. 2:1047-1052 (Nov. 21) 1959 [London].

The authors report on a 47-year-old woman with the syndrome of potassium depletion and hypertension due to a benign adrenocortical adenoma, first described by Conn, who named the syndrome "primary aldosteronism." The patient had recurrent attacks of severe muscular weakness and showed pronounced hypopotassemia, but without hypernatremia or alkalosis. Renal function tests showed selective impairment of urinary concentration and acidification. The abnormal renal potassium loss was readily shown, but it was uncertain whether this was due to Conn's syndrome or to potassium-losing nephritis. Renal biopsy showed slight tubular vacuolation only. The absence of pyelonephritic changes in the renal biopsy favored Conn's syndrome, but no increase in urinary aldosterone excretion was found, nor could an adrenal tumor be shown radiologically with the aid of air insufflation.

The electrolyte composition of saliva and feces was normal. The previous history of urinary infection and a culture positive on one occasion for Escherichia coli favored pyelonephritis. The response to high-potassium and low-potassium intakes was studied, and despite continued potassium supply, further potassium depletion occurred, partly explaining the marked increase in extracellular fluid volume. An excessive renal response to sodium restriction was observed. A paradoxical response to stress (such as air insufflation, start of an intercurrent infection, lumbar puncture, renal biopsy) was noted, with increased urinary sodium loss and a less constant potassium diuresis.

Because of the equivocal results, an adrenal exploration was performed on the woman. The left adrenal gland was enlarged, and, on removal, was seen to be largely replaced by a round encapsulated tumor with a striking orange color on section. Microscopic examination of the specimen revealed a benign cortical adenoma, closely resembling those reported in Conn's syndrome. The distinction between Conn's syndrome and potassium-losing nephritis may be very difficult. In patients such as this, even when renal damage is slight, the diagnosis may only be presumptive when biochemical changes other than hypopotassemia are absent, and when no evidence of an adrenal tumor or increased aldosterone production can be shown. These studies are of little value if negative, and in these circumstances the discovery of excessive sodium retention after sodium restriction, and an abnormal electrolyte excretion in response to stress, may be of help. At present the distinction from potassium-losing renal disease may be made only at operation.

Survival of Breast-Cancer Patients in Connecticut, 1935-54. S. J. Cutler, F. Ederer, M. H. Griswold and R. A. Greenberg. J. Nat. Cancer Inst. 23:1137-1156 (Nov.) 1959 [Washington, D. C.].

The authors analyzed the survival of breast-cancer patients in Connecticut over the 20-year period from 1935 to 1954. Attention was given to the stage of the cancer and to the age of the patients at the time of diagnosis and of treatment. The authors used the actuarial method. Survival was measured relative to expected survival in the general population. The 5-year relative survival rate for patients in whom breast cancer was diagnosed during the first 10-year period (1935-1944) was 50%. The mortality among the 5-year survivors was far in excess of that of the general population. The 5-year relative survival rate for patients in whom breast cancer was diagnosed during the second 10-year period (1945-1954) was 56%, but there was no evidence of improvement in the 10-year survival rates. In general, there was little variation in survival rates with regard to age of the patients, except that among those with localized lesions, women ranging in age from 75 to 84 had a somewhat more favorable survival experience than did women under 75 years of age. Among patients with regional spread, women under 35 had a lower survival rate than did older women.

Survival with regard to treatment of breast cancer is about the same in Connecticut as in several well-known treatment centers. Yet the authors feel that this stability of survival rates should not be interpreted as an indication that treatment is futile. From the fact that incidence, mortality, and survival rates have all been stable for a good many years, they infer that future improvement is more likely to result from development of new therapeutic techniques than from further refinement of current methods.

Study of the Cardioplegic Action of Potassium Ion During Normothermia and Hypothermia. A. Kaplan and B. Fisher. Ann. Surg. 150:833-840 (Nov.) 1959 [Philadelphia].

A divergence of opinion exists concerning the clinical use of potassium as a cardioplegic agent during surgical interventions on the heart. The authors began studies on the metabolism of potassium when injected as a cardioplegic agent under various conditions, such as in normothermia, hypothermia, coronary perfusion, and with the pump oxygenator. In this paper they present observations made on normothermic and hypothermic animals concerning the fate of radio potassium (K^{42}) when used for this purpose. Thirty-two mongrel dogs were divided into 3 groups, 1 normothermic and 2 hypothermic groups, one of the latter being given digitalis. Hypothermia was induced by means of a water bath at 2 C (35.6 F). The dog was removed from the bath when its temperature had reached 29 C (84.2 F), but the temperature was allowed to drift down to 25 C (77 F). The further procedure was the same in all 3 groups of dogs. After bilateral thoracotomy, the azygos vein was ligated, and both cavae prepared for venous inflow occlusion. The latter were clamped, as was the aorta, and cardiac arrest was accomplished by the injection of a solution of 25% potassium citrate (2 ml.), isotonic sodium chloride solution (18 ml.), and heparin (0.5 ml.) containing K^{42}. Because of its *half-life* (12½ hours), K^{42} was added to the solution in varying volumes, i. e., 0.02 ml. the day of arrival, 0.06 ml. the second day, and 0.1 ml. the third day. The activity of the solution to be injected was determined by placing the loaded syringe under the scintillation tube just prior to injection. If the activity was found to be reduced, more K^{42} was added to the solution.

From observations on the dogs, the authors conclude that, although large amounts of potassium will compromise the possibility of recovery, in general no uniform relationship exists between the amount of potassium injected and the reversibility of cardioplegia. Simply "washing" out potassium does not necessarily imply that normal rhythm will be resumed, for reversibility does not seem to be entirely related to the concentration of potassium in the myocardium. From its pattern of behavior it would seem that injected potassium is probably distributed into a fast elimination "compartment," from which it is easily removed during resuscitation, and a "compartment" from which there is slower elimination. Normothermic animals with potassium-induced cardiac arrest suffered a 25% mortality, in contrast to one of 70% in the hypothermic dogs. With prior digitalization of the hypothermic group, this figure was reduced to 30%.

Surgical Experiences with Tumors of the Carotid Body, Glomus Jugulare and Retroperitoneal Nonchromaffin Paraganglia. R. T. Sessions, B. McSwain, R. I. Carlson and H. W. Scott Jr. Ann. Surg. 150:808-823 (Nov.) 1959 [Philadelphia].

Neoplasms of the chemoreceptor system have been referred to as chemodectoma, nonchromaffin paraganglioma, or carotid-body tumor. The authors reviewed all tumors of the carotid body and of related structures observed at Vanderbilt University Hospital, Thayer VA Hospital, and 4 other Nashville (Tenn.) institutions. Sixteen carotid-body tumors, 4 tumors of the glomus jugulare, and 2 infradiaphragmatic nonchromaffin paragangliomas were collected over a 30-year period. Of the 16 patients with carotid-body tumors, 10 were treated by simple excision of the tumor. In 3 patients removal of the tumor involved ligation of the common, internal, and external carotid arteries, and in 2 other patients excision of the tumor necessitated ligation of the external carotid artery alone. One patient refused surgery. There was no operative mortality, but only 5 of the 15 patients operated on experienced completely uneventful postoperative courses, while the other 10 showed evidence of neurological damage. The neurological side-effects, which varied from a slight ptosis to hemiplegia and aphasia, were most marked in those patients in whom the internal and common carotid arteries were ligated. The most common mechanism of neurological impairment was operative injury to cranial and cervical sympathetic nerves, such as the vagus, hypoglossal, cervical sympathetic, glossopharyngeal, and spinal accessory nerves. While many of these palsies were transitory, 6 patients have permanent residual neurological impairment.

The anatomic situation of the glomus jugulare in the adventitia of the jugular bulb immediately beneath the floor of the middle ear leads to the development of symptoms only after the tumor erodes into the middle ear or into the cranial vault. The diagnosis of glomus jugulare tumor has been verified histologically in all 4 instances in this series. Two of these patients, both of whom complained of deafness and tinnitus on the involved side, had long histories of chronically draining ears and had previously undergone simple mastoidectomies or "polypectomies" in an effort to control the discharge. A third patient complained only of bleeding from the ear. In each case surgical manipulation of the tumor was associated with copious bleeding, which could be controlled only by packing the middle ear cavity. In the fourth patient the glomus jugulare tumor eroded into the cranial vault and gave rise to signs of brain tumor without either aural symptoms or cranial nerve palsies.

The term "nonchromaffin paraganglioma" is applied to the chemodectomas located in regions other than the head and neck. In the first of the 2 patients with nonchromaffin paraganglioma presented, masses of greatly enlarged lymph nodes were found along the aorta and the pelvic brim during laparotomy. Tissue removed for biopsy revealed clusters of cells in an alveolar arrangement surrounded by a reticulated network containing capillaries and was compatible with nonchromaffin paraganglioma. The second patient with nonchromaffin paraganglioma had a tumor in the retroperitoneal space. The history of this patient illustrates the importance of radical excisional surgery, because of the tendency to invasion and local recurrence of retroperitoneal nonchromaffin paragangliomas. The authors feel that the generally benign biological behavior of tumors of the carotid body and glomus jugulare indicates treatment by simple excision.

Surgical Treatment of Mitral Stenosis with Particular Reference to the Transventricular Approach with a Mechanical Dilator. A. Logan and R. Turner. Lancet 2:874-880 (Nov. 21) 1959 [London].

The authors comment on the difficulties with the atrial approach in the surgical treatment of mitral stenosis. As the result of failures with the atrial approach, they decided to approach the mitral valve from the ventricle and to guide the instrument into position by transatrial palpation. In 1954 one of the authors observed Dubost perform mitral valvulotomy with use of the transatrial dilator, which he had introduced because of dissatisfaction with the finger-and-knife technique. It was intended to follow his technique, and with this in view an expanding dilator was devised. This instrument was first used in a case in which digital valvulotomy had failed. The handle was found to be so shaped that the expanding head could not be directed into the mitral valve. Consequently the instrument had to be introduced through the anterior ventricular wall. The commissures were successfully divided. At first there was much doubt about the propriety of using the ventricular route when the transatrial alternative was so successful in Dubost's hands. This doubt was increased when, in the 6th case in which the transventricular route was used, death from hemorrhage followed shortly after the operation, and the source was believed to be the ventricular wound. During the next year the ventricular route was used only sporadically. When Dubost's instrument became available it was used by the transatrial route in 19 cases, but trouble from entanglement of the instrument in the chordae tendineae and the personal preference acquired for the transventricular route combined to establish the latter as the preferable approach.

The transventricular approach to the mitral valve with a mechanical dilator was adopted in 438 patients requiring valvulotomy. The use of the dilator was associated with a striking increase in the incidence of complete anterior and posterior commissural division and a decrease in incomplete division of both commissures. The operative mortality has been slightly higher (6.4% compared with 5.0%), but the conditions of more patients have been improved. Results have been good in a surprisingly high proportion of cases with heavy calcification of the valves. Death from traumatic mitral incompetence has not been more frequent than with other techniques, but with improved commissural division there has been a slightly higher incidence of postoperative systolic murmurs. What will be achieved at operation cannot be predicted from preoperative examination. In the experience of the authors, the advantages of the use of the transventricular dilator have made it a valuable addition to the techniques of mitral valvulotomy.

Transventricular Mitral Valvotomy: Report of 50 Consecutive Cases. H. B. Crum and M. J. C. Tsapogas. Lancet 2:880-883 (Nov. 21) 1959 [London].

The authors were introduced to the transventricular approach to the mitral valve by Logan in 1956, and their experience with it began in August, 1957. It had been intended to reserve the method for cases where finger-fracture of the commissure was difficult or impossible. The first results were so satisfactory, however, that the method was subsequently employed in every case. This series comprises the first 50 patients operated on by one of the authors. After the operation, patients are nursed in an oxygen tent for the first 12 hours and are allowed up on the third day, early activity being encouraged. All patients receive digitalis before and after the operation. The amount of digitalis is reduced to a suitable maintenance dose in those who are in atrial fibrillation. Patients in regular rhythm are given digitalis only for a few days after the operation.

Three deaths occurred, and the histories of these patients are reported. All 3 were poor-risk patients. Forty-four patients improved greatly, and 2 others have limited improvement; one is not substantially better because of postoperative pulmonary embolism. An impressive feature has been the excellence of the results in those patients in regular rhythm, many of whom are now fully employed in manual work, often with heart-sounds which are normal or very nearly so. Patients with preoperative atrial fibrillation and the 3 patients in whom persistent fibrillation developed after the operation have, all but one, a greatly improved exercise tolerance. There has been no falling off in the activity of those patients operated on 13 to 18 months ago. The "moderate" patients in this group are 2 of the 3 in whom fibrillation became established after the operation.

Study of Two Cases of Operation with Artificial Heart-Lung. G. N. Guastavino, J. A. Wikinski and others. Semana méd. 64:647-655 (Oct. 22) 1959 (In Spanish) [Buenos Aires].

Two patients with heart abnormalities were operated on under extracorporeal circulation, withou hypothermia. These were the first 2 cases of cardiac surgery performed with this technique in Argentina by Argentine surgeons. The apparatus used was a modified oxygenator of the Björk-Kay-Cross type Anesthesia was induced with 2.5% Pentothal and a small dose of succinylcholine. Subsequently endotracheal intubation was instituted. Arterial and venous pressures were manometrically controlled The surgical approach was through a transsterna bilateral thoracotomy, opening of the pericardium widening of the incision to the left, and exploration of the heart.

The first patient was a 14-year-old girl who had received a diagnosis of congenital heart disease and malformations. Atriotomy was performed, and the interatrial defect was found in the upper two-thirds of the septum, measuring 40 by 20 mm. A little lower and behind the septum was a second defect, measuring 10 by 5 mm. The defects and the inferior orifice were sutured. The wound was closed in planes, and bilateral pleural drainage was performed. The postoperative period was uneventful, and the recovery excellent. The second patient, a 5-year-old girl, had an interatrial communication demonstrated by oximetry and catheterization. Atriotomy was performed under extracorporeal circulation, without hypothermia. A large interatrial defect of the ostium secundum type was found, measuring 60 by 40 mm. The defect was sutured with a continuous suture, and the atrial wall was closed. After this procedure, which lasted 18 minutes, a pulmonary arteriotomy was started at 1 cm. above the origin of the valve. As the blood afflux was much larger than was expected, a retrograde digital valvulotomy was performed, and the arteriotomy was closed. When the extracorporeal circulation stopped, the heart sounds were normal. The patient woke and responded to stimuli. Approximately 30 minutes later a hemorrhage occurred, due to hypoplasia of the pulmonary artery. The patient died 7 hours after the operation. The authors believe that atriotomy under extracorporeal circulation, without hypothermia, is the procedure which allows most time and guarantees most precision in the closure of defects of the interatrial septum, especially when there are associated defects.

Corrected Transposition of the Great Vessels. J. Espino-Vela, E. S. de la Parra and G. Anselmi Ch. Arch. Inst. cardiol. Mexico 29:573-598 (Sept.-Oct.) 1959 (In Spanish) [Mexico, D. F.].

The abnormality described as corrected transposition of the great vessels raises a serious diagnostic problem, both in relation to the transposition itself and to the associated malformations which requently occur. Three cases of this transposition re reported. In one patient the diagnosis was esablished by the angiocardiographic findings; in he other 2 it was established by exploration durng surgical treatment for an associated atrial septal efect. The 3 patients had 2 anatomic traits in ommon. (1) the abnormal situation of the great essels (anterior and abdominal aorta and pulnonary artery) and (2) the normal position of the tria. The first patient, a 28-year-old woman, had een cyanotic during the first 8 months of her life. yspnea of effort started at the age of 9 years. alpitation spells of short duration, ending in preordial pain, were the main symptoms in adulthood. he roentgenographic examination revealed thorcic asymmetry, enlarged right ventricle, and small eft ventricle. The angiographic study showed that he pulmonary artery, filled with opaque substance n the first plate, started behind a clear, semilunar pace, which in subsequent plates was identified as he aorta. The diagnosis of corrected transposition f the great vessels was established, and no surgical reatment was attempted because of the possibility hat the defect might have a compensating role (a iew that the authors have abandoned).

The second patient, a 12-year-old girl, had been xamined at different ages and received different iagnoses. Phonocardiographic findings suggested ersistence of ductus arteriosus, while electrocariographic findings suggested an interatrial comnunication of the ostium primum type. At operation he aorta was found before and to the left of the ulmonary artery, which was posterior and situated to the right. The ventricle, situated to the eft, seemed to have an infundibulum. The diagosis of corrected transposition of the great vessels vas established, and the thorax was closed without losing the interatrial communication.

The third patient, a 5-year-old boy, had had narked cardiac murmurs since the age of 3 months. ulging of the precordial area, bronchitis, and crises of temporary cyanosis were his main symptoms. Auscultation and catheterization findings led to the diagnosis of interventricular communication. The patient underwent surgical treatment, during which the great vessels were found transposed. A ventriculotomy was performed, with closure of the interventricular communication. The patient died a few hours after the operation. The authors conclude that in corrected transposition of the great vessels the anatomically right ventricle, which is actually at the left, is able to function as an anatomically left ventricle. The electrocardiographic leads behave as if the ventricles were in their normal position. Because of this misleading electrocardiographic picture, the authors believe that angiocardiography is the best method for diagnosing corrected transposition of the great vessels.

Late Findings After Operations on the Adrenals. H. Eufinger and J. Alslev. Beitr. klin. Chir. 199: 129-142 (no. 2) 1959 (In German) [Munich, Germany].

The authors review operations on 31 patients who, in the course of the 14 years from 1943 to 1957, underwent 36 operations on the adrenals at the surgical clinics of the University of Kiel. Nine operations were carried out for adrenal cortical hyperfunction (Cushing's syndrome), 6 for the adrenogenital syndrome, 6 for paroxysmal hypertension, 8 for chronic hypertension, and 2 for metastasizing mammary cancer. Hyperplasia of the cortex was found in 17 patients, mostly in those with the adrenogenital syndrome or with hypertension but also in 3 of those with Cushing's syndrome. Of the other 6 patients with Cushing's syndrome, 3 had cortical adenoma, 2 had cortical carcinoma, and 1 had a cortical tumor, the histological nature of which could not be clarified. Of the patients with paroxysmal hypertension, 1 had pheochromocytoma; 2, medullary hemorrhages; 1, medullary malacia; and 1, a medullary cyst. In 3 patients, namely, in 2 with chronic hypertension and 1 with paroxysmal hypertension, the adrenals were found to be morphologically normal.

In patients with Cushing's syndrome, the existing tumor was usually extirpated, or unilateral adrenalectomy was carried out, while in patients with the adrenogenital syndrome unilateral or bilateral adrenalectomy was the rule. For paroxysmal hypertension ectomies or resections were performed, and in patients with chronic hypertension interventions on the adrenals were combined with sympathectomy. Patients with mammary cancer were subjected to bilateral adrenalectomy.

Eight of the 31 patients died after the operation, 2 of each of the following: Cushing's syndrome, paroxysmal hypertension, chronic hypertension, and metastasizing mammary carcinoma. Follow-up was possible in 21 of the 23 survivors. Lasting clinical improvement was achieved in 5 of 6 patients with Cushing's syndrome, in none of 5 with the adrenogenital syndrome, in 3 of 4 with paroxysmal hypertension, and in 2 of 6 with chronic hypertension. One patient with Cushing's syndrome and one with chronic hypertension succumbed to their primary diseases, namely, adrenocortical carcinoma and malignant nephrosclerosis, 14 months and 1 month, respectively, after the operation. One patient with the adrenogenital syndrome died in a traffic accident. One patient with chronic hypertension required permanent substitutional therapy. The authors conclude that surgical interventions on the adrenals produce satisfactory results in patients with Cushing's syndrome and in those with paroxysmal hypertension, but not in those with the adrenogenital syndrome or with chronic hypertension.

Regional Enteritis and Crohn's Disease. R. Buchberger. Beitr. klin. Chir. 199:220-236 (no. 2) 1959 (In German) [Munich, Germany].

Crohn and associates in 1932 described a chronic, ulcerating, granulomatous terminal ileitis. Later, the changes characteristic of Crohn's disease were found also in other sections of the gastrointestinal tract, and the concept of regional enteritis evolved. The morphologic concept of regional enteritis includes a series of inflammatory intestinal diseases, which have a segmental involvement. Crohn's disease is probably the most chronic and the most readily recurring form. The author reviews observations on 12 patients with Crohn's form of regional enteritis observed at the second surgical clinic of the University of Vienna between 1933 and 1957. In 11 of the patients the diagnosis was histologically verified. Ten of the patients had had symptoms for from 2 to 10 years. Seven of the patients had undergone appendectomy, one of them several years before the appearance of the symptoms of regional enteritis, but the other 6 appendectomies must be regarded as "operations in a quandary"; they were performed during regional enteritis, and the changes typical of enteritis were observed in the course of some of the operations.

Although this was not the case in the patients reviewed here, acute appendicitis may develop in the course of chronic regional enteritis, either because the enteritis spreads to the appendix or because it impairs the communication between the appendix and the cecum. External fistulas in 3 of the patients could be traced to the appendectomy. One of the patients had had an attack of paratyphoid some years before the onset of regional enteritis. Of the 2 children in the group, one had had a pelvic fracture and the other a vertebral fracture from one to several years before the onset of the regional enteritis, and in this connection the author mentions the traumatic genesis of regional enteritis. Colic-like pain in the lower abdomen was a complaint in all but 2 of the 12 patients. Difficulties with defecation, either diarrhea or constipation, were also frequent. Roentgenologic examination will reveal irregular contours, signs of papilomatous areas in the mucosa, internal fistulas, and defective peristalsis. Stenosis, combined with spasms produces in the roentgenogram "string signs" and "skip areas."

Surgical therapy is indicated only after conservative measures, particularly dietetic therapy, have failed. The primary operations carried out in 11 of the patients included typical ileocecal resection in 7, while the remaining 4 were subjected to one of the following: (1) hemicolectomy; (2) resection of the ileocecum and of a part of the small intestine; (3) resection of part of the small intestine only; and (4) ileotransversostomy. Three patients later required operations for recurrences; 2 of these patients died. Follow-up examination on 8 of the 10 survivors showed that 4 were well, but 2 others, while improved, still had chronic intestinal disturbances. While the 2 children felt well and had developed fairly normally, they still had symptoms and roentgenologic signs of enteritis, which, however, could be controlled by medical treatment.

In the last part of his paper, the author discusses observations on 11 patients with acute terminal ileitis and on 22 with postoperative enterocolitis. The regional appearance of these diseases seems to be due to a disturbance in the neurosympathetic regulation.

Malignant Melanoma: Treatment. J. L. Viaggio, D. Neustadt, R. Jufe and S. Kohan. Rev. Asoc. méd. argent. 73:424-427 (Oct.) 1959 (In Spanish) [Buenos Aires].

Eighteen patients, between the ages of 15 and 85 years, with malignant melanoma were observed. On first consultation, 9 patients had an intact tumor; 3 had an ulcerating bleeding tumor; 2 presented metastases; 1 had a cancer on the scar of a nevus, which had been surgically removed 6 years previously; 1 was blind from melanoma of the choroid; 1 had a tumor on a plaque of varicose angiodermatitis; and 1 had diffuse metastases of a primary tumor of unknown localization. Ten patients had not received any treatment; the remaining 8 had had either a partial biopsy of the melanotic lesion, economical resection with the electric knife, coagulation, or application of carbon dioxide snow. Regional metastases were observed at the first consultation in 9 patients. In one patient the metastases appeared during treatment of the local lesion, and in 7 patients the metastases had not appeared up to the present time, after a short period of observation. The treatment consisted of ample resection of the melanotic lesion and removal of the regional lymph nodes, either immediately or a few weeks after the resection of the primary lesion. In some of the patients the regional lymph nodes were normal before and for 2 years after the resection of the primary lesion. These lymph nodes were surgically removed as soon as they became enlarged. Follow-up of the patients included clinical, roentgenographic, and laboratory examinations every 2 or 3 months.

By the end of 5 years, 3 patients had disappeared from observation, but 8 patients are still living (5 without clinical symptoms and 3 with recurrence of melanoma and lymph node and visceral metastases). Six patients died of melanoma within 5 years of treatment. The authors conclude that malignant melanoma is a highly metastasizing lesion. Its malignancy depends on the size and location of the primary lesion and on the age and biological condition of the patient. The larger the primary lesion, the lower its location in the body (on the sole or in the malleolar region), and the younger the patient, the higher the degree of malignancy. Puberty and pregnancy increase the possibility of malignancy.

Temporal Lobe Tumors: Study of 100 Cases. H. N. Usarralda, E. A. Saint-Martin and others. Prensa méd. argent. 46:1376-1381 (May 29) 1959 (In Spanish) [Buenos Aires].

The authors report on 100 cases of tumors of the temporal lobe in a series of 500 intracranial tumors observed at several hospitals in Buenos Aires during a 10-year period. The patients' ages ranged from 12 to 71 years, with an average of 46. The most frequent types of tumor were glioblastoma-astroblastoma in 22 patients, heteromorphous glioblastoma in 21, meningioma in 19, and metastatic tumors in 11. The metastatic forms were secondary o bronchopulmonary carcinoma and represented 15.7% of the tumors in male patients. Malignant gangliomas represented 55% of the tumors in men and 52% of the tumors in women. The symptoms were headache in 70% of the patients, hemiparesia n 66%, and intracranial hypertension in 49%. Less frequent were mental disturbances, hemianopsia, aphasia, and epilepsy. Carotid angiography, which was performed more frequently in the last than in he first 5 years of the study, provided positive diagnosis in 35 patients. Pneumoencephalography and ventriculography were also used as diagnostic aids.

The treatment of the 100 patients was craniotomy, with an attempt at total resection; this was possible in 47 patients, whereas partial, or subotal, resection was performed on 45. There was no record of the surgical technique for the remainng 8 patients. Twenty-eight patients were alive at the time this article was written. The survivals corresponded to approximately 45% of the patients who underwent total resection and to 13% of those who underwent partial resection, whereas the operative mortality was the same for both types of operation. Forty-seven of the 72 patients who died had a malignant glioma; 10 had metastatic temporal tumors; and 1 had a sarcoma. These figures represented 80% of the malignant tumors.

Clinical Experience with Bronchogenic Carcinoma: A Review of 149 Cases. M. A. Polacek and R. K. Brown. Am. Surgeon 25:944-949 (Dec.) 1959 [Baltimore].

The authors report on 149 male patients with microscopically documented bronchogenic carcinoma, who were treated at the Veterans Administration Hospital in Denver between 1951 and 1958. Of these, 148 were followed up to the end of this period or to death. Over 85% of the patients gave a history of having smoked at least 1½ packages of cigarettes per day for 20 or more years. The findings in this series with regard to age distribution, histological patterns, location of the tumor, symptomatology, and survival rates among the patients with and without resection did not differ significantly from those of the series reported by other workers. Surgical exploration was carried out in 57 patients (38%), with definite extirpation done in 30 patients (20% of the total group). Lobectomy, with indicated dissection of mediastinal nodes, was the chosen procedure and comprised 50% of the resections. Of 52 patients who were operated on more than 30 months ago, 15 had definitive surgical resection. Six of these have lived for 30 to 81 months without evidence of recurrence, a survival rate of 11.5%. A policy which is liberal toward exploratory thoracotomy but conservative in regard to technique of resection has, in this series, given the patient the same long-term survival opportunity, with less postoperative morbidity and mortality, as have the more radical procedures now frequently employed.

Postoperative Chylothorax. W. M. Levi Jr. and E. F. Parker. Am. Surgeon 25:960-964 (Dec.) 1959 [Baltimore].

The authors report the occurrence of postoperative chylothorax in a 50-year-old man one month after a partial esophagectomy with intrathoracic esophagogastrostomy for a probably carcinomatous constricting lesion of the esophagus, and in a 5-year-old girl 5 days after obliteration of a patent ductus arteriosus. Five thoracenteses were performed because of a right-sided chylous effusion in the man; 3,500 cc., 1,150 cc., 2,800 cc., 2,200 cc., and 750 cc., respectively, of milky fluid were removed. The chylous fluid contained fat globules on microscopic examination. Its specific gravity was 1,014. The reaction was alkaline. No further thoracenteses were required. Ten thoracente were performed on the girl, and an aver 1,000 cc. of milky fluid was removed every improvement was achieved in 5 of 6 patients with Cushing's syndrome, in none of 5 with the adrenogenital syndrome, in 3 of 4 with paroxysmal hypertension, and in 2 of 6 with chronic hypertension. One patient with Cushing's syndrome and one with chronic hypertension succumbed to their primary diseases, namely, adrenocortical carcinoma and malignant nephrosclerosis, 14 months and 1 month, respectively, after the operation. One patient with the adrenogenital syndrome died in a traffic accident. One patient with chronic hypertension required permanent substitutional therapy. The authors conclude that surgical interventions on the adrenals produce satisfactory results in patients with Cushing's syndrome and in those with paroxysmal hypertension, but not in those with the adrenogenital syndrome or with chronic hypertension.

Regional Enteritis and Crohn's Disease. R. Buchberger. Beitr. klin. Chir. 199:220-236 (no. 2) 1959 (In German) [Munich, Germany].

Crohn and associates in 1932 described a chronic, ulcerating, granulomatous terminal ileitis. Later, the changes characteristic of Crohn's disease were found also in other sections of the gastrointestinal tract, and the concept of regional enteritis evolved. The morphologic concept of regional enteritis includes a series of inflammatory intestinal diseases, which have a segmental involvement. Crohn's disease is probably the most chronic and the most readily recurring form. The author reviews observations on 12 patients with Crohn's form of regional enteritis observed at the second surgical clinic of the University of Vienna between 1933 and 1957. In 11 of the patients the diagnosis was histologically verified. Ten of the patients had had symptoms for from 2 to 10 years. Seven of the patients had undergone appendectomy, one of them several years before the appearance of the symptoms of regional enteritis, but the other 6 appendectomies must be regarded as "operations in a quandary"; they were performed during regional enteritis, and the changes typical of enteritis were observed in the course of some of the operations.

Although this was not the case in the patients reviewed here, acute appendicitis may develop in the course of chronic regional enteritis, either because the enteritis spreads to the appendix or because it impairs the communication between the appendix and the cecum. External fistulas in 3 of the patients could be traced to the appendectomy. One of the patients had had an attack of paratyphoid some years before the onset of regional enteritis. Of the 2 children in the group, one had had a pelvic fracture and the other a vertebral fracture from one to several years before the onset of the regional enteritis, and in this connection the author mentions the traumatic genesis of regional enteritis. Colic-like pain in the lower abdomen was a complaint in all but 2 of the 12 patients. Difficulties with defecation, either diarrhea or constipation, were also frequent. Roentgenologic examination will reveal irregular contours, signs of papilomatous areas in the mucosa, internal fistulas, and defective peristalsis. Stenosis, combined with spasms produces in the roentgenogram "string signs" and "skip areas."

Surgical therapy is indicated only after conservative measures, particularly dietetic therapy, have failed. The primary operations carried out in 11 of the patients included typical ileocecal resection in 7, while the remaining 4 were subjected to one of the following: (1) hemicolectomy; (2) resection of the ileocecum and of a part of the small intestine; (3) resection of part of the small intestine only; and (4) ileotransversostomy. Three patients later required operations for recurrences; 2 of these patients died. Follow-up examination on 8 of the 10 survivors showed that 4 were well, but 2 others, while improved, still had chronic intestinal disturbances. While the 2 children felt well and had developed fairly normally, they still had symptoms and roentgenologic signs of enteritis, which, however, could be controlled by medical treatment.

In the last part of his paper, the author discusses observations on 11 patients with acute terminal ileitis and on 22 with postoperative enterocolitis. The regional appearance of these diseases seems to be due to a disturbance in the neurosympathetic regulation.

Malignant Melanoma: Treatment. J. L. Viaggio, D. Neustadt, R. Jufe and S. Kohan. Rev. Asoc. méd. argent. 73:424-427 (Oct.) 1959 (In Spanish) [Buenos Aires].

Eighteen patients, between the ages of 15 and 85 years, with malignant melanoma were observed. On first consultation, 9 patients had an intact tumor; 3 had an ulcerating bleeding tumor; 2 presented metastases; 1 had a cancer on the scar of a nevus, which had been surgically removed 6 years previously; 1 was blind from melanoma of the choroid; 1 had a tumor on a plaque of varicose angiodermatitis; and 1 had diffuse metastases of a primary tumor of unknown localization. Ten patients had not received any treatment; the remaining 8 had had either a partial biopsy of the melanotic lesion, economical resection with the electric knife, coagulation, or application of carbon dioxide snow. Regional metastases were observed at the first consultation in 9 patients. In one patient the metastases appeared during treatment of the local lesion, and in 7 patients the metastases had not appeared up to the present time, after a short period of observation. The treatment consisted of ample resection of the melanotic lesion and removal of the regional lymph nodes, either immediately or a few weeks after the resection of the initial surgical resection. These factors ordinarily predict an inevitably poor prognosis. Yet the patient survived 23 years after gastric resection before recurrent neoplasm about the anastomotic site made itself evident. There were additional features observed in the second surgical specimen of this patient which predicted the outcome. This time the neoplasm had changed its morphologic character from Broders class 2 to class 3, and there was permeation of gastric submucosal lymphatics to the surgical line of transection. The neoplasm found at the second surgical intervention, although considered to be a recurrence, may possibly be a second primary neoplasm occurring at the anastomotic site. The first time a progressive chronic gastritis associated with glandular metaplasia and hyperplasia began, and the second time the gastric mucosa, apart from the neoplasm, showed extensive intestinal metaplasia and adenomatous hyperplasia. This is the environment considered by many workers to be the fertile soil for formation of adenomatous polyps, as well as single and multicentric foci of carcinoma.

The numerous factors that play a role in the survival of a patient with a gastric resection for neoplasm are complex and often coexistent with many not reviewed or unknown. Recurrent or newly formed carcinoma in the gastric stump is no longer viewed as a formidable fatal experience. Some of these patients may be saved by prompt and adequate secondary surgical procedures. Early recognition of cancer in the residual gastric remnant is difficult because of the long symptomless interval and because roentgenologic diagnosis of the residual stomach pouch is often less informative. Gastroscopy studies at intervals may be indicated.

Intestinal Bleeding and Perforation Complicating Treatment with Vasoconstrictors. R. B. Brown, B. H. Rice and J. E. Szakacs. Ann. Surg. **150**:790-798 (Nov.) 1959 [Philadelphia].

The authors observed 2 unusual cases of intestinal bleeding and perforation. One was that of an 8-year-old girl in whom a large pheochromocytoma was found and was removed. The other was that of a 61-year-old man, who was operated on for aneurysm of the abdominal aorta; to counteract a precipitous drop in blood pressure, he was given large doses of Neosynephrine. Both patients died, and the postmortem examinations revealed gastrointestinal hemorrhage and perforation not associated with the common etiological factors of trauma, infection, obstruction, neoplasm, or occlusion of the larger mesenteric vessels. A proliferative and occlusive arteritis of the smaller vessels in the intestinal wall was evident. The authors raise the question as to whether these intestinal complications could be related in any way to the obvious common factor in these 2 cases, that of exposure to abnormal amounts of vasopressor substances, endogenous in one and exogenous in the other. Further investigation of this possibility was directed into 3 main channels: (1) a review of the literature to learn whether others had observed similar complications in patients with pheochromocytoma or in those who had been treated with vasopressor agents; (2) a study of clinical and pathological material in these 2 categories; and (3) an experiment to determine whether intestinal lesions can be produced in dogs by the administration of levarterenol.

While it has not been possible to prove conclusively that the intestinal hemorrhage and perforation observed in the 2 patients was due to the vasoconstrictors, it has been demonstrated that localized hemorrhages and necrotizing arteritis can be produced in the intestinal wall of dogs by the administration of levarterenol. Further experiments are being initiated to control and quantitate these preliminary observations in terms of dosage of drugs, time intervals, degree of hypertension produced, and plasma catechol amine levels. In the light of the evidence accumulated to date the authors consider gastrointestinal bleeding and perforation as potential complications of the clinical use of these drugs in high concentration and in patients with pheochromocytoma.

NEUROLOGY & PSYCHIATRY

The Electroencephalogram in Parkinson's Syndrome. A. C. England, R. S. Schwab and E. Peterson. Electroencephalog. & Clin. Neurophysiol. **11**: 723-731 (Nov.) 1959 [Montreal].

The authors found that there were increasingly more exceptions to the impression that the electroencephalogram (EEG) in patients with paralysis agitans (Parkinson's disease) is within normal limits, as more and more patients were studied at their special clinic, which is now in its 10th year. When they began to refer their patients for neurosurgical interventions, they began to look for laboratory tests that might lead to better selection of patients for surgical treatment. In 1957 they began to collect a new series of electroencephalograms of patients with paralysis agitans.

Thirty-nine of 75 patients with paralysis agitans were found to have an abnormal EEG. The abnormality was usually a random, diffuse, slow activity in the theta and delta range, most often restricted to the posterior portion of the head, occasionally dominant on one side or less commonly restricted to one side. There was no obvious correlation with the clinical diagnoses of postencephalitic, arteriosclerotic, or idiopathic types of paralysis agitans. The authors found this clinical subclassification of very limited usefulness. Abnormalities in the EEG were not related to the age of the patients or to the duration of the disease. They days. Observations on the thoracentesis fluid included: specific gravity, 1,010; serum lipids, 9,113 mg. per 100 cc.; cholesterol, 125 mg. per 100 cc.; total proteins, 1.09 Gm. per 100 cc. On the 28th postoperative day, the patient underwent thoracotomy through the previous incision; 800 cc. of chyle was present in the left pleural cavity. On opening the chest and retracting the lung, chyle was visible, leaking from a defect in the mediastinal pleura, about 3 cm. distal to the aortic end of the divided ductus arteriosus. The mediastinal pleura was reopened in this area. The thoracic duct was dissected. A small defect in the duct was found, from which chyle emerged. The duct was divided at the site of the defect, and its proximal and distal ends were ligated with silk. The chest was closed with drainage, and the child made an uneventful recovery.

Chylothorax is the presence of chyle in the pleural cavity, secondary to a loss in continuity of the thoracic duct, at a level above the aortic hiatus, with a fistula into the pleural cavity. Twenty-two cases of chylothorax occurring in patients after cardiovascular and other intrathoracic operations were collected from the literature. Eight of these 22 patients required reoperation and were treated successfully by ligation of the thoracic duct. Of the authors' 2 patients, one required reoperation and was treated successfully by ligation of the thoracic duct, while the other recovered with conservative treatment.

Antrectomy with Vagectomy for Chronic Duodenal Ulcer. L. T. Palumbo, W. S. Sharpe, D. J. Lulu and others. Surgery 46:1005-1011 (Dec.) 1959 [St. Louis].

The authors report on 115 consecutive male patients, between the ages of 24 and 71 years, who underwent antrectomy with bilateral infradiaphragmatic vagus resection for chronic duodenal ulcer at the Veterans Administration Hospital in Des Moines, Iowa, between 1957 and 1959. There was one postoperative death (0.87%), which was due to an acute necrotizing pancreatitis. No deaths occurred in 23 patients (22%) on whom the operation was performed as an emergency procedure during the time of continued and/or massive bleeding. On 85% of the patients the operation was performed by the senior house officers under the direct supervision of the full-time surgical staff. The operating time required was at least one-half of that of a partial gastrectomy with or without a vagus resection. The hospital stay was shortened by 2½ days, as compared with that required for other surgical procedures formerly used by the authors for chronic duodenal ulcer. Achlorhydria has persisted in 75 patients for 12 to 18 months postoperatively, and it is unlikely that a recurrent or marginal ulcer will develop in this group of patients. All patients gained weight after the operation. Ninety-five per cent of the patients maintained themselves on 3 meals a day with an occasional snack between meals, without any major restrictions in dietary measures. Diarrhea and the dumping syndrome were infrequent and were not seriously handicapping any patient. The over-all evaluation of the results in the 115 patients was considered excellent to good in 94% of them.

Antrectomy with bilateral infradiaphragmatic vagus resection is at present the authors' operation of choice for chronic duodenal ulcer. Its advantages include lower morbidity and mortality, more rapid rehabilitation, less side-effects, shorter operating time and hospital stay, least chance, if any, for recurrent or marginal ulcer formation, and over-all results superior to practically all other operative procedures.

Factors in Long-Term Survival of Carcinoma of the Stomach: Two Case Reports of 21- and 23-Year Survival. L. Sperling and L. Kaplan. Am. Surgeon 25:976-985 (Dec.) 1959 [Baltimore].

The authors report on a 54-year-old woman and a 75-year-old man, both of whom had undergone subtotal gastric resection for carcinoma of the stomach 21 and 23 years previously. On reexamination, the woman was well and free of symptoms; there was no evidence of recurrent carcinoma. The man, however, complained of a 30-lb. (13.6-kg.) loss of weight in 3 months, anorexia, postprandial distress, and progressive weakness. There was a suggestive mass in the left upper quadrant of the abdomen. Surgical exploration revealed an indurated mass at the site of the previous retrocolic gastrojejunostomy. The stomal mass, one-half of the remaining stomach, and both the efferent and afferent loops of the jejunum were resected along with the adjacent jejunal mesentery. The old duodenal stump was exposed, and a Billroth 1 gastroduodenostomy was made. The gastric malignancy observed in the operative specimen, despite slight morphologic differences, was sufficiently similar to that observed 23 years ago to suggest relatedness, and the localization to the gastrojejunostomy stoma and adjacent tissue strangely suggested a much delayed recurrence. One year after the second operation the patient was still feeling good, despite the palliative nature of the resection.

The survival of the woman appeared to be the function of the presence of a stage 1, fungating, polypoid, exophytic, antral adenocarcinoma, which was within the lines of transection surgically, had not extended to serosa or neighboring tissues, and had not metastasized to the lymph nodes. In the man, the initial operative specimen revealed a stage 3, large crater-forming, ulcerating, elevated, antral adenocarcinoma, which had extended to serosa, omentum, and mesentery, and had metastasized to regional lymph nodes by the time of the

Among the 600 children of group 2, the prematurely born children were found to come from a poorer socioeconomic background than the mature controls. When the premature infants were matched for sex, family placing, and social background with children mature at birth, it was found that there was no difference in subsequent mental development between those premature infants who weighed more than 4½ lb. at birth and the control group. Among the children with a birth weight of 4½ lb. or less, there was an increasing proportion of dull, retarded, and grossly defective children as birth weight decreased. When the mothers of handicapped children were compared with those of infants of like birth weight but without handicap, and with those of mature controls, the following factors appeared to be of importance in the handicapped group: 1. There was an excessive number of older mothers. 2. The incidence of poverty was strikingly high. 3. There were higher incidences of previous and subsequent abnormal pregnancies and of relative infertility.

The Outcome of Pregnancy in Diabetic Women: I. Fetal Wastage, Mortality, and Morbidity in the Offspring of Diabetic and Normal Control Mothers. A. Dekaban and R. Baird. J. Pediat. 55:563-576 (Nov.) 1959 [St. Louis].

The 48 diabetic women investigated were selected from a number of hospitals on the basis of 2 criteria: 1. The women were under 43 years of age. 2. They had had at least 2 pregnancies after the diagnosis of diabetes had been established. The authors interviewed all the mothers and personally examined most of their offspring. When no personal contact with the children was possible, a medical report from the family or school physician was obtained. A control mother for each diabetic mother was chosen from the same hospital in which the diabetic subject had had her last delivery. All terminations of pregnancy before 26 weeks were classified as abortion. All deaths within 4 weeks from birth were classified as neonatal death. The surviving offspring was regarded as abnormal if there was a severe congenital malformation or an intellectual or neurological deficiency interfering seriously with the spontaneous activities appropriate to the child's age. Of the 48 diabetic mothers, 9 had a mild degree of the disease, i. e., they required only a diet, or a diet plus a daily insulin dose not higher than 20 units; 22 had moderate diabetes (requirement of a diet plus a daily insulin dose of 20 to 40 units); and 17 had severe diabetes (diet plus an insulin requirement of more than 40 units daily).

There were 157 pregnancies among the 48 diabetic mothers. Their outcome was abortion in 47 (29.9%), stillbirth in 18 (11.5%), neonatal death in 13 (8.3%), surviving abnormal child in 6 (3.8%), and surviving normal offspring in 73 (46.5%). There were 78 pregnancies among the same women during their prediabetic stage, with the following outcome: 16 abortions (20.5%), 4 stillbirths (5.1%), 1 neonatal death (1.3%), 2 abnormal (2.6%) and 55 (70.5%) normal surviving children. Among the 48 normal controls there were 249 pregnancies with the following outcome: 31 abortions (12.4%), 3 stillbirths (1.2%), 9 neonatal deaths (3.6%), 1 surviving abnormal child (0.4%), and 205 surviving normal children (82.3%). The total pregnancy wastage in the sample of diabetic mothers was 49.5%—3 times higher than the wastage rate (17.2%) in the sample of normal matched controls. The total wastage of pregnancy during the prediabetic stage was 26.9%, which is higher than in the normal controls but much lower than in the diabetic stage. There was no significant difference associated with the degree of diabetes, or with the occurrence of complications during the pregnancy.

Significant differences were found in association with adequate control of the diabetes at the time of delivery, and with the type of delivery. In the group of 39 deliveries carried out by cesarean section or after induction, the total incidence of stillbirths, neonatal deaths, and live abnormal offspring was 20.6%, whereas in the group of spontaneous deliveries this incidence was of 40.8%. This difference suggests that the outcome of pregnancy was more satisfactory when the delivery took place 2 or 4 weeks before term, by means of cesarean section or after induction. There were 6 surviving abnormal children in the sample of 157 pregnancies of diabetic women, while in the control sample of 249 pregnancies there was one only. The difference in percentages (7.6 and 0.4%, respectively) is significant at $p < 0.01$. The abnormalities in these children included mental deficiency, congenital malformations, birth injury, and epilepsy.

The Outcome of Pregnancy in Diabetic Women: II. Analysis of Clinical Abnormalities and Pathologic Lesions in Offspring of Diabetic Mothers. A. S. Dekaban. J. Pediat. 55:767-776 (Dec.) 1959 [St. Louis].

The author analyzes the factors involved in the stillbirths, neonatal deaths, and live abnormal offspring of 48 diabetic mothers who were investigated in part 1 of this study. Autopsy was performed on the 18 stillborn infants in this sample and on 11 of the 13 infants who died during the neonatal period. Follow-up studies were made of the 6 live abnormal children. The findings were grouped into 5 main categories: (1) stillbirths without evident major lesions, although some infants were edematous; (2) pulmonary hyaline membrane disease; (3) congenital malformations; (4) birth injuries; and (5) mental deficiency.

were most closely related to the existence of those phenomena of paralysis agitans entitled "akinetic," and their appearance was an unfavorable sign for basal ganglion neurolytic surgery, as well as for improvement by the commonly used medications.

The preliminary observations from depth recording, in connection with surgery in paralysis agitans on the globus pallidus and related structures, appeared unfruitful, as they disclosed nothing that could be distinguished as a source of either tremor or rigidity. The postoperative records, in contrast, demonstrated that a permanent focal slow-wave focus is usually produced by destructive operations on the basal ganglions.

Electrocardiographic Changes in Poliomyelitis Patients. R. T. McReynolds and O. L. Huddleston. Arch. Phys. Med. 40:489-491 (Nov.) 1959 [Chicago].

Electrocardiographic studies were made on 70 patients with poliomyelitis, who were severely paralyzed with either the spinal or the bulbospinal type. Four of the patients had severe respiratory paralysis and required the use of the respirator for a period of 5 to 15 months. Six patients showed electrocardiographic changes indicating myocardial involvement, and these changes persisted for a period of 7 to 12 months after the onset of poliomyelitis. None of the patients gave any history of rheumatic fever or heart disease prior to the onset of poliomyelitis. Only 4 of the 70 patients were children; the ages of the adults ranged from 25 to 45 years. The most common abnormalities noted were found in the T waves (low isoelectric or inverted in leads 2 to 6), depression of or abnormal S-T segments, and abnormalities of the QRS complex. The abnormalities are regarded as possibly permanent in nature. This interpretation, however, is to be checked in most of these patients after an interval of more than 5 years.

Some Evidence of a Relationship Between Hodgkin's Disease and Intelligence. L. LeShan, S. Marvin and O. Lyerly. A. M. A. Arch. Gen. Psychiat. 1:477-479 (Nov.) 1959 [Chicago].

It has been a recurring impression that patients with a diagnosis of Hodgkin's disease seem to be of more than average intelligence. However, no objective data on a representative group of patients have been reported in the literature. With this in mind, 408 partial or complete clinical records of Army personnel who had received the diagnosis of Hodgkin's disease during the period 1942-1945 were studied for evidence of the general intelligence level of this group. The mean Army General Classification Test (AGCT) score for 97 white enlisted men, whose cases were diagnosed as Hodgkin's disease during World War II, was found to be significantly higher than that for the Army population mean. In 209 cases of Hodgkin's disease among white male enlisted men, the greater proportion of prewar occupations was found to be in those occupational groups whose median AGCT scores were highest. The data yielded no significant relationship between AGCT scores and severity of the disease, as indicated by duration or histological type. The authors offer no interpretations or attempts to account for these findings.

Urinary Excretion of Phenolic Acids by Normal and Schizophrenic Male Patients. J. D. Mann and E. H. LaBrosse. A. M. A. Arch. Gen. Psychiat. 1:547-551 (Nov.) 1959 [Chicago].

The urinary excretion of phenolic acids by male schizophrenic patients and normal male subjects while on a supposedly uniform diet was investigated. A statistically significant difference between the 2 groups was found for 4 phenolic acids. Since these same compounds had been reported as metabolic products of substances present in coffee, a careful examination of the coffee-drinking habits of the subjects under study was made. The excretion of these 4 compounds and 2 others, in addition, was found to correlate at a highly significant level with coffee drinking. The authors feel that this finding emphasizes the importance of a careful search for uncontrolled variables when metabolic differences are found between schizophrenic patients and normal controls, and the high sensitivity of paper chromatographic methods to certain dietary variables.

PEDIATRICS

Physical and Mental Handicap in the Prematurely Born. C. M. Drillien. J. Obst. & Gynaec. Brit. Emp. 66:721-728 (Oct.) 1959 [London].

The data presented were obtained from 2 groups of children: Group 1 consisted of 92 children, born between 1948 and 1959, whose weight at birth was 3 lb. (1,361 Gm.) or less, and group 2 consisted of 600 children, born between 1953 and 1955, approximately two-thirds weighing 5½ lb. (2,495 Gm.) or less at birth, and one-third being mature controls. Of the prematurely born, about one-half weighed 4½ lb. 2,041 Gm.) or less at birth. These children have been seen at regular intervals since birth. A study of the later development of the 92 prematurely born children in group 1 revealed that the majority were considerably retarded in weight and to a less extent in height; only 11% were at, or above, the expected weight for their age. Fourteen per cent had an estimated IQ of less than 70 and will need special schooling; 49% with an IQ of between 70 and 85 were considered very dull; only 13% were considered average or above average in intelligence. Twenty-two per cent of the children in group 1 have a major physical handicap.

Oestrogen and Psychosexual Disorders. L. H. Whitaker. M. J. Australia. 2:547-549 (Oct. 17) 1959 [Sydney].

It has been routine surgical practice to administer preoperatively large doses of estrogen to adult males who are to be circumcized. This is done with a view to inhibiting the erectile mechanism for some time after operation, so that healing will not be impaired by the occurrence of spontaneous erections. When estrogen has been administered to prevent orchitis after infective parotitis, men so treated reported impotence for some weeks after such treatment. These observations suggested that estrogen might inhibit male sexuality at psychological and physiological levels, and that, if this were true, it might be useful in the treatment of the paraphilias, the more so since reports indicate that castration and irradiation of the testes are not dependable methods of treatment.

The author presents observations on 26 patients who were treated with estrogen. This group included 9 patients with facultative homosexuality, 7 true constitutional homosexuals, 5 with abnormally powerful heterosexual drive, 2 exhibitionists, and 3 with miscellaneous disorders. In 18 cases in which it was desired to inhibit completely sexual desire and the erectile mechanism, it was decided to administer daily 5 mg. of Stilbestrol by mouth for 2 weeks. The shortest period of complete inhibition was 6 weeks, while the longest was 6 months. In 8 cases in which it was desired merely to reduce the intensity of libidinal drive to a controllable level, 1 mg. of Stilbestrol was given daily until the patient first noticed a reduction in his drive. With one exception, oral administration of estrogen to 26 patients presenting with a variety of psychosexual disorders produced the anticipated effects. This form of treatment controls, but does not cure, the deviation of aim or object of the sexual drive. Treatment must be repeated at intervals if it is to be effective.

THERAPEUTICS

The Antineoplastic Effect of a Cyclic Phosphamide Ester of Nitrogen Mustard (Endoxan, or B 518): Clinical Experience. S. Di Pietro. Minerva med. 50:3450-3454 (Oct. 27) 1959 (In Italian) [Turin, Italy].

The author reports the effect of a new antineoplastic drug, cyclophosphamide (Endoxan [B 518]), on 36 patients, 11 with malignant lymphogranuloma, 5 with lymphosarcoma, 7 with reticulosarcoma, 7 with nondifferentiated carcinoma, 4 with sarcoma, and 2 with melanoblastoma. The total dose given intravenously amounted to 4 Gm. The maintenance dose amounted to 50 to 100 mg. per day by mouth or, when given intravenously, to 200 mg. once or twice per week. The drug was well tolerated by most patients, but one patient vomited, and 3 women suffered a temporary loss of hair. The average leukocyte count in 30 patients was 4,000 per cubic millimeter; the leukocyte count remained above 5,000 in 14 patients, was below 5,000 in 14, and was 3,000 in 2. The lowest leukocyte count was observed after 7 days of treatment in 1 patient, after 15 days in 3 patients, after 20 days in 6, after 15 and 20 days in 2, after 15 and 25 days in 2, and after 80 days in 1. The erythrocyte count of 30 patients remained stationary after the treatment in 6 patients, but it increased in 4 and declined in the remaining 20.

The best effect of Endoxan was obtained in those forms of neoplasm most sensitive to antimitotic drugs and especially to nitrogen mustard. Satisfactory results were obtained in the patients with malignant lymphogranuloma; good results were obtained in 2 patients with lymphosarcoma; and very good results were obtained in the patients with reticulosarcoma. In carcinoma, sarcoma, and melanoblastoma, Endoxan had an effect in more than one patient superior to the effect obtained with other drugs. The results in these patients, however, were partial and did not last long. Remission of from 5 to 9 months was observed in patients with lymphogranuloma, lymphosarcoma, and reticulosarcoma. Remission lasted longer in the patients who received a maintenance dose.

The author believes that, because of its low toxicity and the good tolerance shown by most patients, Endoxan may be employed in combination with roentgen-ray treatment. Roentgen-ray treatment, begun shortly after treatment with Endoxan in 5 patients with lymphogranuloma, in 3 with lymphosarcoma, in 1 with reticulosarcoma, and in 1 with round-cell sarcoma, was very effective in inducing a complete regression of the neoplastic masses which had already been partially reduced by Endoxan. The effect of combined treatment with Endoxan and roentgen rays on the hemopoiesis was similar to that observed in patients treated with roentgen-ray therapy alone.

Clinical Observations on a New Oral Diuretic: Chlorothiazide. E. Dispensa and M. Cagnacci. Policlinico (sez. med.) 66:402-421 (Oct.) 1959 (In Italian) [Rome].

The authors report on the effect of chlorothiazide, a new diuretic, on 67 patients, 46 with chronic cardiac insufficiency, 9 with cirrhosis of the liver, and 12 with chronic nephritis; all of them had pronounced edema and marked oliguria. Chlorothiazide was administered orally in a dose of 2 Gm. per day, divided into 4 daily subdoses of 500 mg.

The cause of the increased rate of stillbirths in diabetic mothers is still unknown. Serious disturbances in tissue respiration and electrolyte and hormonal imbalance are the most accepted factors. Pulmonary hyaline membrane disease was diagnosed in 8 of the 11 infants who died during the neonatal period. Six malformations were found in this series, namely, 2 skeletal anomalies in the form of aplasia and dysgenesis; 2 congenital heart abnormalities; 1 microphthalmia with hypoplasia of the retina and of the optic nerve; and 1 communicating hydrocephalus which became apparent at 6 weeks of age. With the exception of the latter, embryonal development must have been disturbed before the 10th week of pregnancy. Although the immediate cause of these congenital malformations is still undemonstrated, hypoglycemia, ketosis, and hormonal disturbances can be suspected. Birth injuries of a mechanical type were present in 3 offspring. The first was a stillborn infant with massive cerebral hemorrhage; the second died within 15 minutes after the birth; and the third had brachial plexus palsy and epilepsy. The oversize of children of diabetic mothers who are delivered spontaneously at term is probably a factor in the occurrence of these injuries. Mental deficiency was the only major abnormality in 2 of the 6 surviving abnormal children studied. No specific underlying lesion could be demonstrated in them.

Disseminated Herpes Simplex in the Newborn. T. Bird and P. S. Gardner. Brit. M. J. 2:993-996 (Nov. 14) 1959 [London].

Herpes simplex virus may produce in children with eczema a severe generalized infection called Kaposi's varicelliform eruption or eczema herpeticum. At first this was thought to be only an involvement of the skin, but widespread concomitant visceral lesions have since been described. Another severe form of disseminated visceral herpes occurs in the absence of eczema; this was first reported from the United States in 1951-1952, and thereafter in England and Australia. The postmortem and histological appearances are fairly characteristic, but establishment of the diagnosis depends on the isolation of the virus. This has been accomplished in only a few cases.

The patient presented was a male infant who had been born at term. He never cried or moved much and ate poorly. The abdomen was noticed to be rather full during the third week, and on the day of admission to hospital, at 21 days, he became suddenly pale and collapsed, with rolling eyes and continuous moaning, but no convulsions. He was pale and thin, with involuntary writhing movements of the limbs. There were a large left parieto-occipital cephalhematoma and a small blister on the back. The abdomen was distended; the liver and spleen were enlarged. No abnormality was found in the chest, but breathing appeared to be embarrassed by the large liver. The infant died 3 hours after admission. The clinical diagnosis was cirrhosis, probably due to reticuloendotheliosis or a storage disease. Characteristic focal lesions were found in the liver and adrenals, but intranuclear inclusions were scanty. The diagnosis of disseminated herpes simplex was definitely established by the isolation of the virus from the liver in tissue culture.

ENDOCRINOLOGY

Cushing's Syndrome Due to Adrenocortical Carcinoma in a 34-Month-Old Girl: Clinical, Laboratory, and Anatomicopathological Study of a Case: Review of Literature. J. M. Cerviño, A. Navarro J. A. Folle and others. An. Fac. med. Montevideo 44:36-52 (Jan.-April) 1959 (In Spanish) [Montevideo Uruguay].

Although adrenal cortical hyperfunction (Cushing's syndrome) is rare in children, it occurs more frequently among girls than among boys. In the cases previously reported the syndrome was caused by an adrenocortical carcinoma. Of the 18 cases reported in the literature, 13 were those of children between the ages of 2 and 13 years and were those of infants between the ages of 3 and 10 months. The tumor probably developed during the fetal life. The subject of this report was a twin girl, born at the 8th delivery to a normal multipara. The patient was observed for the first time at the age of 23 months with the Cushing syndrome completely developed. Her parents, brothers, and sisters, including the twin sister, were normal, but an older sister had died at the age of 15 months with this syndrome. The maternal grandmother had goiter and hyperthyroidism.

Diagnosis of a malignant adrenocortical tumor was made on the basis of the typical symptoms the age of the patient, the high values of ketosteroids and gonadotropins in the urine, and the positive Allen, Hayward, and Pinto tests. The metabolic changes consisted of hyperlipemia, hypercholesterolemia, hyperglobulinemia, and hypocalcemia, as well as increased alkaline reserve and pathological curves of glycemia and polyuria. Death occurred at the age of 34 months from cardiac insufficiency and hypertension. Autopsy showed right adreno cortical carcinoma, necrosis and suppuration of the left adrenocortical tissue, and metastases into the left lung and the liver. There was hyalinization of the basophilic cells of the hypophysis, angiosclerosis and calcification of the renal tubules, serofibrinous pleurisy, hypertrophy of the heart, passive pulmonary congestion, diffuse osteoporosis, and diffuse adipose tissue.

to reproduce the miliary pattern exactly by roentgenography of a whole-lung section after inflation and fixation. The authors feel that mitral pulmonary hemosiderosis, seen roentgenologically, is no contraindication to mitral valvotomy. Successful valvotomy may be followed by gradual disappearance of the miliary infiltration.

Cancer Cells in the Circulating Blood. R. A. Malmgren and J. F. Potter. South. M. J. 52:1359-1362 (Nov.) 1959 [Birmingham, Ala.].

Cytological evaluation of cancer cells was made in 183 blood specimens obtained from 121 patients with various types of cancer, 20 ml. of blood being collected from the antecubital vein in all the patients, and, in addition, 10 ml. of blood being drawn from the vein draining the tumor site in the patients who were operated on. When the cancer types in which there were enough cases to warrant analysis were studied, i. e., 13 patients with carcinoma of the breast, 17 with melanoma, 16 with choriocarcinoma, and 12 with connective tissue sarcoma, cancer cells were demonstrated in the blood of 20 to 39% of these 58 patients, as compared with cancer cells found in an average of 28% of the total series. It is of interest that there were relatively few positive cytological findings in the blood of patients with cancer of the kidney, thyroid, lung, and of unknown localization. The percentage of tumor cells was higher in the blood draining the tumor site (55%) than in the blood from the antecubital vein (24%). Single cancer cells were also more numerous in the blood draining the tumor site than in the peripheral blood. These cells were more often present in the peripheral blood of a patient in whom cancer cells had previously been found than in that of one in whom no cancer cells had been previously demonstrated. No tumor cells were found in the blood of several patients with metastases, but a large number of cancer cells were found in the blood of some patients without any clinical evidence of metastasis. In some blood specimens the cancer cells were in groups and appeared cytologically undifferentiated. The relationship of the circulating cancer cells in the blood to the ultimate course of the disease in a given patient is not known.

Liver Cell Necrosis in Chlorpromazine Jaundice (Allergic Cholangitis): A Serial Study of Twenty-Six Needle Biopsy Specimens in Nine Patients. S. Zelman. Am. J. Med. 27:708-728 (Nov.) 1959 [New York].

The course of jaundice induced by the administration of chlorpromazine was observed during periods which varied from 43 days to more than 3 years in 9 patients of a psychiatric hospital. There were 7 men and 2 women whose ages ranged from 28 to 69 years. Peripheral blood eosinophilia was observed in 7 patients. The serum total bilirubin was elevated in all 9, the peak values varying from 1.9 to 25.3 mg. per 100 cc. The serum alkaline phosphatase reached its peak value at the time of the peak serum bilirubin, or within 11 days thereafter. Rises in the total lipids were observed in the 4 patients for whom this determination was available. The serum glutamic pyruvic transaminase was determined in 6 patients and was elevated in all of them. The serum glutamic oxalacetic transaminase was elevated in 4 of these and remained normal in 2. Liver enlargement was detected by palpation or by roentgenologic examination.

A total of 26 needle aspiration biopsies were performed, varying from 1 to 5 specimens per patient. Cholestasis was apparent in the earliest specimens as granules of bile pigment within cytoplasms of the centrolobular liver cells; later specimens showed distended canaliculi containing large, deeply stained masses of pigment. Some degree of portal fibrosis was found as early as the 25th day of illness and as late as 16 months after the onset. Unicellular liver-cell necrosis was found in significant extent in all 9 patients. Regeneration of liver cells was evident in the centrolobular zones of all the patients, while necrosis of interlobular bile ducts occurred in 2. The findings suggest that necrosis of liver cells (hepatitis) may play a more important role in the causation of chlorpromazine jaundice than is generally recognized. The disease is of prolonged duration histologically, although it has a transitory symptomatology. This duration is reflected in the laboratory measurements, particularly in the serum alkaline phosphatase and often in persisting eosinophilia. There was no evidence of the development of permanent residual damage or fibrosis in the liver in any of the 9 patients reported, although a transient portal fibrosis was observed after resolution of the portal infiltration. The necrosis and subsequent regeneration observed in 2 patients suggest the extension of a destructive process ordinarily limited to the intralobular cholangioles.

PHYSIOLOGY

A Study on the Possible Bronchodilating Effect of Corticotropin (ACTH) in the Therapy of Bronchial Asthma. E. Cerchiai. Minerva med. 50:3078-3084 (Sept. 29) 1959 (In Italian) [Turin, Italy].

The author reports an experimental study on the possible direct effect of corticotropin (ACTH) on the bronchial muscles of the isolated lungs of guinea pigs. The results of this study seem to warrant the hypothesis that the antiasthmatic effect of corticotropin may occur through a direct, pharmacodynamic effect of corticotropin itself, with the need of no other mediating factors, this every 6 hours, in 8-to-15-day cycles repeated at intervals of 5 to 6 days. The drug was administered in 4-to-5-day cycles in some patients, and in cycles of up to 20 days each in others. Diuresis was observed after 48 hours of treatment in 42 of the 46 patients with cardiac insufficiency. A direct relationship between the increased output of urine and absorption of the edema was noticed. The drug had no effect on the remaining 4 patients, who presented heart decompensation complicated by infection and who died. An increase in the elimination of chlorine, of sodium especially in patients with anasarca, and of potassium was observed. Chloremia, sodemia, and potassemia declined a few days after the beginning of treatment. Chlorothiazide had no effect on the function of the kidney or on the blood bicarbonate of the patients with heart disease.

One of the 12 patients with nephrosis presented increased albuminuria; the others presented moderate albuminuria and a marked water salt retention. Two patients suffered from hyposthenuria, and 2 from isosthenuria. Chlorothiazide was always followed by diuresis and increase in the quantity of sodium, potassium, and chlorine excreted. The effect of the drug, however, in these patients was not as marked and as constant as the effect obtained in patients with heart disease. The best results were obtained in patients with chronic nephritis who also presented cardiac complications. Arterial pressure fell in these patients.

The administration of chlorothiazide was followed by an increase in the excretion of water and cations and a slower formation of ascites in the patients with cirrhosis of the liver. A marked potassium excretion was a characteristic effect of the drug in this last group of patients, some of whom received the drug for periods of up to 20 consecutive days. A decline in sodemia and potassemia was observed only 7 to 10 days after the beginning of treatment. The drug was well tolerated by all the patients, and no relevant side-effect derived from its administration. Stranguria, which was observed after some days of treatment in a few patients, disappeared as soon as the drug was withdrawn. Chlorothiazide causes a fall in arterial pressure, but it also potentiates markedly the effect of ganglionoplegic drugs, and especially of mecamylamine which cannot be given in large quantities because it may cause serious side-effects. The mechanism by which chlorothiazide potentiates the effect of mecamylamine appears to be related to the reduced excretion of mecamylamine, which thus remains longer in the organism and has a better hypotensive effect even though the dosage is not increased. This phenomenon, however, seems to be present only during the first days of combined therapy with the 2 drugs.

PATHOLOGY

Serum Vitamin B_{12} Levels in Liver Disease. D. C. Cowling and I. R. Mackay. M. J. Australia 2:555-562 (Oct. 17) 1959 [Sydney].

Raised serum levels of vitamin B_{12} have been observed in liver disease, particularly in the presence of parenchymal cell damage and necrosis. The authors assayed the vitamin B_{12} level in the serum of 57 patients with various types of liver disease, in order to correlate the serum vitamin B_{12} levels with the clinical status, biochemical findings, and histological changes. Raised serum levels of vitamin B_{12} were demonstrated in neoplastic and diffuse parenchymatous liver disease. Levels were highest in acute necrosis and in metastatic cancer of the liver. The raised levels in active chronic hepatitis and nutritional hepatitis usually, but not always, paralleled the activity of the disease as assessed by biochemical and biopsy criteria. Both release of stored vitamin B_{12} from necrosed liver cells and an increase in the vitamin B_{12} binding capacity of the serum may account for elevated serum vitamin B_{12} levels. Biliary obstruction and increased vitamin B_{12} absorption from the intestine were considered unimportant factors.

Association of Cardiac Pulmonary Haemosiderosis and Fibrosis. P. Ellman and R. A. M. Oliver. Brit. M. J. 2:988-990 (Nov. 14) 1959 [London].

Pulmonary hemosiderosis in association with valvular heart disease was reported by Fahr in 1928, when he described autopsy studies on 2 patients with mitral stenosis and on 1 with aortic incompetence. This endogenous hemosiderin has been supposed to lead to pulmonary fibrosis, and the term "brown induration" has been used to summarize the changes. Recent experience with 2 patients under the care of one of the authors has led them to believe that endogenous hemosiderin in the lungs may be less fibrogenic than has been supposed hitherto.

The 2 patients had mitral stenosis, but no significant pulmonary fibrosis developed. In one of these patients, chest roentgenograms had shown a miliary pattern for 18 years, and, since the lung fields cleared gradually after successful mitral valvotomy, it was concluded that the opacities were due to hemosiderin unassociated with fibrosis. The other patient had a 6-year history of hemoptyses, and a miliary roentgenologic pattern had been noticed in the chest when he was first seen in 1954. A satisfactory valvotomy could not be performed, owing to calcification of the mitral valve. The patient died of pulmonary edema after a cerebral embolism. The lungs showed heavy focal hemosiderosis but no significant fibrosis, either macroscopically or microscopically. It was possible to reproduce the miliary pattern exactly by roentgenography of a whole-lung section after inflation and fixation. The authors feel that mitral pulmonary hemosiderosis, seen roentgenologically, is no contraindication to mitral valvotomy. Successful valvotomy may be followed by gradual disappearance of the miliary infiltration.

Cancer Cells in the Circulating Blood. R. A. Malmgren and J. F. Potter. South. M. J. 52:1359-1362 (Nov.) 1959 [Birmingham, Ala.].

Cytological evaluation of cancer cells was made in 183 blood specimens obtained from 121 patients with various types of cancer, 20 ml. of blood being collected from the antecubital vein in all the patients, and, in addition, 10 ml. of blood being drawn from the vein draining the tumor site in the patients who were operated on. PHYSIOLOGY

A Study on the Possible Bronchodilating Effect of Corticotropin (ACTH) in the Therapy of Bronchial Asthma. E. Cerchiai. Minerva med. 50:3078-3084 (Sept. 29) 1959 (In Italian) [Turin, Italy].

The author reports an experimental study on the possible direct effect of corticotropin (ACTH) on the bronchial muscles of the isolated lungs of guinea pigs. The results of this study seem to warrant the hypothesis that the antiasthmatic effect of corticotropin may occur through a direct, pharmacodynamic effect of corticotropin itself, with the need of no other mediating factors, this effect being independent from the main hormonal function of the compound itself. This hypothesis was suggested by the observation that some asthmatic patients do not respond to cortisone, while they do respond to corticotropin. The effect of corticotropin on the lung after the administration of histamine and the effect of histamine after the administration of corticotropin were studied. A dose of 5 units of corticotropin dissolved in 2/10 cc. of isotonic sodium chloride solution was used. Corticotropin had a marked dilating effect on the lung in basal condition; this effect, however, took longer than the effect of ephedrine to become manifest. The degree and duration of the bronchodilatation were in proportion to the dosage of the drug used. Histamine, given 3 minutes after the administration of corticotropin, caused a bronchoconstriction which was gradual and delayed; this bronchoconstriction was less intense and lasted less than that observed when histamine was administered with the lung in basal condition. Different dosages of the 2 drugs caused quantitatively different effects. Corticotropin administered after histamine had a clear bronchospasmolytic effect, which was more delayed, however, than the effect obtained with ephedrine. The dosage used in this experiment did not cause a complete return to basal condition. Increasing the dose of corticotropin did not shorten the period of time necessary for the manifestation of the dilating effect; when the dilatation occurred, however, it was more marked than the dilatation obtained with the 5-unit dose.

The author believes that corticotropin may have a direct effect on the bronchial muscles without the need of mediating factors. Corticotropin manifests this direct effect when it causes the dilatation of a bronchus which has not undergone drug-provoked spasm and when it prevents the bronchoconstriction caused by histamine. The effect of corticotropin is not as rapid as that of ephedrine, and its intensity is proportional to the dose used. The author believes also that the spasmolytic effect of corticotropin, when given after the administration of histamine, does not occur through an antihistaminic mechanism, but is the result of the bronchodilating effect of corticotropin and of the bronchoconstricting effect of histamine.

Investigation of the "Diego" Blood Factor in a General Chilean Population and in Mapuche Indians. C. Meza Arrau, J. Staeding and A. Nijamkin. Rev. méd. Chile 87:690-692 (Sept.) 1959 (In Spanish) [Santiago].

The "Diego" blood antigen is found in the blood of persons having Mongolian ancestors. The antigen is serologically independent from all other known blood factors. It gives rise to a weak, incomplete, immune antibody which does not agglutinate the erythrocytes of normal blood. Frequently, although not always, it causes maternal-fetal incompatibility with production of erythroblastotic fetuses. The blood of the mothers, as well as that of the fetuses, reacts positively to the classical indirect Coombs test, in which the anti-Diego blood serum is used. The Diego blood factor has been previously identified among small groups of Caribbean Indians (29%), Brazilian Indians (45%), Inca Indians (25%), Chippewa Canadian Indians (10%), Chinese (5%), and Japanese (12%). Apparently all these groups are of Mongolian origin. This factor does not exist in the blood of Europeans, pure African Negroes, and pure American Indians. Its presence in the blood of American Indians is a proof of the Mongolian origin of those Indians, whereas its absence in the blood of certain groups of Indians shows pure American Indian ancestry.

The Diego factor was investigated in the blood of 120 Chileans and 100 Mapuche Indians of the O blood group. The parents of the Indians were 88 Indian couples and 12 couples consisting of an Indian and a mestizo. The classical indirect Coombs test was used. The test was positive in one person out of the 120 Chileans (0.8%) and in 4 Indians (4%). The Rh$_0$ Diego factor was positive in all 100 Indians. The authors conclude that the Diego factor is of value for determining the exact racial ancestry (Caucasian, Mongolian, or Negro) of a population and also for determining the Mongolian origin of American Indians, the test being positive only in persons with Mongolian ancesters.

BIOCHEMISTRY

Substances Released from the Skin Following Thermal Injury: "Burn Toxin." R. Rosenthal. Surgery 46:932-947 (Nov.) 1959 [St. Louis].

Rats were anesthetized with pentobarbital (Nembutal), and subcutaneous air pockets were made on their backs by injecting 30 cc. of air. The rats were held by their feet and immersed in a water bath at the desired temperature and for certain lengths of time. The burned animals were suspended by their feet, with the dorsal pockets down. Five cubic centimeters of triple-distilled water was injected into each pocket and gently shaken over the inner surface of the burned skin in such a way that the fluid came in contact only with the undersurface of the skin involved. After 5 minutes this water was removed, and another 5 cc. was injected into the pocket. This procedure was repeated 20 to 25 times over a period of 2 hours immediately after the burning of the skin. The fluid containing the diffusible materials from the burned skin was placed immediately in an ice bath, or was frozen by immersion of the container in a mixture of dry ice and alcohol. Diffusates were obtained by the same procedure from not burned rats. In more han 400 burned and not burned animals the av- rage yield of dry material perfused for 2 hours t 5-minute intervals was approximately 30 mg. er animal. The amount of material by dry weight vas similar in both groups.

The protein content and the protein nitrogen con- ent were the same in the lyophilized diffusates f both burned and not burned rats for the first our of collection, then increased appreciably in he burned sample during the second hour. The ost significant difference between the 2 samples as the higher content of potassium and phos- horus in the burned fluid. There was approxi- ately 1.2 to 1.4 mcg. per cubic centimeter of istamine in the crude dried material from the urn" perfusate. The lyophilized material was issolved in water or in a 0.9% sodium chloride lution and injected subcutaneously in small rats. qual volumes of 0.9% sodium chloride solution, ncentrated hemoglobin, or concentrated skin ex- acts were injected in control rats. Doses of 108 210 mg. of the "burn" diffusate solution caused rostration, marked decrease in activity, and diffi- lty in locomotion. Doses of 280 to 600 mg. caused eath within 5 hours. The average lethal dose, dministered subcutaneously, was approximately 7 mg. of the crude material per gram of body eight. The "burn" perfusate was also adminis- red in peritoneal, intravenous, and intracerebral jections.

The author affirms the existence of a "burn xin," originating in the skin proper and having unknown chemical composition. It is lethal to ice and rats in subcutaneous, intraperitoneal, travenous, or intracerebral injections, producing ute or chronic symptoms, depending on the dose d on the route of administration. Immunological udies showed that this toxin enters the circulation.

therosclerosis and Deficiency of Essential Fatty cids. H. Malmros and G. Wigand. Lancet 2:749-51 (Nov. 7) 1959 [London].

The authors report the results of dietary experi- ents made on rats in the department of clinical emistry of the University in Lund, Sweden. A misynthetic diet containing sugar, starch, cellu- se, casein, vitamins, and salts, but neither cho- sterol nor fat, induced hypercholesteremia and bsequent atherosclerosis in full-grown rabbits. part from hypercholesteremia, the animals did t show any clear signs of deficiency of essential tty acids. Hypercholesteremia disappeared when rn oil in a concentration of 8% was added to the eviously fat-free diet. The semisynthetic diet ith the addition of coconut fat or butter in con- ntrations of 8% also induced hypercholesteremia and atherosclerosis. The addition of glyceryl trilaurate in a concentration of 8% to the semisynthetic basic diet produced a considerable rise in the serum cholesterol level of the animals. This enhancing effect was diminished, though not completely abolished, by the addition of corn oil or pure linoleic acid in concentrations of 4%. This was probably due to a relative deficiency of essential fatty acids. There is much to suggest that the same nutritional-metabolic changes may occur in man on an unbalanced high-fat diet, and that atherosclerosis is thus a symptom of relative deficiency of essential fatty acids.

Peripheral Venous Blood Concentrations of Epinephrine and Norepinephrine in Primary Raynaud's Disease. J. H. Peacock. Circulation Res. 7:821-827 (Nov.) 1959 [New York].

The author performed chromatographic separation and biological assay of extracts from the peripheral venous blood of 9 women and 2 men, between the ages of 22 and 54 years, with primary Raynaud's disease, who had been admitted to the University Hospital in Ann Arbor, Mich. Of the 11 patients, 2 had clinically mild disease, 8 had moderately severe disease with pain being a dominant symptom, and 1 had severe disease with secondary ulceration of several digits. The results showed that the concentrations of epinephrine and of arterenol (norepinephrine) in the peripheral venous blood samples, obtained at the patient's wrist, were higher than normal when estimated by chromatography and biological assay under warm resting conditions. An increase, mainly of the arterenol fraction, which appeared to reflect the clinical severity of the condition, was observed in most patients after sympathetic nervous stimulation by cold. The high concentrations are considered to be due to an abnormal metabolism of these substances which probably arise mainly, if not entirely, from the peripheral sympathetic nerve endings.

The possible reasons for this abnormality are discussed, and it seems possible that the intense peripheral vasoconstriction and high concentration of vasoconstrictor substances seen in these patients could be related to the incomplete destruction of the amines liberated from the peripheral sympathetic nerve endings in the wall of the arteries of the hands and digits. This concept is supported by the findings in a finger amputated for terminal gangrene in a 22-year-old woman with Raynaud's disease. The proximal portions of 2 digital arteries were patent and microscopically normal, and no amine oxidase could be detected. In 2 other digital arteries taken from 2 digits amputated for nonvascular reasons, the amine oxidase activity was 552 microliter oxygen per gram per hour.

PUBLIC HEALTH

Lung Cancer Among White South Africans. G. Dean. Brit. M. J. 2:852-857 (Oct. 31) 1959 [London].

The author analyzed the deaths from lung cancer, occurring among white men in the Union of South Africa, by age, country of birth, and place of residence according to death certificates issued between 1947 and 1956. Results showed that among those dying between the ages of 45 and 64 years, but not among those dying at the age of 65 or over, the proportions of deaths from lung cancer were much higher among the British immigrants than among Union-born men or immigrants from other countries. Moreover, among all 3 categories of the white population in South Africa—Union-born men, British male immigrants, and male immigrants from other countries—the lung cancer mortality rates increased approximately with the level of urbanization and industrialization. Neither the differences between the lung cancer mortality rates of these 3 groups nor the urban/rural gradient can be attributed to differences in smoking habits. Instead, both would seem to have been due to the exposure of the men concerned to different degrees of atmospheric pollution. The excess lung cancer mortality among British immigrants dying under the age of 65, as compared with Union-born white men, would seem to have been due to their exposure in Britain to some form of atmospheric pollution to which those emigrating before 1910 had not been subject, since above that age there have been no significant differences between the lung cancer mortality rates in the 2 groups. The urban/rural lung cancer mortality gradient in South Africa would appear to reflect the increasing atmospheric pollution that is observed in passing from rural areas to areas of increasing industrialization.

Factors Affecting the Incidence and Severity of Poliomyelitis: An Analysis of the 1958 Epidemic in New Jersey. W. J. Dougherty and S. N. Faro. New England J. Med. 261:934-936 (Nov. 5) 1959 [Boston].

The 1958 epidemic of poliomyelitis in New Jersey accounted for 266 cases, an incidence rate of 5 per 100,000 population. Of these 266 patients, 186 had paralytic poliomyelitis and 80 the nonparalytic disease. Thirty-five per cent of the patients with paralytic symptoms were of preschool age. The incidence rate for paralytic poliomyelitis among nonwhites was 5 times that of the white population, and the incidence rate for nonparalytic poliomyelitis was 2.6 times that of the white population. Poliomyelitis in New Jersey in 1958 was essentially an illness of nonvaccinated persons. Of 186 patients with paralytic disease, 142 were unvaccinated, and of 80 patients with nonparalytic poliomyelitis, 39 were unvaccinated; 31 patients of the latter group, however, had received 3 inoculations of Salk vaccine. Poliomyelitis was confirmed by virus isolation in 119 of 149 patients with paralytic symptoms and in 13 of 58 patients with nonparalytic symptoms. Eight of the 266 patients died, 6 of them not having been vaccinated against the disease. One 11-year-old girl who died had received 3 inoculations, the third of which had been given in November, 1957. Among 178 patients with paralytic poliomyelitis, 155 had some residual paralysis on follow-up examination, and half of the patients who had not received Salk vaccine suffered moderate to severe residual involvement. The degree of residual involvement of 149 patients, on whom laboratory results have been obtained, does not appear to differ in infections due to type 1 and type 3 poliomyelitis virus.

Studies on an Outbreak of Echo Virus Infection in a Circumscribed Population. M. I. Goldenberg and M. Gudnadottir. Connecticut Med. 23:693-696 (Nov.) 1959 [New Haven].

A survey was conducted from Aug. 1 to Nov. 1, 1958, of a circumscribed population in New Haven, Conn., to determine the etiology, incidence, and symptomatology of enteric cytopathogenic human orphan (ECHO) virus infection. The study involved 120 (88%) of the families living in a housing development, with a total of 345 persons. There were 105 infants and children, ranging in age from 6 months to 12 years, and 240 adults, between the ages of 19 and 36 years. The study showed that 49 (23 infants and children, and 26 adults) of the 345 individuals had been ill with symptoms and signs suggestive of ECHO 9 virus infection. A different clinical picture was seen in the 2 age groups. The cardinal signs in infants and children were exanthema and fever, particularly among those ranging in age from 6 months to 4 years, whereas in adults the disease was more often characterized by meningeal symptoms, such as occipital headache and/or stiff neck. The disease was not severe enough in any of the patients to require hospitalization, and no lumbar punctures were made. Other symptoms, such as fever, anorexia, or nausea and gastrointestinal disturbances, were common in both groups. Stool samples obtained from 7 of the 49 individuals with varying degrees of illness were tested, and ECHO 9 virus was isolated from 4 specimens. It was possible to ascertain the date of onset of symptoms in 41 of the 49 persons studied. The data indicated that the peak incidence of diseases occurred in August and the first half of September; a smaller peak occurred in the first week of October.

BOOK REVIEWS

The Surgical Treatment of Facial Injuries. By Varaztad Hovhannes Kazanjian, C.M.G., D.M.D., M.D., Plastic Surgeon, Senior Active Staff, New England Deaconess Hospital, Boston, and John Marquis Converse, M.D., F.A.C.S., Lawrence D. Bell Professor of Plastic Surgery, New York University College of Medicine, New York. Second edition. Cloth. $22. Pp. 1110, with 1155 illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2, 1959.

This revised textbook covers completely the subject of soft tissue and bone injuries of the face. The first four chapters cover the basic principles involved in repairing soft tissue defects and are well presented. Chapters 5 to 12 describe the treatment of facial bone fractures. Many will disagree with some of the corrective methods shown. Too much emphasis is placed on the use of cumbersome plaster of Paris headgear with various wires and levers attached. Most plastic surgeons consider this out of date and frequently ineffective. The same may be said of the use of external pin fixation. The use of various types of open reduction with wire and Kirschner pins is simpler and more accurate and is not accompanied by the numerous complications resulting from head cap and external pin techniques.

Roentgenographic demonstration of facial bone fractures is frequently difficult, but chapter 13 demonstrates these techniques unusually well. Chapters 15 to 19 discuss the transplantation of skin, mucosa, flaps, bone, and cartilage. These are good chapters and the techniques are accurately portrayed. One wonders, however (fig. 452), how many modern operating rooms stock sulfanilamide powder to aid in removal of a skin graft from the Padgett dermatome. The remaining chapters deal with the surgical reconstruction of specific parts of the face, scalp, eyelids, orbits, nose, and jaws. The treatment of facial paralysis is covered in a separate chapter.

The book is long but is filled with illustrations. It should find a useful place on the reference shelves of any large medical library. It would probably not be of interest to many plastic surgeons because it covers only a limited portion of their specialty. The publishers are to be complimented on the excellent printing and the fine reproduction of photographs, roentgenograms, and illustrations.

American Universities and Federal Research. By Charles V. Kidd. Foreword by Paul E. Klopsteg. Cloth. $6. Pp. 272. Belknap Press of Harvard University Press, Cambridge, Mass.; Oxford University Press, Amen House, Warwick Sq., London, E. C. 4, England, 1959.

Physicians will miss little if they are unable to find the time to read this book. Approaching the problem of the impact of federal research grants on the universities of America in a variety of ways, the book contains much repetition. It is characterized by equivocal conclusions. In brief, the author concludes that "the effects of federal research funds on universities cannot be determined objectively and precisely" (p. 208). He adds that cultural pressures affect government and universities and constitute the basic influencing force in our society. The nature of his conclusions is also revealed by such passages as: "University research in virtually all fields is more extensive, and in most fields of higher average quality, as a result of federal funds" (p. 211). This appraisal would hardly seem to comfort the taxpayer for the vast amount of funds expended and the detour via government his funds had to take to become available for research.

"Only 10% of university research," says Kidd, "is self-financed whereas more than 70% is financed by the federal government." It is not surprising therefore that "the central thesis of this book is that large-scale federal financing of research has set in motion irreversible forces that are affecting the nature of universities, altering their capacity to teach, changing their financial status, modifying the character of parts of the federal administrative structure, establishing new political relations, and changing the way research itself is organized" (p. v). Practically all of the conclusions constitute opinions which unfortunately cannot be tested by use of quantitative evidence.

Special attention is given to medical schools and federal funds because of problems of financing medical schools and because of medical schools' research programs. These programs have placed severe pressures on availability of medical school faculty and funds available for instruction. These conditions are especially serious since there are many people who believe that continued expansion of medical schools will be necessary. The author believes that if financing of medical education from private sources is not greatly increased, the universities will be forced to accept federal support for medical education as well as for medical research.

One difficulty with federal financing of university research, which the author notes, is that federal research funds may have attracted many faculty scientists away from their role of teaching. The relationship, however, between federal research funds and the decrease in the quality of instruction at universities may be as important as the relationship between federal funds and university research. A statistical appendix provides a brief summarization of the data used in this study.

Child Research in Psychopharmacology. Organized and edited by Seymour Fisher, Ph.D., Research Psychologist, Psychopharmacology Service Center, National Institute of Mental Health, U. S. Public Health Service, Bethesda, Md. With foreword by R. H. Felix, M.D., Director, National Institute of Mental Health. Cloth. $6.50. Pp. 216, with 7 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This volume is a report of a multidisciplinary conference that was intended to focus on short-term and long-term problems of drug effects. The primary objects of the conference were as follows: (1) to focus on basic short-term and long-term problems of drug effects on psychological functions, family relationships and community adjustment, maturational and developmental processes, and the central nervous system; on the type of child (i. e., disturbed, psychotic, or normal); and on research methodology and measuring instruments; (2) to develop new hypotheses and approaches to the study of drug-effects in children, taking into consideration historical background variables and personality differences; situational variables such as stress, motivation, rewards and punishments; and socio-environmental variables such as clinic, school, and family atmospheres; (3) to pave the way for initiating long-term developmental studies; and (4) to stimulate further interest in drug research with children.

Throughout the discussion, various contributors emphasized and reemphasized the possible effects of drug research on developmental aspects of the child. Contrast was made between children and adults, for investigative purposes. Of particular significance is the chapter by Sherman Ross on comparative drug behavior and the discussion that followed. The different effects of the same drug at different age levels in relation to the developmental problems are stressed. There is an excellent essay by Senn on the possible misuse of drugs as substitutes for adequate diagnosis and psychotherapeutic procedures. The volume has a valuable annotated reference list on the use of pharmacology for children, with a subject index which should be valuable to those interested in the field. This volume achieves its purpose as a report of a pioneering effort.

Anesthesia for Infants and Children. *By Robert M. Smith,* M.D., Anesthesiologist, Children's Medical Center, Boston. Foreword by Robert E. Gross, M.D. Cloth. $12. Pp. 418, with 182 illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3; Henry Kimpton, 134 Great Portland St., London, W. 1, England, 1959.

"The purpose of this book is to assemble as much practical information as is available concerning the basic responses of children to anesthesia." The author writes from his own experience and knowledge and emphasizes the differential diagnosis and general principles and procedures of clinical management rather than detailed descriptions of specific techniques and complicated treatment. Emphasis is placed on information on pathology, pediatrics, and surgery, which the anesthetist usually lacks when called on to care for infants and children.

In each chapter are references which include only articles that have made definite contributions to the subject matter of the chapter. Bibliography and index are adequate. Of particular interest are the discussions of basic requirements in pediatric anesthesia, biology and behavior, hypothermic anesthesia for thoracic surgery, fluid therapy, and blood replacement. The excellent chapter on respiratory physiology was written by C. D. Cook. Fluothane is mentioned only briefly. More space could have been given to this timely subject.

This excellent book contains comprehensive review of clinical management of pediatric anesthesia. It stresses differential diagnosis and general principles and procedures rather than specific techniques and complicated treatments. It is well illustrated and should prove a welcome addition to the library of every anesthesiologist and student interested in anesthesia care of infants and children.

The Law of Medical Practice. By Burke Shartel, Professor of Law, University of Michigan, Ann Arbor, and Marcus L. Plant, Professor of Law, University of Michigan. Cloth. $12.50. Pp. 445. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This book deals with law as it may relate to or influence the practice of a physician as he conducts his professional activities. The authors express hope that the book will meet the daily need of established practitioners, offer medical students more than the bare minimum of medicolegal information needed to pass an examination for licensure, and aid lawyers who are called on to assist physicians in matters relating to medical practice. The authors have made wide use of medicolegal cases, abstracted by the American Medical Association's Law Division and published in THE JOURNAL. They rightly point out that so far no medicolegal book has made systematic use of this material.

The book represents an attempt to cover a wide field in one volume. The subject is comprehensive because, in medical practice, sooner or later, almost every problem known to law may be encountered. A major criticism of this work might be that an attempt has been made to cover too much, as a book could be written about the subject of each chapter. The authors, however, deserve credit for bringing many medicolegal discussions together.

An indication of the scope of the book is its eight chapters entitled The Physician's Professional Services, Compensation for Medical Care, The Physician's Liability for Medical Care, Other Tort Liability Incident to Medical Practice, Licensure of Physicians and Other Practitioners of the Healing

Art, The Physician's Business Transactions and Relationships, The Physician's Public Duties and Liabilities, and Operation of the Legal System: General View. Each chapter is practical, well written, and well documented. The authors do not write abstractly or from the strictly legal point of view. Examples and illustrations demonstrate the rule or point under discussion.

No physician could be expected to read this book from cover to cover. He could, however, refer to it for general information to guide him in making his decisions or to encourage him to seek advice from his attorney in other situations. The book could be used by medical students who wish to enter practice with some knowledge of the effect that statutes and court decisions have on the conduct of their profession. Lawyers who are called on from time to time to advise physicians may expect this book to furnish helpful perspectives to medicolegal issues and to furnish leads to reported court cases and existing statutes related to the issue under consideration.

This book is a contribution to the medicolegal literature and may be recommended to the physician or medical student as an acceptable exposition of the law as it affects the practice of medicine.

Klinik und Praxis der Urologie: Klinik, Indikation, Diagnostik, operative und instrumentelle Eingriffe, Nachbehandlung. [In zwei Banden.] Band I. Von Prof. Dr. Werner Staehler. Mit einem Geleitwort von Prof. Dr. Th. Naegeli. Cloth. 240 marks; $57.15. Pp. 892, with 1034 illustrations. Georg Thieme Verlag, Herdweg 63, (14a) Stuttgart, West Germany; [Intercontinental Medical Book Corporation, 381 Fourth Ave., New York 16], 1959.

Klinik und Praxis der Urologie: Klinik, Indikation, Diagnostik, operative und instrumentelle Eingriffe Nachbehandlung. Band II. Von Prof. Dr. Werner Staehler. Mit Namen- und Sachverzeichnis für Band I und II. Cloth. 240 marks; $57.15. Pp. 893-1755, with 641 illustrations. Georg Thieme Verlag, Herdweg 63, (14a) Stuttgart, West Germany; [Intercontinental Medical Book Corporation, 381 Fourth Ave., New York 16], 1959.

Each of these volumes presents a vast amount of information on urology. The photographs and drawings, with their legends, are storehouses of information.

Volume 1 is an orderly presentation of historic developments of urology. Malformations are discussed, and the embryology of the urogenital system is described. Modern concepts of therapy and dangers encountered with antibiotics are presented, and infections occurring in various parts of the urinary tract are discussed. Urinary calculus, urinary retention, prostatic hypertrophy, cancer of the prostate, bladder neck contractures, and tumors of the kidney are described, and their sequela and treatment are discussed. At the end of each chapter is an excellent summary.

Volume 2 discusses anuria and its treatment and indications for dialysis, nephritis, hypertension, hematuria, stenosis of the renal artery, trauma to urinary tract, foreign bodies, parasitic disease, and disturbances in genital function of the male such as infertility, impotence, and climacteric.

The final chapter deals with physical examinations, laboratory tests, cystoscopy, surgical techniques, kidney transplantations, and operative and postoperative complications. These volumes are classics and should be read by all urologists.

Medical Discoveries: Who and When. By J. E. Schmidt, Ph.B.S., M.D., Litt.D. Dictionary listing thousands of medical and related scientific discoveries in alphabetical order, giving in each case name of discoverer, his profession, nationality, and floruit, and date of discovery. Cloth. $14.75. Pp. 555. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This collection of useful information lists more than 6,000 discoveries in medicine and related fields of science. Arranged by subject in encyclopedic style, each brief entry includes the name of the discoverer or inventor, some biographical data, and eponyms or synonyms for the subject. It is current enough to include information about the Salk vaccine. An introductory chapter explains the arrangement in some detail and offers suggestions as to how to locate desirable information.

One drawback to its use as a quick-reference tool is a lack of entries under proper names. For instance, the Salk vaccine entry is listed under "Poliomyelitis Vaccine, introduction of." Thus it offers little help in learning what a person did (unless there is an eponymic or syndromal type of entry, such as Hodgkin's disease), but it is an excellent source of information for facts on first accounts of various operations, anatomic discoveries, and diseases.

This book can be recommended as an excellent reference work on medical history. It is useful to the practicing physician as well as to the librarian or student of medicine or science. It is certainly a much-needed supplement to the existing reference books of its kind, such as Kelley's Encyclopedia of Medical Sources, which it somewhat resembles.

Diagnosis of Congenital Heart Disease: A Clinical and Technical Study by the Cardiologic Team of the Pediatric Clinic, Karolinska, Sjukhuset, Stockholm. By Sven R. Kjellberg, Edgar Mannheimer, Ulf Rudhe, and Bengt Jonsson. Second edition. Cloth. $28. Pp. 866, with 727 illustrations. Year Book Publishers, Inc., 200 E. Illinois St., Chicago 11, 1959.

This is the second edition of a work that is already a classic and standard reference in the field. The first edition, published in 1955, was based on 396 cases of congenital heart disease, and the case material has now nearly doubled in amount. The presentation is outstanding in respect to the angiocardiographic analysis. These detailed studies are clearly presented, and the radiographic reproductions represent a definitive atlas of congenital heart disease. The value of the radiographic material is enhanced by an abundance of carefully correlated postmortem illustrations.

The authors first present a concise embryologic survey of the circulatory system. The second chapter is an invaluable discussion of the anatomic and physiological features that are considered to be of importance for angiocardiographic interpretation. Special technical aids such as cardiac catheterization, angiocardiography, roentgenography, electrokymography, and phonocardiography, which make possible a detailed functional and anatomic diagnosis, are next presented in adequate detail. Separate chapters are devoted to a detailed presentation of clinical and laboratory diagnoses of major cardiovascular defects. Although this volume is not to be considered a textbook of general pediatric cardiology since there is little about the clinical course on therapy of congenital heart disease, it represents an outstanding and indispensable volume for all those interested in this subject.

Atlas and Manual of Dermatology and Venereology. By Professor Dr. W. Burckhardt, Director of Municipal Policlinic for Skin and Venereal Diseases, Zürich, Switzerland. Translated and edited by Stephan Epstein, M.D., Clinical Associate Professor of Dermatology, University of Minnesota School of Medicine, Minneapolis. Translation of "Atlas und Praktikum der Dermatologie and Venerologie" published by Urban & Schwarzenberg. Cloth. $14. Pp. 276, with 172 illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2, 1959.

When this book first appeared in German, it met with immediate success. The English translation is therefore most welcome. It contains 99 color plates of excellent quality and good size so that details of lesions are easy to see. The black and white illustrations are well selected. The text is brief, yet adequate, and the suggestions for treatment are standard, practical, and current. The emphasis is on the more commonly encountered diseases with a view to meeting the needs of nondermatological specialists, general practitioners, and students. The book is well indexed and has an excellent list of references.

The Management of Oral Disease: A Treatise on the Recognition, Identification, and Treatment of Diseases of the Oral Regions. By Joseph L. Bernier, D.D.S., M.S., F.D.S., Second edition. Cloth. $15. Pp. 875, with 1036 illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3; Henry Kimpton, 134 Great Portland St., London, W. 1, England, 1959.

As chief of the Oral Pathology Division, Armed Forces Institute of Pathology, the author has been in a position to observe numerous lesions of oral structures, clinically and histologically, and he has taken advantage of these opportunities.

This new edition is a further elaboration of the first one, which was published in 1955. New illustrations have been added, the text has been elaborated on, and some important changes have been made. The effect of high-speed instruments on the dental pulp has produced new problems for the dentist which are discussed here.

The section on the cause of lymphoid lesions of the salivary glands has been extensively revised. Throughout the book, diagnosis has been stressed, although treatment is suggested for many of the conditions described.

The text is well organized and readily readable. Illustrations are good, but many of them would have been better in color. The quality of the paper and size and style of the type are good. This book can be recommended as a textbook and reference volume. It should make a welcome addition to the library of dentists and physicians.

Clinical Disorders of Hydration and Acid-Base Equilibrium. By Louis G. Welt, M.D., Professor of Medicine, Department of Medicine, University of North Carolina, Chapel Hill. Second edition. Cloth. $7. Pp. 336, with illustrations. Little, Brown & Company, 34 Beacon St., Boston 6; J. & A. Churchill, Ltd., 104 Gloucester Pl., Portman Sq., London, W. 1, England, 1959.

The mere fact that this second edition appears within so short a time after the first attests to its value and to the great interest which the field elicits. The book covers a rapidly expanding field and has been improved through revision without being unduly lengthened. A complete chapter on the problems of acid-base equilibrium in pediatrics has been added, and familial periodic paralysis and hypernatremia with edema are discussed in detail. The style in many places is easier to read than that of the first edition. This volume can be highly recommended to anyone interested in the clinical problem of mineral metabolism.

Clinical Prosthetics for Physicians and Therapists: A Handbook of Clinical Practices Related to Artificial Limbs. By Miles H. Anderson, Ed.D., Director, Prosthetics Education Project, School of Medicine, University of California, Los Angeles, Charles O. Bechtol, M.D., Professor of Surgery (Orthopedics), Department of Surgery, School of Medicine, University of California, and Raymond E. Sollars, Associate Director, Prosthetics, Education Project, University of California. Cloth. $10.50. Pp. 393, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This text deals primarily with the upper-extremity amputee and the lower-extremity, above-knee amputee. It is written in a clear outline form. The author considers basic types of arm amputees, fundamentals of amputee training, and problems of crippled children. Information is provided on useful matters such as problems encountered in driving an automobile, assessment of amputee training, special devices, and adaptations for artificial limbs. The principles of locomotion, preparation and care of the stump, therapeutic exercise programs, and training in the use of the limb are reviewed as *they pertain to the lower extremity amputee.* This book should be helpful to the physician handling such patients and should be particularly helpful as a training aid for therapists working with amputees.

The Physiology and Treatment of Peptic Ulcer. J. Garrott Allen, editor. [Contributors:] Charles B. Clayman and others. Cloth. $7.50. Pp. 236, with illustrations. University of Chicago Press, 5750 Ellis Ave., Chicago 37; Cambridge University Press, Bentley House, 200 Euston Rd., London, N.W. 1, England; University of Toronto Press, Toronto 5, Canada, 1959.

This monograph was prepared by Dr. Lester R. Dragstedt's associates and students. It is outstanding for its timely, clear, and concise exposition of our present concepts of duodenal and gastric ulcers. The first four chapters, which are devoted to the physiological aspects of gastric secretion on the basis of knowledge developed and presented by Dr. Dragstedt, justify the preparation of this volume in its entirety. In chapter 5, the roentgenologic diagnosis and treatment of peptic ulcer are detailed. In chapter 6, the medical management of the ulcer problem is considered. In chapter 7, surgical procedures and the indications for them are well presented. In chapter 8, the problem of vagotomy and the rationale of the operation are reviewed. In chapters 9 and 10, the authors deal with the problem of the gastric ulcer. The influence of physiological observations on the treatment of peptic ulcer is considered in the final chapter. The book is extremely well written and is recommended as profitable reading for the internist, surgeon, gastroenterologist, and general practitioner.

Principles of Human Pathology. By Edward B. Smith, M.D., Professor of Pathology, Parker R. Beamer, Ph.D., M.D., Professor of Pathology, Frank Vellios, M.D., Associate Professor of Pathology, and Dale M. Schulz, M.S., M.D., Associate Professor of Pathology, Indiana University School of Medicine, Indianapolis. Cloth. $15. Pp. 1123, with illustrations, Oxford University Press, 417 Fifth Ave., New York 16, 1959.

Four authors have collaborated on the writing of this text. Dr. Smith is an expert in hematopoietic tissues, Dr. Beamer is well known in microbiology and immunology, Dr. Vellios has wide experience in surgical pathology, and Dr. Schulz is a chemist. About half of the 69 chapters deal with the basic principles of degenerative or retrogressive changes, abnormalities in metabolism, disturbances in growth of cells and tissues, and effects of injury by biological, physical, and chemical agents, including certain substances used for therapy. These are followed by chapters emphasizing in greater detail the chemical and pathological features of diseases that affect predominantly the organ systems of the body. The text is well written and has an abundance of illustrations and an extensive index. This is an excellent textbook for beginning and advanced students of pathology.

Biochemistry of Blood in Health and Disease. By
ton Kugelmass, M.D., Ph.D., Sc.D. Publication numbe
American Lecture Series, monograph in Bannerstone D
sion of American Lectures in Living Chemistry. Edited b
I. Newton Kugelmass. Cloth. $15.75. Pp. 543, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This compact textbook presents a summary of physiology, pathology, clinical medicine, and biochemistry. Although the author is to be commended for the wealth of material presented in a concise fashion, there are several drawbacks. Many theories and controversial opinions are presented as fact, and the bibliography is inadequate. Repeatedly the critical reader will be frustrated by dogmatic statements he wishes to challenge but which are not documented by evidence or reference to original work in the literature. Furthermore, a number of errors of content as well as typographical errors detract from the value of the book. This book is too brief to suffice as a textbook and too opinionated without documentation to be of more than limited value to the experienced reader.

A Synopsis of Skin Diseases. By Bethel Solomons, Jun., M.A., M.D., F.R.C.P.I. Cloth. $6.75. Pp. 293. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2; John Wright & Sons, Ltd., 42-44, Triangle West, Bristol 8, England, 1959.

The author of this pocket-sized volume has skillfully condensed into outline form material ordinarily included in standard textbooks of dermatology. The scope is broad with mention of rare as well as common dermatoses. The book is intended as a rapid source of information for the busy practitioner and as a concise review for the student or resident preparing for an examination. The typography and arrangement of the material facilitate rapid reference. The tables are helpful, particularly one on concentrations and vehicles to be used in patch testing. There are no illustrations of individual skin lesions. While one might wish to further subdivide and reclassify the inflammatory diseases and eczema, the organization of the book follows orthodox lines. Sections on treatment are up to date. This synopsis can be recommended as an aid to those who have some orientation in dermatology.

Low-Fat Cookery. By Evelyn S. Stea
Warren. With introduction by Eugene
and James Warren, M.D. Second ed
284, with illustrations by Frank
Book Company, Inc., Trade Boo
St., New York 36; 95 Farrin
land; 253 Spadina Rd., T

The information
to the patient
intake of fat
and the

disease. The value of the radiographic material is enhanced by an abundance of carefully correlated postmortem illustrations.

The authors first present a concise embryologic survey of the circulatory system. The second chapter is an invaluable discussion of the anatomic and physiological features that are considered to be of importance for angiocardiographic interpretation. Special technical aids such as cardiac catheterization, angiocardiography, roentgenography, electrokymography, and phonocardiography, which make possible a detailed functional and anatomic diagnosis, are next presented in adequate detail. Separate chapters are devoted to a detailed presentation of clinical and laboratory diagnoses of major cardiovascular defects. Although this volume is not to be considered a textbook of general pediatric cardiology since there is little about the clinical course on therapy of congenital heart disease, it represents an outstanding and indispensable volume for all those interested in this subject.

Atlas and Manual of Dermatology and Venereology. By Professor Dr. W. Burckhardt, Director of Municipal Policlinic for Skin and Venereal Diseases, Zürich, Switzerland. Translated and edited by Stephan Epstein, M.D., Clinical Associate Professor of Dermatology, University of Minnesota School of Medicine, Minneapolis. Translation of "Atlas und Praktikum der Dermatologie and Venerologie" published by Urban & Schwarzenberg. Cloth. $14. Pp. 276, with 172 illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2, 1959.

When this book first appeared in German, it met with immediate success. The English translation is therefore most welcome. It contains 99 color plates of excellent quality and good size so that details of lesions are easy to see. The black and white illustrations are well selected. The text is brief, yet adequate, and the suggestions for treatment are standard, practical, and current. The emphasis is on the more commonly encountered diseases with a view to meeting the needs of nondermatological specialists, general practitioners, and students. The book is well indexed and has an excellent list of references.

The Management of Oral Disease: A Treatise on the Recognition, Identification, and Treatment of Diseases of the Oral Regions. By Joseph L. Bernier, D.D.S., M.S., F.D.S., Second edition. Cloth. $15. Pp. 875, with 1036 illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3; Henry Kimpton, 134 Great Portland St., London, W. 1, England, 1959.

As chief of the Oral Pathology Division, Armed Forces Institute of Pathology, the author has been in a position to observe numerous lesions of oral structures, clinically and histologically, and he has taken advantage of these opportunities.

This new edition is a further elaboration of the first one, which was published in 1955. New illustrations have been added, the text has been elaborated on, and some important changes have been made. The effect of high-speed instruments on the dental pulp has produced new problems for the dentist which are discussed here.

The section on the cause of lymphoid lesions of the salivary glands has been extensively revised. Throughout the book, diagnosis has been stressed, although treatment is suggested for many of the conditions described.

The text is well organized and readily readable. Illustrations are good, but many of them would have been better in color. The quality of the paper and size and style of the type are good. This book can be recommended as a textbook and reference volume. It should make a welcome addition to the library of dentists and physicians.

Clinical Disorders of Hydration and Acid-Base Equilibrium. By Louis G. Welt, M.D., Professor of Medicine, Department of Medicine, University of North Carolina, Chapel Hill. Second edition. Cloth. $7. Pp. 336, with illustrations. Little, Brown & Company, 34 Beacon St., Boston 6; J. & A. Churchill, Ltd., 104 Gloucester Pl., Portman Sq., London, W. 1, England, 1959.

The mere fact that this second edition appears within so short a time after the first attests to its value and to the great interest which the field elicits. The book covers a rapidly expanding field and has been improved through revision without being unduly lengthened. A complete chapter on the problems of acid-base equilibrium in pediatrics has been added, and familial periodic paralysis and hypernatremia with edema are discussed in detail. The style in many places is easier to read than that of the first edition. This volume can be highly recommended to anyone interested in the clinical problem of mineral metabolism.

Clinical Prosthetics for Physicians and Therapists: A Handbook of Clinical Practices Related to Artificial Limbs. By Miles H. Anderson, Ed.D., Director, Prosthetics Education Project, School of Medicine, University of California, Los Angeles, Charles O. Bechtol, M.D., Professor of Surgery (Orthopedics), Department of Surgery, School of Medicine, University of California, and Raymond E. Sollars, Associate Director, Prosthetics, Education Project, University of California. Cloth. $10.50. Pp. 393, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This text deals primarily with the upper-extremity amputee and the lower-extremity, above-knee amputee. It is written in a clear outline form. The author considers basic types of arm amputees, fundamentals of amputee training, and problems of crippled children. Information is provided on useful matters such as problems encountered in driving an automobile, assessment of amputee training, special devices, and adaptations for artificial limbs. The principles of locomotion, preparation and care of the stump, therapeutic exercise programs, and training in the use of the limb are reviewed as they pertain to the lower extremity amputee. This book should be helpful to the physician handling such patients and should be particularly helpful as a training aid for therapists working with amputees.

The Physiology and Treatment of Peptic Ulcer. J. Garrott Allen, editor. [Contributors:] Charles B. Clayman and others. Cloth. $7.50. Pp. 236, with illustrations. University of Chicago Press, 5750 Ellis Ave., Chicago 37; Cambridge University Press, Bentley House, 200 Euston Rd., London, N.W. 1, England; University of Toronto Press, Toronto 5, Canada, 1959.

This monograph was prepared by Dr. Lester R. Dragstedt's associates and students. It is outstanding for its timely, clear, and concise exposition of our present concepts of duodenal and gastric ulcers. The first four chapters, which are devoted to the physiological aspects of gastric secretion on the basis of knowledge developed and presented by Dr. Dragstedt, justify the preparation of this volume in its entirety. In chapter 5, the roentgenologic diagnosis and treatment of peptic ulcer are detailed. In chapter 6, the medical management of the ulcer problem is considered. In chapter 7, surgical procedures and the indications for them are well presented. In chapter 8, the problem of vagotomy and the rationale of the operation are reviewed. In chapters 9 and 10, the authors deal with the problem of the gastric ulcer. The influence of physiological observations on the treatment of peptic ulcer is considered in the final chapter. The book is extremely well written and is recommended as profitable reading for the internist, surgeon, gastroenterologist, and general practitioner.

Principles of Human Pathology. By Edward B. Smith, M.D., Professor of Pathology, Parker R. Beamer, Ph.D., M.D., Professor of Pathology, Frank Vellios, M.D., Associate Professor of Pathology, and Dale M. Schulz, M.S., M.D., Associate Professor of Pathology, Indiana University School of Medicine, Indianapolis. Cloth. $15. Pp. 1123, with illustrations, Oxford University Press, 417 Fifth Ave., New York 16, 1959.

Four authors have collaborated on the writing of this text. Dr. Smith is an expert in hematopoietic tissues, Dr. Beamer is well known in microbiology and immunology, Dr. Vellios has wide experience in surgical pathology, and Dr. Schulz is a chemist. About half of the 69 chapters deal with the basic principles of degenerative or retrogressive changes, abnormalities in metabolism, disturbances in growth of cells and tissues, and effects of injury by biological, physical, and chemical agents, including certain substances used for therapy. These are followed by chapters emphasizing in greater detail the chemical and pathological features of diseases that affect predominantly the organ systems of the body. The text is well written and has an abundance of illustrations and an extensive index. This is an excellent textbook for beginning and advanced students of pathology.

Biochemistry of Blood in Health and Disease. By ton Kugelmass, M.D., Ph.D., Sc.D. Publication numbe American Lecture Series, monograph in Bannerstone D sion of American Lectures in Living Chemistry. Edited b I. Newton Kugelmass. Cloth. $15.75. Pp. 543, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This compact textbook presents a summary of physiology, pathology, clinical medicine, and biochemistry. Although the author is to be commended for the wealth of material presented in a concise fashion, there are several drawbacks. Many theories and controversial opinions are presented as fact, and the bibliography is inadequate. Repeatedly the critical reader will be frustrated by dogmatic statements he wishes to challenge but which are not documented by evidence or reference to original work in the literature. Furthermore, a number of errors of content as well as typographical errors detract from the value of the book. This book is too brief to suffice as a textbook and too opinionated without documentation to be of more than limited value to the experienced reader.

A Synopsis of Skin Diseases. By Bethel Solomons, Jun., M.A., M.D., F.R.C.P.I. Cloth. $6.75. Pp. 293. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2; John Wright & Sons, Ltd., 42-44, Triangle West, Bristol 8, England, 1959.

The author of this pocket-sized volume has skillfully condensed into outline form material ordinarily included in standard textbooks of dermatology. The scope is broad with mention of rare as well as common dermatoses. The book is intended as a rapid source of information for the busy practitioner and as a concise review for the student or resident preparing for an examination. ESTIONS AND ANSWERS

LACERATIONS

edicament should a boxing when a fighter suffers a cut on the face?

James M. Willett, M.D., Elizabethton, Tenn.

Answer.—The ideal medicament to be applied, during a bout, to a laceration on the face of a fighter has long been the subject of controversy among physicians and trainers. To be ideal a medicament would have to be satisfactory for both the immediate and the later care of the wound, such as a topically applied lotion or ointment which effects rapid hemostasis and has no deleterious effect on the wound. Various solutions (Monsell's, ferric chloride, and epinephrine), pastes, and ointments (bismuth subgallate, zinc oxide, tannic acid, and carpenter's glues) are still being used at the ringside, a practice which should be condemned.

Topically applied thrombin or any of the approved thromboplastic substances appear to be the most effective coagulants and least injurious to the wound. Sterile petroleum jelly can be used but should be removed as soon as the fight is finished. Ice or water compresses may be effective adjunctive measures.

FUNGICIDAL ACTION OF ALCOHOL

To the Editor:—*Before a specimen is taken for culture of a suspected mycotic organism, the skin area from which it is taken is commonly cleansed with a 70% solution of ethyl alcohol. This practice apparently is based on the assumption that alcohol has no lethal effect on fungus growths. I wish to know whether or not this assumption has been challenged by experimental evidence?*

Kurt Loewenthal, M.D., Freeport, N. Y.

Answer.—There are few reliable documented data on the fungicidal action of ethyl or isopropyl alcohol. Textbooks and reviews occasionally state that alcohol is not an efficient fungicide, but the meager observations which have been recorded suggest that this is not the case. Spaulding (*Surg. Gynec. & Obst.* 69:738 [Dec.] 1939) asserted that Candida albicans organisms were rapidly killed by alcohol, even though embedded in blood or in pus on knife blades. With respect to the ringworm fungi, Emmons (*Arch. Dermat. & Syph.* 28:15 [July] 1933) noted that 80% alcohol destroyed the spores of Trichophyton, a ringworm fungus, within 30 minutes. Whether or not a shorter exposure time would also be lethal is not stated.

In view of the increasing recognition of ethyl and isopropyl alcohol as superior degerming agents, it seems wise to assume that fungi, especially the hyphal elements, are susceptible to alcohol. Cleansing of the lesion with soap and water would be a better way to decontaminate lesions prior to the collection of material for culture.

GRANULOSA CELL CARCINOMA

To the Editor:—*A 21-year-old woman has a granulosa cell carcinoma of the ovary which was incompletely removed. She is scheduled to hav therapeutic irradiation for this tumor, and he attending physician raised the question whethe administration of testosterone would inhibit th growth of the tumor. The patient has symptom of hyperestrogen effect. What should be done?*

M.D., Oregon.

Answer.—It is mandatory, if the tumor is ope able, that a second operation be performed. Thes tumors are radiosensitive, but, if irradiation is uti ized, the other ovary will also be damaged an the patient's normal physiology will be altered. If, the time of the first operation, the primary tum was confined to one ovary, unilateral oophorectom will suffice and the remaining ovary, if found fre of disease, will remain so for a number of year During this time the patient could, if married, be several children before hysterectomy and ooph rectomy become necessary. When all of the tum tissue is removed, her hyperestrogenism will disa pear. The only use of androgen therapy would b to hasten this change. There is no information whic suggests that administration of androgens wi destroy a granulosa cell tumor or enhance oth therapeutic measures used to overcome it.

SNORING SOUNDS DUE TO PARALYSIS AGITANS

To the Editor:—*Is there any way to control th moaning expiratory noise emitted by an elder patient with paralysis agitans (Parkinson's di ease) due to arteriosclerosis? The noise is made i voluntarily and occurs frequently while she sleeping; when she is awake, she can stop th sound if it is brought to her attention.*

Morton J. Silk, M.D., Morris Plains, N. J.

Answer.—Snoring of this nature is exceeding difficult to control, and nothing other than perform ance of a tracheotomy will stop it. If it is disturbin to someone nearby, the simplest remedy would b for either person to sleep in another room. Encou aging the patient to sleep on her side rather than o her back may help, but this might be difficult f her to do. Administration of sedatives usually a gravates rather than helps this condition.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any medical or other organization unless specifically so stated in the reply. ◆

WARNS AGAINST HASTY ACTION ON AGED-HEALTH BILLS

The top Republican on the House Ways and Means Committee urged Congress to hold off action on legislation to provide health care of the aged before next year's White House Conference on Aging makes its recommendations.

Rep. Noah M. Mason (R., Ill.) charged that "certain organizations" are bringing pressure on Congress to act on such measures this year "without the benefits of adequate study and investigation" of the problems of older persons.

He declared Congress had considered the problems of the aged "so vast and so complicated as to require a White House Conference at a large expenditure of effort and funds."

Rep. Mason made public an exchange of correspondence with former Rep. Robert W. Kean (R., N. J.), Chairman of the National Advisory Committee supervising preparations for the White House Conference in January, 1961.

Representative Mason had written Kean for information for the House Ways and Means Committee on preparations for the White House Conference. The Committee was scheduled to start March 14 considering Social Security legislation, including a controversial bill introduced by Rep. Aime Forand (D., R. I.) that would provide hospitalization, surgical services, and nursing home care for social security beneficiaries through an increase in social security taxes.

Kean said he believed that "in all probability" most of the White House Conference's recommendations "will be for state and local activity." He said state and local action "seems most effective" in dealing with problems of older persons. However, he added that "certainly some suggestions as to additional executive and legislative level may be included" in recommendations of the conference, which will be held here next January.

Kean reported that the White House Conference of 2,800 delegates and the preliminary state and local conferences would cost the federal government about 2 million dollars. He outlined the extensive activities of his advisory Committee and said most states have scheduled their conferences.

Kean expressed hope "that in every activity the conference will be truly nonpartisan." He pointed out that Democrats controlled Congress when the law was passed in 1958 and that it is being carried out under a Republican Administration.

Meanwhile, three officials of the American Medical Association met with Arthur S. Flemming, Secretary of Health, Education, and Welfare to discuss the Forand bill situation. After the meeting, attended by Dr. F. J. L. Blasingame, A. M. A. Executive Vice-president, Dr. Julian Price, member of the A. M. A. Board of Trustees, and Dr. David Allman, past-president of the A. M. A., Flemming told a news conference that he had invited the A. M. A. representatives to talk over their ideas on the problem of health care of the aged, particularly in the area of catastrophic coverage.

Flemming disclosed that insurance and hospital representatives would also be called on for their views. He said the administration was exploring various possibilities as alternatives to the Forand bill. These would be in the areas of social security, public assistance, or some form of supplementary private insurance, he said.

COMMITTEE CLEARS WARNING LABEL BILL

The Senate Commerce Committee approved legislation endorsed by the American Medical Association to require the precautionary labeling of hazardous substances such as certain household products not now covered by federal regulations.

The bill, also supported by the administration, would replace existing statutes and provide more encompassing coverage of products requiring labeling. In addition, more detailed labeling would be required for flammable as well as potentially poisonous products.

The committee rejected suggestions, opposed by the A. M. A., to weaken the bill by omitting toxicological tests in determining the necessity of the word "danger" on products and applying the term only to very toxic substances, which also would be labeled "poison."

Commenting on the bill, HEW Secretary Flemming said, "There is wide agreement that present legislation in this field . . . has been greatly outmoded by the rapid increase in the number of chemical compounds available for household use. The 1927 act has helped to save many lives, but it is not applicable to many poisons and other hazardous substances and devices that are being used in homes today in ever-increasing numbers.

"A number of ordinary household materials, when swallowed, are poisonous and can cause death.

(Continued on next page)

Frequently—and often because parents are not aware of their danger—they are placed within easy reach of small children. These include paint and paint thinners and removers, cleaning agents, furniture waxes and polishes, bleaches, detergents, lighter fluids, and, of course, drugs and sometimes cosmetics."

ADMINISTRATION SUBMITS AIR POLLUTION BILL

The administration, with bipartisan backing, sent Congress a new program for expanding the government's efforts to attack the problem of air pollution in metropolitan areas.

The bill, introduced by Senators Thomas Kuchel (R., Calif.), Clair Engle (D., Calif.), Hugh Scott (R., Pa.), and Joseph Clark (D., Pa.), would make the present temporary air pollution control program permanent and give the Public Health Service stronger powers.

Under it, PHS would be authorized to hold public hearings on air pollution problems which are interstate in nature or of broad significance, and the 5-million-dollar ceiling on appropriations for the program would be eliminated.

In submitting the bill, Arthur S. Flemming, Secretary of Health, Education, and Welfare, declared, "Increasing evidence has accumulated of a causative relationship between air pollution and the incidence of respiratory chronic disease conditions. Further studies are urgently needed to investigate more fully these relationships and delineate practical procedures applicable in air pollution control practice."

"Continuing research and control efforts will be necessary if major adverse effects on the public health and welfare are to be prevented," he declared.

DRUG HEARINGS CALLED OFF TEMPORARILY

Sen. Estes Kefauver (D., Tenn.) indefinitely postponed hearings of his Senate antitrust subcommittee on drug industry practices, because of the lengthy civil rights debate on the Senate floor. In making the move after several postmidnight sessions, Kefauver said he hoped physicians would give serious thought to writing prescriptions by the generic or scientific term rather than the trade name.

At the abbreviated hearings, spokesmen for the drug industry took issue with the Senator's suggestion. Dr. Austin Smith, president of the Pharmaceutical Manufacturers Association, said that in the first place prescribing by generic terms would not necessarily mean any savings for the patient. Furthermore, he said, "behind brand names lie the reputation, reliability, and skill of the manufacturer. Any system to substitute generic term for trade names also would restrict the physician's choice and transfer some of his responsibility to the

thorities. ist."
or other organi
mous communication
the writer's name and ad

"By brand name prescription, too, the doct orders for a patient a specific product in which h has absolute knowledge of quality, purity, and an side-effects that might have importance for a pa ticular patient," he testified. "In the case of combi nation formulations, brand names stand not onl for the active ingredient or ingredients but also fo special excipients, vehicles, and bases, frequentl developed by costly research to be nonallergeni specially buffered to promote tolerance, sugar-fre for the obese and diabetic, and many other impor tant variations for individual patient needs. So called generic equivalents often do not."

The wind-up witnesses were Drs. Haskell J Weinstein and Martin Seidell, who once worked fo Charles Pfizer & Co. They said that sometime there were conflicts between the marketing depart ments and the medical departments of drug com panies as far as drug advertising and promotio were concerned. In a statement, Pfizer flatly denie the charge.

When the hearings resume, spokesmen for th American Medical Association were expected t present to the lawmakers a rundown on how th A. M. A. carefully screens advertising in its journal

RADIATION LIMIT LOWERED BY GOVERNMENT

The maximum permissible "safe" radiation limi as gauged by the federal government, was sharpl reduced in a move that was described as purel precautionary. The limit, based on a lifetime e posure, was slashed for radioactive strontiu (Sr^{90})—one of the most dangerous and commo byproducts of nuclear fall-out—from 80 μμc to 3 μμc. The move was made shortly after an ad ho committee of the semiofficial National Committe on Radiation Protection and Measurements recom mended a lowering of permissible ceilings to on fifth of the existing national standards.

Arthur S. Flemming, Secretary of Health, Educa tion, and Welfare, said the government would im mediately use the reduced standards in its testin of levels of radioactivity on air, water, milk, an other products. Actually, radioactivity levels hav been dropping generally since the cessation by th United States and Russia of nuclear test explosion Only a few of thousands of samples have exceede the permissible ceilings, and these were unusua cases due in large part to location near plants pro ducing radioactive materials. The government ha repeatedly stressed that as far as can be ascertaine at the present time there is no danger to the popu lace from radioactivity levels.

Flemming said much more research needs to b done before scientists understand fully the bio logical effects of radiation on human beings. Notin that there has always been a certain amount o background radiation from natural sources, he sai that the lower limit is an attempt to peg radiatio safety levels more realistically to natural radiation The new standard, he said, would have little or n practical effect on the government's testing pro grams.

Pro-Banthīne®...what it will do and what it will not do...in Peptic Ulcer

uch consideration has been devoted ently to a reappraisal of the role of ticholinergic drugs in the manage- nt of peptic ulcer.

uch reappraisal has presented no dif- lties at Searle. At no time have we gested that Pro-Banthīne should be stituted for antacids, rest, psycho- rapy or even common sense in man- g the patient with peptic ulcer.

tion of Pro-Banthīne:

action of Pro-Banthīne (brand of pantheline bromide) is simple and its cts, allowing for the variability of the nan estate, are predictable. Pro- thīne competes with and, in compet- inhibits the action of acetylcholine. competition is highly effective at sympathetic effector sites and, ex- t with high dosage, somewhat less so e autonomic ganglia.

ince parasympathetic nerves are mo- and secretory to the stomach and or to the intestines, Pro-Banthīne re- es both motility and secretions in the ach and motility in the intestines. se actions have often been demon- ted experimentally and clinically.

at It Does:

eves Pain—One of the natural con- ences of the actions of Pro-Banthīne reduce or to eliminate pain in pep- lcer. Whether the pain is attributa- to acid, to excessive motility or, to r a middle course, to spasm induced cid, the pronounced inhibitory effect ro-Banthīne on both secretion and ility might be expected to suppress characteristic distress of ulcer.

point of fact, relief of pain is one he most prominent effects of Pro- thīne in peptic ulcer. Phrases such as xcelled" and "almost invariably ef- ive" dot the literature referring to it.

uces **Acidity**—Since reduction of and rest for the hypermotile stom- and duodenum are accepted means upporting the regenerative processes e gastroduodenal mucosa, the phys- gic modifications induced by Pro- thīne should be expected to have apeutic implications in the healing lcers also. They do. Not only does -Banthīne reduce gastric acid and ility but, through these actions, it potentiates and prolongs the neu- izing property of antacids.

s Healing—Schwartz, Lehman, Os- e and Seibel prescribed 120 to 180 of Pro-Banthīne daily for 129 ulcer ients and found definite evidence, both clinical and roentgenographic, of accelerated healing.

With high doses (270 to 330 mg. daily) Barowsky, Schwartz and Lister reduced the mean duration of treatment in twenty-five patients with refractory ulcers from 135 to 17 days.

Helps Prevent Recurrences—Much the same considerations argue for the value of Pro-Banthīne in holding the reactivation of healed ulcers in abeyance, but the difficulty of regulating the diet, medication and mode of living of ulcer patients over long periods of time makes assessment of the role of Pro-Banthīne in preventing recurrences difficult. Nevertheless, in a study of 250 patients with established patterns of recurrence Texter and associates found that patients maintained on methantheline, less potent analogue of Pro-Banthīne, had significantly fewer recurrences than a control series taking atropine.

Schwartz and his co-workers considered freedom from symptoms when recurrences would be expected, together with tolerance and relief of symptoms, as a standard in establishing successful treatment in 118 of 129 patients.

Provides Selective Action—In inhibiting the action of acetylcholine in the stomach and intestines Pro-Banthīne also, though to a lesser extent, influences other cholinergically activated organs. That this influence sometimes leads to such secondary effects as dryness of the mouth, blurring of vision and hesitancy of urination is well known and bears consideration. It is one of the distinct advantages of Pro-Banthīne that it acts more effectively on the gastrointestinal tract than elsewhere. Secondary effects usually disappear during the course of treatment and only rarely limit therapy.

Evidence of selective action has been recorded by several investigators, but the most interesting confirmation of this selectivity was reported by Barowsky, Schwartz and Lister. They prescribed 30 to 45 mg. of Pro-Banthīne every hour and a half, except for the hour before and the hour following meals, for their patients with refractory ulcers. They were surprised and gratified by how few anticipated side reactions materialized. No serious toxic effects or side reactions occurred. The incidence of good response on double or triple the usual doses rose from 31 to 88 per cent.

Lowers Incidence of Failures—Variable results might be anticipated in a disease in which the psychic component plays such a large part and, of course, response to treatment does vary in patients with peptic ulcer. Observations of Lichstein and associates show that the 11 per cent of their patients who failed to respond to Pro-Banthīne had deeply ingrained anxiety on a psychoneurotic basis.

Successful management of such patients may well depend more on the patient's intelligence, the modification of his social environment and the skill of his physician in psychotherapy than on any medication. However, the successful experience of Barowsky and his colleagues in using large, frequent doses of Pro-Banthīne in patients with refractory ulcers might be borne in mind before Pro-Banthīne is abandoned as ineffective. Also worthy of trial in these patients is Pro-Banthīne® with Dartal® (brand of propantheline bromide with thiopropazate dihydrochloride), which combines the outstanding anticholinergic action of Pro-Banthīne with the highly efficient tranquilizing action of Dartal.

What It Will Not Do:

There are aspects of the medical management of peptic ulcer in which Pro-Banthīne has no demonstrable benefit. There is no reliable evidence that Pro-Banthīne reduces the incidence of complications or the need for surgery.

It will not abolish the obligation of physicians to evaluate each patient individually and to modify therapeutic measures to each patient's requirements. Nor will it do away with the necessity for the patient to regulate his life to the demands of his disease. But the modifying action of Pro-Banthīne on the physiologic activity of the gastrointestinal tract and its beneficial effects on the course of peptic ulcer have been established by too many investigators to be seriously questioned. Wisely used in conjunction with other standard therapeutic measures, Pro-Banthīne can inhibit pain, hasten healing and space out the intervals of peptic ulcer recurrence and do so without serious discomfort to the patient.

MALIGNANT TUMORS IN CHILDHOOD

W. B. Kiesewetter, M.D.
and
Edward J. Mason, M.D., Pittsburgh

Malignant disease was diagnosed in 404 of 38,967 children admitted to a hospital during six and one-half years. In children less than one year old, renal and adrenosympathetic tumors were the most frequent type. Thereafter leukemia and lymphoma predominated until the age of 8 years. In the 10-to-13-year age groups, inclusive, tumors of the central nervous system and eye predominated. Twelve cases of bone tumor were observed, all in children past their second birthday. About one-third of the 404 patients came to medical attention because of a mass. The most frequent error at the initial examination was a diagnosis of upper respiratory infection. The two types of malignancy most frequently misdiagnosed were Hodgkin's disease and neuroblastoma. The fact that 75% of those who died from malignant disease were dead at the end of the first 12 months indicates the need for prompt action when the diagnosis is made.

THE importance of malignancy in childhood is growing. Although few articles are published on this subject, the importance of the problem is well reflected by statistics from two other sources. The figure, a modification of a chart put out by the Department of Health, Education, and Welfare Children's Bureau, shows the chief causes of death in persons between 1 and 14 years of age in 1945 and 1955. It is significant that, while there has been a marked decrease in over-all mortality in this decade, there has been an increase in the absolute incidence of malignant neoplasms and congenital malformations. Correspondingly, there has been a relative increase in the importance of malignant neoplasms in the over-all death rate; they now account for 1 in every 8 or 9 deaths in this age group. It is interesting also that malignancy now represents the second most frequent cause of death, having been third in 1945.

Another source of statistical evidence that malignant disease is important in childhood is the fact that in a six-and-one-half-year period ending Dec. 31, 1957, there were 404 cases at the Children's Hospital of Pittsburgh. In the same period there were 38,967 admissions to the hospital, which means that more than 1% of admissions during this period were for malignant disease. The purpose of reporting a statistical analysis of cancer at a children's institution is to examine the problem from the viewpoints both of scope and of success in meeting it. This experience and the follow-up data on these 404 cases are presented in this paper.

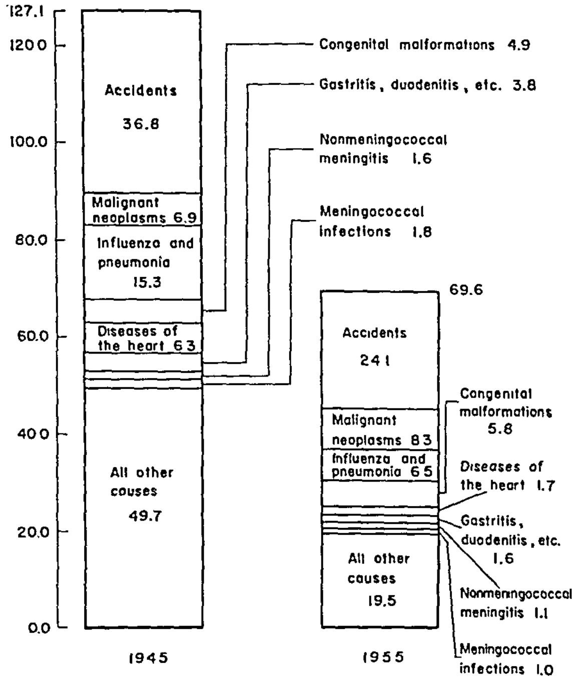
A well-rounded hospital service is offered at this pediatric institution. With the exception of an ophthalmological service, all major medical and surgical subspecialties are represented, and a balanced number of patients are seen and treated by each.

Surgeon-in-Chief, Children's Hospital of Pittsburgh, and Professor of Pediatric Surgery (Dr. Kiesewetter), and Teaching Fellow in Surgery (Dr. Mason), University of Pittsburgh School of Medicine.

Incidence of Cancer

Age and Organ System.—To analyze the material at hand, it is necessary to classify the malignant neoplasms under five general categories, based solely on the anatomic area or organ system, as follows: (1) leukemia and lymphoma; (2) tumors of the kidney, adrenals, and sympathetic nerves; (3) tumors of the central nervous system and eye; (4) bone tumors; and (5) miscellaneous tumors.

In table 1, which portrays the age and organ system incidence of cancer in the total series, several things become apparent. In the over-all aggregate of neoplasms, a child is much more vulnerable to malignant disease under the age of 5 years than thereafter. If one considers those tumors that occur in children from the newborn period through 2 years of age, it is apparent that neuroblastomas and Wilms's tumors predominate in this series. In children from 2 through 5 years of age, leukemia is the principal killer. Above the age of 5 years, while leukemia still takes a large toll, tumors of the central nervous system and eye occur almost equally frequently.



Childhood mortality in United States.

Leukemia and lymphoma are the major killers in this series, accounting for 42% of all cases seen. Second in importance are malignant neoplasms occurring in the so-called flank area, embracing neuroblastomas and Wilms's tumors; these accounted for 21% of the series. In third place were the central nervous system and eye tumors, accounting for an additional 19%. The only other homogeneous group which could be analyzed was that of those occurring in bone; these represented only 3% of the cases. Finally, there was a heterogeneous group of malignancies which could not be broken down into individual groups, and these accounted for the remaining 15%.

Sex and Race.—Negroid and sinoid children appear to be far less vulnerable to malignancy than caucasoid. In spite of the high percentage of negroid children seen as outpatients in the hospital, 391 of the 404 total tumors were in caucasoid children. In this series, there was an approximate three-to-two predominance of males over females, with malignant disease being found in 230 males as against 174 females.

Diagnosis

Attempts to arrive at a diagnosis in the case of these tumors usually center around four different factors. First, if a child had any rapid or chronic changes in growth, this would arouse suspicion of an abnormality, although not necessarily of malignant disease. Such growth changes might be of the entire body or, more commonly, of individual members of the body. Second, any swelling of nontraumatic origin certainly would raise the question of a "tumor." It is usually the "lump" of unexplained origin which does not disappear rapidly that causes a child to be brought under medical surveillance. Third, while changes in temperament, behavior, or intelligence may be due to other causes than a malignant tumor of the brain, these changes occur frequently enough to be a clue not only to this type of malignancy but to malignant processes elsewhere in the body. Such personality changes may occur long before there are manifest signs of the cause underlying alteration of behavior pattern. Finally, more than in the case of adults with tumors, one must be alert to the possibility that any undiagnosed disorder of short or long duration may be caused by an undisclosed malignancy, e. g., leukemia or neuroblastoma.

There are many ways in which total experience with tumors may be approached diagnostically. To make this analysis more comprehensible, patients in this series have been grouped under three headings as they might have appeared to the first physician who encountered the patient. First, the child may have been brought to medical attention because of a mass. Second, a physician might have seen the child because of symptoms directly referable to the mass. Finally, the child might be brought in with nonspecific symptoms which ultimately turned out to be due to malignancy.

Specific Symptoms.—When a mass is the presenting complaint, one thinks of Wilms's tumor or neuroblastoma, in which cases a definite abdominal tumor was palpated either by the mother or by the family physician. Furthermore, the lymphadenopathy which attends leukemia and lymphoma, together with the hepatomegaly or splenomegaly, or both, would be another example of a mass being the initial presenting factor. About one-third (31%) of the total series came to medical attention because of a mass.

An example of the most common symptoms directly referable to the mass in a child would be headache, vomiting, and gait disturbance as the clinical picture of a central nervous system tumor. A child who complained of pain and who limped because of an osteogenic sarcoma would present another example. Of patients in the series, 48% exhibited evidence of the fact that a malignant tumor underlay their symptoms.

Nonspecific Symptoms.—The group of those who had only nonspecific symptoms, which might easily be explained as transitory and of no importance, still constituted one of every five (21%) cases of malignancy. Anorexia, listlessness, weight loss, pallor, and ecchymosis are examples of such symptoms in a child first seeking medical attention.

Diagnostic Errors.—Because of the vague and nonspecific complaints that many of the tumor patients showed, it was not surprising to find a high incidence of wrong initial diagnosis. One hundred fourteen (28%) patients in the total series were not given a diagnosis of malignant disease on admission. To get a perspective on what were the common wrong first diagnoses, these were grouped wherever reasonable. The principal wrong first diagnosis was that of an upper respiratory infection (25%); second in occurrence was rheumatic fever (13%); the third most common error was in patients in whom abnormalities of the spleen were suspected (6%); and erroneous diagnoses of poliomyelitis, meningoencephalitis, and appendicitis each accounted for 4%. The rest of the diagnostic errors were too miscellaneous to permit such grouping. Table 2 shows the type of malignancy connected with the highest incidence of diagnostic error; Hodgkin's disease and neuroblastoma were the most common malignancies in which difficulties in diagnosis led to initial error.

Management

In treating children with malignant disease, one must use certain philosophical principles peculiar to the age group with which one is dealing. Since a child has a lifetime before him, there is little purpose in any type of palliative therapy as the initial approach to his malignant disease. An all-out effort must be made to eradicate the disease process. In our analysis it was found that 298 of 317 patients who died of their disease did so within a two-year period, and the highest proportion of these died in the first year. We therefore must attempt to eliminate the source of malignancy by aggressive therapeutic efforts, even at the price of what seems like a mutilating procedure. It is remarkable how children adapt to the loss of extremities or of the use of certain organs. It is equally true that, in our present state of knowledge, surgery is the main therapeutic agent at our command in the treatment of all of the malignant processes except the leukemia-lymphoma group.

There is an element of urgency in the handling of children with malignancy that is perhaps not as apparent in adults. One never knows which is the day of metastasis as far as a tumor is concerned, and therefore extensive study, with much palpation of a mass, would seem to be detrimental to the child's chances for survival. Therapy should be undertaken as soon as possible after studies have been completed.

A high degree of suspicion must be maintained in the management of undetermined childhood disease, if the wrong first diagnosis is to be eliminated in the case of malignant disease and if these children are to be given maximum therapy at the earliest possible time. Any solid tumor must be considered malignant until histologically proved otherwise. Time and again, application of this familiar adage, when aggressively followed up by biopsy (*in toto* where practicable), has discovered unsuspected malignancies. A child with vague history and multiple symptoms must not be written off as a "behavior problem" but must be watched closely, since these symptoms may be a precursor to out-and-out malignant disease.

TABLE 1.—*Incidence of Cancer in Children by Age and Organ System*

	404	114	28

Results

One does not treat children with cancer long before several facts become apparent. There is a much shorter period of time between the onset of symptoms and the ultimate diagnosis of the child's condition in most cases, compared to malignancies in adults. Perhaps of greater significance is the fact that short-term survival is the rule, if patients are not totally cured of their disease process. This can be readily seen in table 3, which shows the over-all life and death figures in our series. Of the total group of 404, 317 were dead at the time of follow-up survey, an over-all mortality of 80%. Of great importance, and certainly significant, is the fact that 75% of those who died from their malignant disease were dead at the end of the first 12 months. Certainly cancer is an early killer in childhood if it is not completely cured initially.

---

[*] 8 patients were unavailable to follow-up investigation.

Of the 79 patients who survived their malignant disease, 20% were alive less than two years after a cancer diagnosis had been made, while an additional 40% were alive two to four years after diagnosis, and a final 40% were alive longer than four years after malignancy was discovered.

Pathology and Survival.—Table 3 also shows that those childhood tumors which had the best prognosis were Wilms's tumor, astrocytoma, carcinoma of the thyroid, and fibrosarcoma. Admittedly, only Wilms's tumor and the astrocytoma occurred in a sufficient number to permit any statistical inferences. Forty-two per cent of patients with Wilms's tumor were alive at the time of the survey, and the greater proportion of these had survived for more than four years. Among the patients with astrocytoma, a 73% survival rate was written into the record and all of these had survived more than two years. Juvenile cancer of the thyroid was of the papillary type in all seven patients, and six out of the seven survived for more than two years. All four patients with fibrosarcoma also were alive at the time of survey. Since 94% of those who died of their malignancy had died by the end of 24 months, it is interesting that a high percentage of the patients with these four types of tumor not only survived but had passed the critical period of the first two years.

One must look at the other side of the coin to get a true picture of the relationship of the pathology and mortality. All but three of the patients with leukemia and Hodgkin's disease were dead at the time of survey. In addition, two-thirds of the patients with bone tumors had died and the remaining one-third had not had sufficient time elapse to finally evaluate their condition. Only 13% of patients with medulloblastomas and only 19% of those with an assortment of 32 other central nervous system malignancies were alive. Even in those with the heterogeneous group of miscellaneous malignancies, survival was found in only one-third of the cases. Finally, among patients with neuroblastoma, which some writers have believed to carry a better prognosis than other malignancies, there was an 86% mortality in the total group of 51 patients.

Age at Onset.—Table 4 depicts the relation of the age at onset of malignancy to the ultimate mortality figures in the major subgroups of cancer patients studied. The significant fact here is that age at onset seems to play little or no part in the over-all mortality figures, except in the case of the patients with Wilms's tumor and, to a smaller degree, with neuroblastoma. The earlier the onset in these two groups, the better the prognosis; this was particularly true if the age at onset was under 1 year. The rest of the data show little difference between those who developed their disease early and those who developed it later. However, patients with central nervous system tumors seem to have a somewhat better prognosis if they were 4 years of age and older when they had their diagnosis made.

[*] A = alive; D = dead.

Follow-up Data

It was gratifying to be able to have follow-up data on 98% of patients in this total series of 404 cases. Follow-up investigation was carried out by reference to hospital charts, by personal knowledge or visit, and by correspondence with families and with other physicians. Among the eight patients whose progress it was not possible to follow, there were three with central nervous system tumors, two with leukemia, two with Wilms's tumor, and one with malignant disease in the miscellaneous group.

Among the 79 patients who were alive at the time of the survey, 5 had evidence of disease. (All ages given are those at time of diagnosis.) One was a 12-year-old boy with carcinoma of the thyroid; he had survived over four years since his original diagnosis and had some evidence of nodulation in the neck. Another carcinoma of the thyroid was in a 7-year-old girl who likewise had survived more than four years since the diagnosis was made; the continuing disease was in the form of roentgenographically visible, asymptomatic lung metastases. A third patient, with a cerebellar astrocytoma, was a 5-year-old boy, and there was local evidence of disease although he had survived over four years since operation. The fourth patient with malignancy still present was a 14-year-old girl who had a mesenchymal mixed tumor of the abdomen diagnosed by biopsy four years previously, with evidence still present of an abdominal mass but no distant metastases. The final patient was a child under one year of age who had a rhabdomyosarcoma of the labia; the patient was unable to have curative surgery performed initially because of the local invasion of the tumor. The recurrence was in the immediate area and extended into the pelvis as an abdominal mass.

Unusual Survivals.—Ten patients in the survival group had unusual histories. Among survivors with central nervous system tumors was one with craniopharyngioma who was alive four years after having his pituitary lesion removed; the only residual difficulty was from diabetes insipidus. In addition, a 10-year-old girl had a medulloblastoma which was treated with excisional surgery and nitrogen mustard; she had been alive for eight years, was married, and, at the time of follow-up, was pregnant for the first time. A pineoblastoma in a 9-year-old girl was apparently successfully removed, for she had survived well over four years but unfortunately was blind.

Among the patients with abdominal neoplasms who have had unusual survivals was an 11-year-old boy with hypernephroma; he had survived over four years. Two patients had histologically demonstrated malignant pheochromocytomas. One was a 12-year-old girl, symptom-free and with no evidence of a lesion four years after surgery, and the other a 6-year-old girl with severe hypertension and what seemed to be an incomplete removal of her malignancy. She was well for two and one-half years with normal blood pressure. One patient with Wilms's tumor, a girl under one year of age at the time of surgery, subsequently had cerebellar metastases which were removed a year after the first operation; her follow-up investigation at the age of 10 years showed her to be completely well.

Three patients with soft tissue malignancies, in which one does not usually expect survival, were of interest. A 5-year-old boy with reticulum cell sarcoma and a 14-year-old boy with giant lymphoblastoma were both living and well two to four years after surgical extirpation. Finally, in a 3-year-old boy with a lymphosarcoma of the nasopharynx excised five years ago, there was no evidence of disease locally or systemically at the time of follow-up investigation.

Summary

A series of 404 children with malignant tumors, seen at the Children's Hospital of Pittsburgh, was analyzed from the standpoints of age incidence, diagnostic leads, management, and results. A six-and-one-half-year survey of malignant disease showed an 80% over-all mortality, with three-quarters of these deaths occurring in the first year after diagnosis.

125 Desota St. (13) (Dr. Kiesewetter).

FEEDING BY INJECTION.—Considered from the standpoint of cellular nutrition, there is little reason to doubt that the needs for various nutrients both in kind and amount are fairly similar whether provided by enteral or parenteral means. The latter differs mainly in that problems concerned with toxicity and availability are accentuated, and in addition the requirements of sterility and non-pyrogenicity are imposed. The fundamental challenge has therefore not been to discover what nutrients are required, but rather how to provide them in suitable forms and amounts. From both experimental or practical standpoints this involves all necessary nutrients, although whether all are employed in practice is a matter of judgment in each particular application.—R. P. Geyer, Parenteral Nutrition, *Physiological Reviews*, January, 1960.

GAS AND OPAQUE CONTRAST IN ROENTGENOGRAPHIC DIAGNOSIS OF PERICARDIAL DISEASE

Herbert M. Stauffer, M.D., Louis A. Soloff, M.D., Jacob Zatuchni, M.D.
and
Barbara L. Carter, M.D., Philadelphia

Differential diagnosis between pericardial disease and other heart conditions has been facilitated by angiography. The hazards of intravenous injections of radio-opaque contrast materials can be avoided by injecting pure carbon dioxide gas. This dissolves rapidly and completely in the blood after serving its purpose. Numerous rapid intravenous injections of 25 to 100 cc. of 100% carbon dioxide have been made in adults without causing subjective discomfort. The apparatus, before the injection, must be flushed thoroughly several times with the gas. The technique of gas angiography described by the authors was used 51 times in 40 patients. With the patient in left lateral position the right atrial border was visualized, which gave positive evidence of disease in 21, normal findings in 18, and equivocal results in 12 cases. In none of the patients studied were there any untoward reactions.

The clinical signs and symptoms, laboratory findings, and roentgenographic changes in pericardial disease are familiar and have been well described. However, the findings from conventional roentgenograms in both pericardial effusion and constrictive pericardial disease are frequently equivocal. Even massive pericardial effusions may at times be difficult to distinguish from cardiac enlargement. Angiocardiography with opaque contrast material has become well recognized in the elucidation of problems in the diagnosis of pericardial disease.[1]

Several years ago one of us, with others,[2] introduced a new method of angiography specifically for studying pericardial disease by outlining the lateral border of the right atrium with intracardiac carbon dioxide gas, which was introduced intravenously. Another group[3] has recently reported favorably on experience with this same technique. This present communication is an evaluation of the relative merits of opaque and gas contrast angiography in the study of problems of pericardial disease in the light of our accumulating experience with the gas contrast method.

Safety of Intracardiac Carbon Dioxide Gas

The studies of Durant and Oppenheimer and their associates[4] established the efficacy of placing the patient with the left side down in the treatment of venous air embolism. In this position, the outflow tract of the right ventricle and the trunk of the pulmonary artery remain dependent and contain blood even though the upper portion of the right ventricle contains gas, so that the blood flow to the lungs and the systemic circulation are maintained. Roentgenograms of dogs' hearts, made during the course of these experimental studies, showed details of intracardiac structures to good advantage. This led to trials of intracardiac carbon dioxide gas injected intravenously for roentgenographic study of the heart. The gas proved to be quite safe for this purpose because of its high coefficient of solubility in blood, which permits it to go rapidly into solution with only fleeting cardiovascular effects. With rapid injection either intravenously or by cardiac catheter the gas remains long enough for roentgenographic visualization of cardiac structure of the right side of the heart.

Studies in dogs[5] showed that large volumes of carbon dioxide gas injected intravenously rapidly (7.5 cc. per kilogram of body weight) produced only a brief decrease in systemic blood pressure, whereas the injection of air causes a prolonged decrease which often causes death. With intravenously injected carbon dioxide there was a brief hypotension and hyperpnea which lasted about 15 seconds. Probably the brief hypotension caused the hyperpnea, since arterial blood and alveolar gases showed only a small deviation from control values. The oxygen level was decreased 0.3 vol. %, and the carbon dioxide level was increased 2.87 vol. %. Alveolar gas levels showed alterations of similar degree. The right ventricular diastolic pressure was increased for 15 seconds when the dog was in the supine position. In all positions the right ventricular systolic pressure was elevated somewhat longer than 15 seconds. The short period of systemic hypotension with high right ventricular systolic pressure resulted from the brief increase in resistance during the time that gaseous carbon dioxide persisted.

Carbon dioxide administered into the left ventricle of dogs by retrograde catheterization produced only slight cardiovascular respiratory changes. The electrocardiogram showed a few extra systoles and an alternans of a few seconds duration. Air injected similarly into the left ventricle killed the dogs to whom it was administered.

From the Departments of Radiology and Medicine, Temple University School of Medicine and Hospital.

Read before the Section on Radiology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

The effects of carbon dioxide gas injected intraenously and reaching the left side of the heart hrough an experimentally created atrial septal deect were studied.[6] After such injections gas was emonstrated in both the left atrium and left venricle as well as in the right side of the heart. Under hese circumstances carbon dioxide gas proved to e quite safe for the experimental animals.

Oppenheimer and associates[7] have also recently hown that carbon dioxide gas is well tolerated hen introduced directly into coronary arteries of nesthetized dogs. They used the selective coronary rtery catheterization technique of West, which ermits evaluation of cardiac effects in the absence f systemic action. There were no deaths of patients ith either normal or freshly infarcted hearts. No ersisting changes in the electrocardiogram of lood pressure were produced when the gas was njected slowly over a period of several seconds. apid injections under pressure produced short ns of extra systoles and changes in the T wave hich lasted for a few seconds.

Repeated intracoronary injections of potassium ere used to produce lasting S-T segment deviaon. Intracoronary injections of carbon dioxide gas id not increase, but rather temporarily abolished, e S-T segment deviation.

Numerous rapid carbon dioxide injections have een made intravenously in adults with volumes of 5 to 100 cc. without any subjective discomfort. In o such patients, who received 50 and 60 cc. of rbon dioxide gas, respectively, simultaneous right ntricular pressure determinations by heart cather and electrocardiograms showed no significant teration. These patients were examined in a suine position, and films made with the biplane ngiocardiographic apparatus showed the outflow act of the right ventricle and trunk of the pulonary artery outlined by gas.

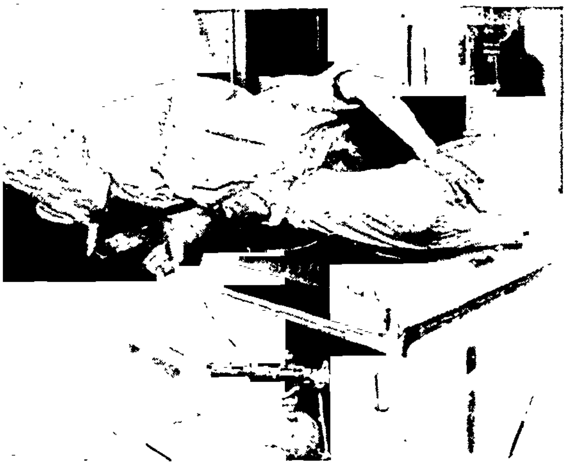

Fig. 1.—Left-side-down position of patient against x-ray ssette changer for intravenous carbon dioxide pericardial udy.

Carbon Dioxide Technique for Pericardial Study

Method.—When the carbon dioxide technique is used for pericardial study, the patient is placed with the left side down and the x-ray beam is horizontal. When the right atrium contains gas its lateral wall appears in the frontal projection as a smoothly curved band, convex laterally, not more than 3 or 4 mm. in thickness under normal circumstances. When pericardial effusion is present a soft tissue shadow appears between that of the right atrial wall and the lung so that a widened band of soft tissue density intervenes between the gas in the atrium and the lung. It has been previously pointed out that this position is the one indicated for the treatment of air embolism. As a further precaution to eliminate any possibility of hazard from a residual bubble, we advocate that the patient be kept in the left-side-down position for 5 to 10 minutes after the last carbon dioxide injection.

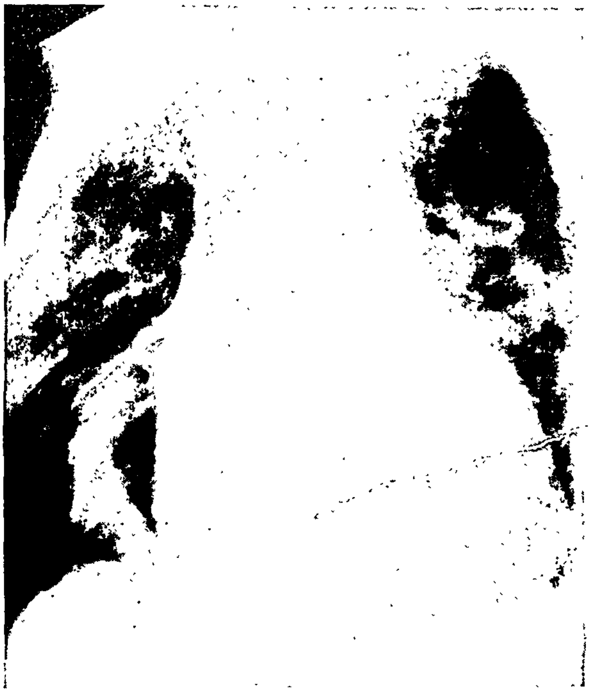

Fig. 2.—Pericardial effusion in heart failure shown by carbon dioxide gas in right atrium.

For the gas angiocardiogram, 100% carbon dioxide has been used. One should be sure that the tank contains pure carbon dioxide and not the usual mixture of carbon dioxide and oxygen available in the hospital. The patient is placed in the left lateral decubitus position, and a 19 or 20 gauge needle is inserted into the median antecubital vein (fig. 1). The needle is connected to an intravenous drip via a three-way stopcock so that the needle can be kept open in the intervals between gas injections. A 100-cc. syringe with another three-way stopcock is thoroughly flushed several times with pure carbon dioxide, and 100 cc. of the gas is then rapidly injected into the vein. An exposure is made at the end of the injection, and a second exposure is made within a few seconds thereafter. The films are checked while wet after processing, and a second injection is made if indicated.

This technique has been adhered to because of our desire to test carbon dioxide visualization in the simplest possible form as a readily available method. The technique of using one or two films, although very simple, has resulted in some difficulties in interpretation which we believe would be obviated by the use of cineradiography or the serial filming technique regularly used with opaque angiocardiography.

Results.—We have done 51 studies of carbon dioxide injection in 40 adult patients with problems of pericardial disease. The volumes injected have varied from 50 to 100 cc. Twenty-one of these studies gave positive evidence of pericardial effusion or pericardial thickening. Eighteen showed negative or normal results with respect to the right atrial border of the heart, and in 12 the findings were regarded as equivocal. In none of the patients studied were there any untoward reactions.

The availability of the carbon dioxide technique has made it possible to undertake a study of the contribution of pericardial effusion to the enlargement of the silhouette in cardiac failure.[8] Nineteen of the patients mentioned above received carbon dioxide injections as part of a preliminary study of this problem. Seven of these patients were demonstrated to have pericardial effusion (fig. 2), in eight the examination showed negative findings, and in four the findings of the carbon dioxide study were equivocal. In the patients with definite evidence of pericardial effusion, review of the original conventional films failed to show distinctive features which would permit the diagnosis of pericardial effusion. It is of interest that reduction in the size of the cardiac silhouette occurred with appropriate treatment for cardiac failure regardless of whether or not pericardial effusion was demonstrated. Also, severe peripheral edema was observed in the absence of pericardial fluid and, conversely, pericardial effusion was noted with only minimal peripheral edema. It is hoped that extension of these studies will provide information of prognostic value.

Scatliff, Kummer, and Janzen[3] have recently reported encouraging results with this carbon dioxide technique in the demonstration of pericardial abnormality. They carried out 19 injections in 16 patients with no serious complications. One patient developed paroxysmal coughing on being turned on his back after the injection of the gas when he was in the left-side-down position. It is not known whether the gas injection was actually directly responsible for this complication.

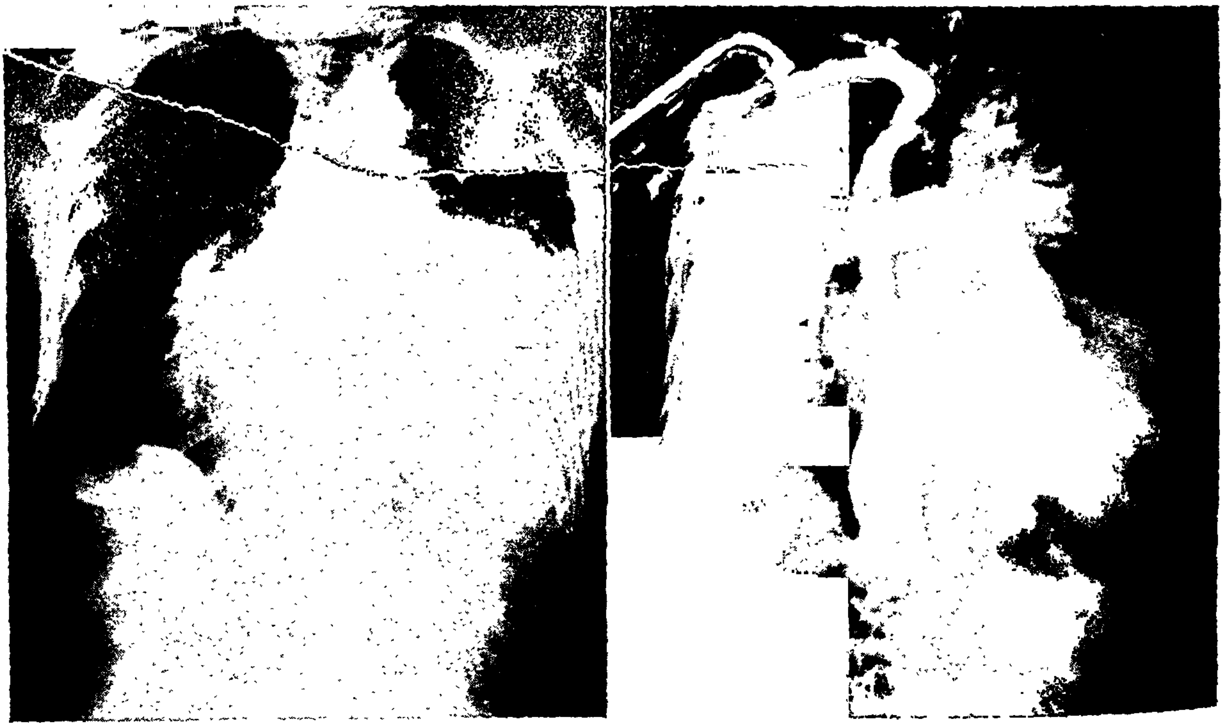

Fig. 3.—Angiocardiogram in massive pericardial effusion.

Relative Merits of Carbon Dioxide and Opaque Angiocardiography

The carbon dioxide technique outlined above for the study of pericardial problems has been demonstrated to be convenient and safe. It may be carried out with the ordinary equipment available in any radiology department. There is minimal trauma to the antecubital vein, since only a small needle need be used. The gas does not irritate the vein. Patients experience no unpleasant sensation with the carbon dioxide injection. On the other hand, opaque contrast material in the high concentrations required for angiocardiography is irritating and may cause vein occlusion; a cutdown is often required for the injection. While improvements in the radio-opaque drugs used for angiocardiography have minimized the hazard due to sensitivity in their use, severe reactions may still occasionally occur. There is no reason to anticipate a sensitivity hazard in connection with the use of carbon dioxide intravenously.

The carbon dioxide contrast technique is particularly valuable in seriously ill patients where a simple nontraumatic and nontoxic method may be vital to demonstrate or exclude pericardial effusion. The treatment is well tolerated even by the acutely ill patient, and it may be used repeatedly to check on the effectiveness of therapy. Although the carbon dioxide method will usually demonstrate the presence of a free pericardial effusion, it does not effectively demonstrate effusions localized elsewhere than over the right atrial border. Similarly, the selective carbon dioxide study permits only a very rough estimate of the size of a free effusion from the thickness of the band of density above the gas in the right atrium. It throws no light on possible cardiac dilatation in association with pericardial effusion. The complete opaque angiocardiogram provides information on these points by showing the relationship between all of the cardiac chambers and the total central mediastinal silhouette (fig. 3).

In constrictive pericarditis there may be characteristic angiocardiographic findings of the kind described by Figley [1a] and by some of us.[1d] These consist of deformity of the right atrial border with loss of the normally smoothly convex contour accompanied by rigidity, which may be demonstrated by the consecutive angiocardiographic films. That such deformity of the right atrial border can be brought out by the carbon dioxide technique is illustrated in figure 4, in which the findings of opaque and gas contrast angiography in the same patient with constrictive pericarditis are compared. The simplified one-or-two-film carbon dioxide technique will not permit recognition of rigidity of the right atrial border. However, such immobility can be demonstrated with carbon dioxide just as with opaque contrast material, provided a serial filming or cineradiographic technique is used. We have encountered one case in which the carbon dioxide study showed a smoothly rounded normal curvature of the right atrial border with some thickening of the wall, which suggested either a small effusion or thickened pericardium. A cineradiographic study was also carried out with carbon dioxide. It showed that the thickened border over the right atrium was quite immobile, which indicated the presence of constrictive pericarditis. This condition was subsequently found on surgical exploration.

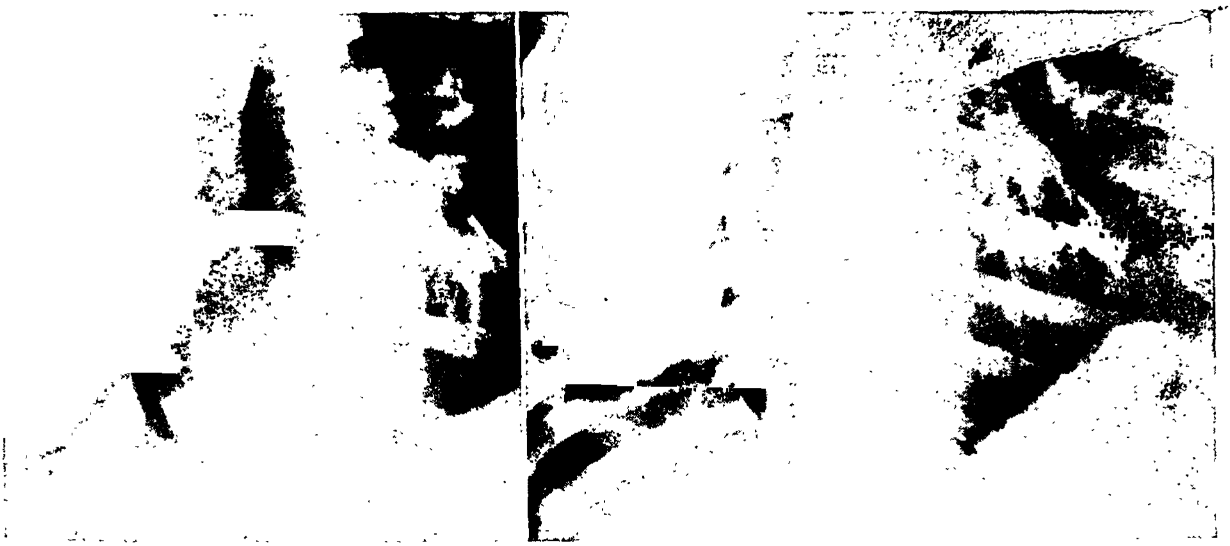

Fig. 4.—Constrictive pericarditis deforming right atrial margin. *Left,* opaque angiocardiogram. *Right,* carbon dioxide study.

Functional information may be obtained by observation of the pattern of flow of intracardiac opaque contrast material in conventional angiocardiography.[9] Thus, the observations of some of us indicate that in pericardial disease prolongation of the intracardiac circulation time is suggestive of underlying myocardial involvement.[1d] Occasional difficulties in interpretation have arisen in using the carbon dioxide technique with one or two films. Extraneous lung markings or pulmonary vessel shadows may sometimes be difficult to distinguish from the right atrial border. An enlarged left atrium may protrude beyond the right heart border and simulate pericardial effusion or thickening of the pericardium. With opaque angiography such overlying structures as the enlarged left atrium and adjacent vessels are outlined with the contrast material and ordinarily do not give rise to confusion. Irregular mixing or streaming of iodide solutions may occasionally occur in the right atrium in opaque angiography and simulate effusion. Evaluation of the pericardial thickness in the presence of pleural effusion, pleural thickening, or extensive abnormal density in the adjacent lung may be difficult or impossible with either gas or opaque angiography.

Conclusions

Intravenous carbon dioxide injection can be safely and conveniently used for roentgenographic demonstration of free pericardial effusion or pericardial thickening localized over the right atrium. Subject to the limitations described, gas contrast study is a useful adjunct to opaque angiography in the study of pericardial disease. It is of particular value in very sick patients or in those needing only a cursory study of the pericardium. Opaque angiocardiography should be done when a more complete study is indicated, particularly for evaluating underlying heart disease. If the findings of gas contrast study prove equivocal, opaque serial angiocardiography may be expected to provide complete morphologic information about the heart chambers, and the flow pattern may provide evidence of underlying myocardial involvement.

PENICILLIN IS A POTENT DRUG.—Penicillin causes more deaths than any other drug. Deaths from immediate reactions to penicillin continue to occur. Seven hundred and fifty tons of penicillin are produced and consumed annually. In 1956 Feinberg & Feinberg . . . estimated that more than 1,000 deaths had already occurred from penicillin. Welch and associates . . . in their excellent paper on "Severe Reactions to Antibiotics" surveyed 800 hospitals and interviewed 1,600 physicians, comprising ⅓ of the hospital beds in the United States. They recorded 2,517 reactions to penicillin. Of the total number of reactions 901 were considered life threatening. There were 83 deaths representing a mortality rate of 9 per cent of the latter. None of these 83 deaths had been recorded in the literature. Penicillin was responsible for 84 per cent of the antibiotic reactions. . . . In anaphylaxis, death comes quickly. Aqueous epinephrine (1:1,000) stands alone as the only drug acting quickly enough and effectively enough to prevent it. Our admonition is to give 1.0 cc. subcutaneously at once at the first suspicion of any systemic reaction. This may be repeated as needed.—T. G. Johnston, M.D., and A. G. Cazort, M.D., *Prevention of Deaths from Penicillin*, *Journal of the Arkansas Medical Society,* November, 1959.

ROUTINE CARDIAC FLUOROSCOPY—AN UNNECESSARY HEALTH HAZARD

Eliot Corday, M.D.
and
Henry Jaffe, M.D., Beverly Hills, Calif.

No amount of ionizing radiation, however small, should be considered inconsequential to the patient, to the physician and others engaged in radiologic work, or to their posterity. Young persons especially should be protected against needless exposure. Fluoroscopy involves considerable exposure. This can be reduced by a number of precautions here described. Fluoroscopy should not be allowed to become routine, and when it is necessary it should be preceded by a study of roentgenograms so that the fluoroscopist can concentrate his examination on specific areas and reduce the exposure.

The danger of exposure of patients, physicians and technicians to radiation during diagnostic roentgenographic procedures has become a problem of increasing importance.[1] Thus, the National Committee on Radiation Protection has made the following statement:[1e] "The increasing use of ionizing radiations make it necessary for the medical profession to exercise great caution and restraint in the use of these agents. Current methods in practice should be reviewed to see if the same results could be obtained with less radiation." Swenson[1h] has said: "We must use the lowest radiation output possible remembering that any radiation one gets unnecessarily is too much." He also states[1h] that we must always ask ourselves the question, "Is this examination necessary? Is the need for the procedure greater than the hazard, small though it might be?" Because of the high radiation output during fluoroscopy, many radiologists recommend that this procedure should be used only when absolutely necessary, especially since more accurate results may be obtained by other techniques with a smaller radiation dosage.[1m] Fluoroscopy is one of the most widespread diagnostic procedures used by physicians in the United States. About one-half of all fluoroscopic examinations are conducted by nonradiologists.

The chief reason for the popularity of fluoroscopy is, of course, that it is simpler to carry out than x-ray film procedures. Furthermore, the results are seen immediately; no time need be spent in developing films. The fluoroscopic unit does not require much space and can fit into a small room; the x-ray film unit requires more floor space. In many physicians' offices, space is limited and room for a full x-ray unit is not available. Another reason fluoroscopy is popular in present practice is that expensive x-ray film is not needed for it. Manufacturers have developed compact x-ray units and developing tanks, and many offices now could have these units installed in a limited floor space. Many clinicians continue to use the fluoroscopic unit without proper precautions, knowing full well that they are apt to obtain radiation burns from their fluoroscopic unit (see figure).

I have recently discussed this problem with a renowned diagnostician whose fingers had been badly burned through the use of fluoroscopy. Even though this authority has required skin grafting because of injury to his fingers from radiation, he continues to use fluoroscopy in his routine examinations because he does not have sufficient floor space to install an x-ray film unit. An x-ray film unit would reduce the amount of radiation to which this diagnostician would be exposed.

Danger of Radiation Exposure

The dangers of exposure to ionizing rays are both gonadal and somatic. It has been demonstrated that when gonads are exposed to primary or spray radiation, mutations in the offspring and even temporary sterilization may result. Permanent sterilization of the ovary will occur with a radiation exposure of 300 r and retardation of bone growth in infants with an exposure of 150 r.[11] For this reason, it is necessary that both the x-ray tube and the fluoroscopic screen be well shielded so that exposure of the gonads is minimized. The hazards of a somatic nature resulting from radiation are the possible induction of malignancies such as leukemia, epithelioma, depression of the bone marrow, depilation, ulceration, and dermatitis.

It is difficult to assess what the safe exposure level may be. The National Committee of Radiation Protection[1e] has recently recommended a maximum permissible dosage of radiation to occupational workers and radiologists. It was stated that the average maximum permissible yearly dose should not exceed 5 r. The maximum permissible dose for various age groups has also been estimated. For persons under the age of 18 years who are exposed nonoccupationally to radiation in

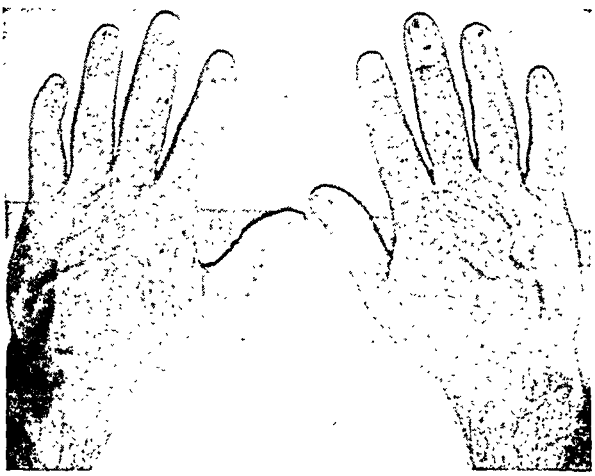
---

Assistant Clinical Professor of Medicine, University of California at Los Angeles, and Co-chief of the Cardiac Clinic, Cedars of Lebanon Hospital (Dr. Corday), and Professor of Radiology, University of Southern California, and Chief of the Department of Radiation Therapy, Cedars of Lebanon Hospital (Dr. Jaffe).

Read before the Section on Radiology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

the course of their normal activities but not at their jobs, protective measures should be taken to make sure that they receive no more than 1.5 r. per year. Of course, these dosages were calculated for total body exposure.

It must be realized that during a fluoroscopic examination of the patient, only part of the body is exposed and this would limit the amount of exposure even though spray radiation may occur. Recent investigators have calculated the fluoroscopic radiation dosages the patient receives during a routine examination. Miller [1d] states, "If the duration of the examination is two to five minutes, the dose would ordinarily be 20 to 100 r at the point of entry into the body." For the purpose of comparison, we may mention that the doses given therapeutically for inflammatory conditions, such as furuncles, or thymic conditions are around 50 to 100 r.[11] In other words, the average radiation to which the patient and the fluoroscopist are exposed is in the range of that used in roentgen therapy.



Dorsum of hands of a 52-year-old pediatrician after 25 years of exposure to routine office fluoroscopy. Photograph demonstrates multiple premalignant keratoses as well as atrophy of skin and telangiectasia. Hardening and discoloration of fingernails is also evident.

It has been estimated that taking an anteroposterior and lateral chest x-ray film exposes the patient to as little as 0.002 to 0.005 r.[2] In other words, *the patient will receive about 0.001 of the* fluoroscopic radiation dose during the routine chest x-ray.

In order to reduce the patient's exposure to the minimum, therefore, it would be of advantage to use roentgenography when possible.

Methods of Reducing Radiation Exposure on Fluoroscopy

Because the dosage varies as the time of exposure of the radiation, measures must be taken to reduce the time that the patient is exposed to the radiation. As is well recognized, detail may be more readily seen and the exposure time may be reduced if the fluoroscopist's eyes are accustomed to the dark before the fluoroscopy. For this reason, the fluoroscope should not be used until the fluoroscopist has been in the dark for at least a 15-minute period. Of course, *if the practicing physician has* become accustomed to the dark for 15 minutes prior to each examination, it is obvious that the time allotted to this procedure would cause the cost of fluoroscopy to far exceed the cost of a simple x-ray film.

If he first studied scout films, the fluoroscopist would be aware of the cardiologic or pulmonary problems prior to the fluoroscopy and thus could reduce the time of exposure to the fluoroscope. For instance, if x-ray films demonstrated a mass in the mediastinum prior to fluoroscopy, the investigator could immediately focus on this disturbance and study its movement. The fluoroscopic screen should be shuttered to the minimum aperture. By so doing, the fluoroscopist will receive the minimum amount of exposure. The fluoroscopist must always be clothed in a protective gown and gloves which reduce the amount of exposure.

Comparative Accuracy of Fluoroscopy and Film Examination

Sherman and Cahan [1m] state: "No morphological lesion is revealed fluoroscopically that could not be better shown by film. The basic fault is that fluor*oscopy as a detection or screening* procedure is inaccurate and inferior by comparison with the corresponding film coverage." It has been demonstrated that fluoroscopy can demonstrate only relatively large structural abnormalities whereas roentgenographic examination [3] can reveal smaller ones also. For example, a water density 3 mm. in diameter is often detectable in the lungs by roentgenography whereas a lesion of similar nature must be 5 to 10 times that size before it is regularly visible by conventional fluoroscopy, even under ideal conditions.[3] Many serious lesions readily demonstrable by film examination are impossible to detect fluoroscopically.

One of the most serious disadvantages of the fluoroscopic examination is its impermanence. No record remains except in the memory of the examiner and perhaps in sketches or diagrams which he may make. These cannot compare in accuracy and availability with the permanent record provided by a roentgenogram. Furthermore, several roentgenograms may be compared side by side at any time.

Fluoroscopy has the further disadvantage that it must be done hurriedly in order to minimize the time of exposure of both patient and physician. Roentgenograms, on the contrary, may be examined and studied carefully and deliberately. In addition, they are always available for the opinion of a colleague or consultant.

Sherman and Cahan [1m] state: "When it is indicated, fluoroscopy can be kept to an absolute minimum only when it is integrated with or follows filming. A directed fluoroscopic study based on prior films permits smaller fields and more rapid judgement. When the same information can be obtained by film, fluoroscopy should never be used."

Indications for Fluoroscopy of the Chest

Knowing that the patient and the fluoroscopist should be exposed to as little radiation as possible, we must reexamine the indications for cardiac fluoroscopy and ask ourselves if there are other ways of obtaining the same information with less radiation. Many radiologists[4] have recommended that the routine or isolated cardiac fluoroscopy be abandoned and that this procedure be used only if the posteroanterior and lateral roentgenograms reveal some cardiac abnormality that requires further investigation. Many[5] have stated that posteroanterior and lateral roentgenograms of the chest will reveal most of the cardiac abnormalities that may be found on fluoroscopy. The radiation to which the patient is exposed is 0.001 of that to which he is exposed during routine fluoroscopic examination. On the other hand, many cardiologists believe that by studying the motion of the heart they have a better understanding of the patient's problem. Their reasons for this belief are difficult to express, which makes one wonder if they are valid.

Actually, there is little to be observed from the motion of the heart that cannot be observed from the routinely taken roentgenogram, except paradoxical pulsations due to ventricular aneurysms, the hilar dance, and movement of the diaphragm. However, the accuracy of the interpretation of the movements of the heart depends on the ability of the fluoroscopist, and more accurate information may be obtained by either the roentgenkymogram, which is a graphic photograph of the degree and direction of movement of the heart, or with the new cinefluorographic technique. Aneurysm of the ventricles can also be suggested by abnormalities shown in an electrocardiogram. Rigler[1n] has made the following statement.

> Fluoroscopy is of value in determining the amplitude of pulsation of the pulmonary artery and its major branches; however, the conventional chest x-ray or Roentgenogram will usually reveal such enlargement of these structures as to indicate clearly that a shunt is present. In a differential diagnosis of post-stenotic dilatation of the pulmonary artery and primary pulmonary hypertension, it may also be of some importance. Fluoroscopic examination for aneurysm of the aorta requires a great deal of radiation exposure because movements of the mediastinum are difficult to visualize. The Roentgen-kymogram will also demonstrate aneurysm of the aorta with much less exposure and more certainty.

A search for calcification of the valves may indicate a need for fluoroscopy, but the calcification can also be demonstrated by special x-ray techniques which require far less exposure to radiation. Fluoroscopic visualization of the barium swallow is often used to demonstrate encroachment on the esophagus by an enlarged left atrium. This information may also be obtained with the barium swallow with the right anterior oblique roentgenogram. Chamber enlargement may be discovered from routine posteroanterior, lateral, and oblique chest films as efficiently as with cardiac fluoroscopy. Electrocardiograms may demonstrate chamber enlargements more accurately than radiologic methods.

The fluoroscope vividly reveals paradoxical movement of the diaphragm, but paralysis of the diaphragm can also be demonstrated by chest films made during maximum inspiration. In summary, there is little information obtainable from fluoroscopy of the chest that cannot be learned from routinely made films of the chest with greater accuracy and much less exposure to radiation.

Cinefluorography

This new technique, which has now been made practical, exposes the patient to far less radiation because of intensifier screens. It records the image with a motion picture camera.[6] Thus, the physician using this technique has the advantage of having permanent records that may be studied time and again without repeatedly exposing the patient to radiation. The image, when projected on the motion picture screen, is many times larger than that seen on the fluoroscopic screen, so that details of the movements of the heart and other structures may be more accurately determined. Cardiac catheterization teams are exposed to large amounts of radiation, and most of the members of the teams studied in our survey that are working with the fluoroscope have developed signs of excessive exposure, such as depilation and splitting of finger nails. The use of the intensifier screen and cinefluorography is definitely indicated for this group of dedicated workers.

Summary and Conclusions

Every physician ordering or using ionizing radiation has the moral responsibility of keeping the exposure of patients to a minimum. Warren has recommended, "If each physician would ask himself before ordering the diagnostic procedure 'Is this really necessary' much unnecessary radiation could be avoided."[11] Many patients believe that the examination is not complete unless the fluoroscope has been used. In some instances, fluoroscopy has been used during each visit of the patient. The clinician must realize that this practice is improper and should be curbed. The patient's demands should not dictate the type of examination. The old axiom that every patient presenting himself to a physician, regardless of his condition, ideally should have a fluoroscopic examination of the chest is now outmoded.

Where possible, roentgenograms of the chest should be routinely used prior to cardiac fluoroscopy and the fluoroscopic examination should be used only when there is a definite indication that cardiac or pulmonary abnormalities require further study. "No amount of radiation, however minute, can be considered entirely inconsequential to the individual and the race."[1m] For this reason, fluoroscopic screens must be used at a minimum aperture, the unit should be checked to be sure that it does not overexpose the patient to radiation, the fluoroscopist must always accustom his eyes to the dark so that the exposure time is minimized, and roentgenograms of the chest should always be made prior to the fluoroscopy so that the fluoroscopist may concentrate his examination on specific areas. Because of the increased danger of gonadal changes in children, radiation of younger persons should be very limited.

PATHOGENESIS OF CORONARY ARTERY DISEASE

M. Jay Flipse, M.D., Miami, Fla.

Many aspects of the pathogenesis of coronary artery disease remain to be clarified, and particular interest centers on the metabolism of fats. The author has studied the reactions of patients to different diets by standard chemical studies of total lipids, phospholipids, and cholesterol in the blood and also by a study of the particle-size of the liproproteins of the blood. The results led to the conviction that the diet of patients with coronary artery disease should be designed to maintain the total blood lipid levels as well as the various fractions within normal limits. This is accomplished by limiting the daily intake of total fat to 50 Gm. and keeping the intake of saturated fats as low as possible.

It is my purpose to outline briefly several modern concepts connected with the pathogenesis of coronary artery disease. Because the literature on the subject is so abundant, I will mention only a few of the authors who are helping to formulate present concepts. The bibliography will accordingly be deficient.

The importance of the subject of coronary artery disease is readily appreciated not only by physicians but also by intelligent laymen. Much has appeared in lay writing about heart disease and its relation to cholesterol levels and obesity. It has been repeatedly emphasized in the press and on the radio that diseases of the heart and blood vessels are responsible for more than half of all deaths and that a large precentage of such diseases develop from coronary artery disease. We must therefore take a stand on diet and medication, not only

Chairman's address, read before the *Section on Diseases of the Chest* at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

for the treatment but also for the prevention of atherosclerosis. During the last decade considerable progress has been made in explaining at least some of the mechanisms of the development of coronary artery disease. It has long been noted that the process of atherosclerosis is begun by the depositing of fat droplets and cholesterol crystals in subintimal plaques and that the plaques follow a specific pattern of evolution which after slow progression ends either with a rupture of the plaque with discharge of the semifluid contents into the lumen of the artery or with the forming of a thrombus at the site of the plaque, which may later cause an occlusion of the artery. However, the exact explanation of the mechanism is still not available. It is presumed that there is first some defect in the arterial wall which marks the location of a future plaque. It has been noted that there is an increase in the vasa vasorum beneath the plaque. Is the increased blood supply to the media at that site the cause or result of the plaque?

Texon[1] has recently advanced an attractive hypothesis to account for this primary location. With use of Bernoulli's theorem pertaining to the lifting effect of fluids passing over a curved surface, he explains by hydrodynamics not only the selection of the site but also the mechanism of the rupture of the plaque when distended with semifluid contents. The fact that forces sufficient to produce these effects are present in the coronary arteries can be accepted in view of the parallel fact that the upper side of the convex surface of an airplane wing exerts sufficient lift to keep the plane aloft in flight. Inquiry into the process of atherosclerosis has also been directed toward the study of experimental atherosclerosis in animals and an attempt to determine some common denominator to explain the process in man.

Heredity, Age, and Sex

It was inevitable that statistical studies would bring out the importance of factors such as heredity and the tendency for atherosclerosis to run in certain families.[2] Many early observers noted the association of atherosclerosis with diabetes and hypertension. Longevity, it was implied, depended on the condition of one's arteries. In words ascribed to our great teacher of medicine, Sir William Osler, "A man is as old as his arteries."

Additional study indicated that there were possibly some racial factors of importance. In Oriental persons, it was noted, atherosclerosis and hypertension were uncommon. However, it was subsequently observed that when Oriental persons were transplanted to families in the United States and lived on their diets, they developed hypertension and atherosclerosis almost as readily as Caucasians. It turned out that what appeared to be a racial immunity perhaps was only related to dietary habits. Additional studies[3] of the ethnic groups of South Africa[4] have likewise indicated the importance of the fat in the diet as a concomitant mechanism associated with the incidence of atherosclerosis and its complications. Sex is also an important factor. Coronary thrombosis is 24 times commoner in men than in women under the age of 40 years. For people in the 40's the ratio is 5:1, 2:1 for those in the 50's, and 1:1 for those over 60.[5] Not as many women as men die of atherosclerosis, either of the coronaries or of other arteries, because they usually do not get it until they are older.

Studies with hormones in experimental laboratories have indicated that estrogenic substances act as a protective mechanism. Robinson and coworkers[6] reported that the lipid pattern of women past the menopause is distinctly different from that of young women and indicated that the post-menopausal pattern may be reversed to the more youthful pattern by the administration of estrogenic hormones. These authors believe that the difference in the lipid pattern is perhaps responsible for the increasing incidence of coronary artery disease in older women.

The relation between the incidence of coronary artery disease and age is well known.[7] The rate of deaths from arteriosclerotic and coronary heart disease is only 10 out of 100,000 males 25 to 37 years old but increases to 88 of those 37 to 45 years old, to 365 of those between 45 and 54 years old, to 870 of those between 55 and 64 years old, and to 1,719 of those between 65 and 74 years old. The index is only 2 in 100,000 for women 25 to 34 years old; 14, 76, and 305 for women in the next three age groups, and 947 for those between the ages of 65 and 74. It is evident then that the index increases with age in both sexes but reaches a maximum earlier in men than in women.

Psychic Stress and Effort

Psychic stress as a factor contributing to coronary disease is the subject of considerable controversy. Dunbar,[8] Arlow,[9] and Menninger[10] think that people with a certain specific personality pattern are predisposed to coronary disease. Others,[11] however, do not agree with this theory. If psychic stress were a prominent factor in coronary disease or acute coronary deaths, Hitler would not have required the gas chamber to eliminate 6 million Jews in his attempt at genocide.

There are factors of increased epinephrine production, increase in clotting tendency, and other mechanisms which have been cited by Wasserman[12] as mechanisms that could contribute to postoperative clotting tendencies. Similar claims have been made by Selye,[13] who cites such factors as contributing to organic changes in the blood vessels and thereby predisposing the blood to intravascular clotting. There is no doubt that coronary pain of true anginal type does develop with both physical and psychic stress. It is, however, less probable that the mechanism is significant in the over-all picture of coronary disease, either in the production of the vascular disease or in the final attack of thrombosis.

Master[14] in a large series of cases showed that coronary thrombosis occurred equally often among people of all trades and professions as well as at all hours of the day and night. His studies indicated that each profession furnished its proportionate share which was numerically similar to the percentage of the population engaged in the specific profession or trade. He also indicated in his studies that the time of the onset of the attack bore no relation to physical activity.

Physical strain or effort is often cited as a cause of acute myocardial infarction. No doubt acute coronary insufficiency occasionally results from a severe and prolonged effort, but this appears to be a rare occurrence. It has been shown that the average man engaged in his regular employment works much less strenuously than he does when employed in pleasurable activities or sports.[15] Plotz[16] believes that workers in strenuous occupations sustain fewer attacks than sedentary workers.

Diet

It would appear that diet is perhaps the most generally accepted and still the most controversial of all etiological factors pertaining to atherosclerosis. The public has already been introduced to the idea of the importance of cholesterol. Whether cholesterol levels per se are directly associated with atherosclerosis has not been established however. The importance of the phospholipid fraction of blood fats has likewise received attention. There is good experimental evidence that the ratio between cholesterol and phospholipid may be of considerable importance in the development of experimental atherosclerosis in laboratory animals.

While, in general, the fats in the diet are held responsible for the vascular changes of atherosclerosis, there is no present agreement about what part the lipid intake or synthesis contributes to the primary source of the trouble. The cholesterol-poor diets of yesterday have been superseded by the low-fat diets or low-saturated-fat diets of today.

The importance of starvation in the reduction of hypertension was well demonstrated by the people of Europe during the last world war. Selye[13] says, "During the second world war, among the undernourished populations of Belgium, Soviet Russia, and German cencentration camps, there was a definite tendency toward hypotension and bradycardia, while the incidence of hypertensive disease was extraordinarily low." Among the obese, starvation or partial starvation in fats and carbohydrates is certainly capable of drastically reducing the total amount of blood fats. Thus the diet of Kempner, in which the fat and sodium were markedly restricted, not only controlled hypertension but also caused a reversal of the atherosclerotic changes in the retinal vessels.[17] This astounding demonstration of the reversibility of the process of atherosclerosis has warranted the hope that some program may be devised which will not only prevent an extension of the disease but also cause a reversal of at least part of the damage that has already been done.

There is another school of thought which is ably supported by Gofman,[18] who has made extensive studies on the size of the fat particles as they appear in the blood plasma. He has identified two classes of lipoproteins as being particularly significant in atherosclerosis. These lipoproteins, which are of a size identified as S_f 0-12 and S_f 12-400, show uniformly increased levels in persons who have sustained myocardial infarction or have symptoms of atherosclerosis. In a series of monographs and other publications, Gofman has expounded his beliefs and pointed out the group of lipoproteins influenced by an increased fat intake and also the group of lipoproteins influenced by an increased carbohydrate intake. In his recent book for the laity, "Dietary Prevention and Treatment of Heart Disease," he has recommended certain diets. A review of these diets will show that they are of ketogenic character but that the fats are derived from unsaturated instead of saturated fats. It would appear that, of all the investigators, Gofman and his associates are at the present time more completely convinced of their own position than are the exponents of any other schools of thought and are ready to gamble on the accuracy of their observations by recommending a complete change in the dietary habits of the nation. Confirmation of the prognostic value of Gofman's atherogenic index has recently been reported by Schlessinger.[19] Others,[20] however, believe that the cholesterol values are as useful as Gofman's index.

I have studied a number of patients not only with Gofman's method but also with the standard chemical studies of total lipid, phospholipid, and cholesterol levels and have observed the reactions to different diets. In most instances the high unsaturated fat intake in Gofman's diets resulted in an increase in total lipid levels, although at times it did reduce the cholesterol level and shift the cholesterol-phospholipid ratio to normal limits. I prefer to maintain all factors, including total lipid levels, as near to normal as possible, and therefore in diets which I prescribe at present I reduce the total fat volume to a modest 50 Gm. daily with as low a saturated-fat intake as possible. The results of this regimen, while not perfect, give me better values for the lipid levels than do other diets.

Most authorities advise cessation of the use of tobacco, particularly cigarettes, in persons with *manifest coronary disease. With this* advice I completely agree. The question of alcohol is more controversial. It appears to me that the decisive factor here is the question of the blood fats. When the lipid levels are high, alcohol adds more calories that behave like fat calories in the diet. I usually, therefore, withhold alcohol from those who have manifest coronary disease and also from others who because of their elevated blood lipid levels are candidates for atherosclerosis. Any resemblance of alcohol to a relaxing drug is purely coincidental. For this purpose a tranquilizer is much more effective and less detrimental.

In spite of the multiplicity of observations and the increasing knowledge pertaining to atherosclerosis, there is as yet no single mechanism which can be generally accepted as the primary etiological factor producing this disease. That the problem will be solved in the future cannot be denied. It is, however, necessary to tell our patients something at this time rather than to defer our advice until some future date.

Summary

On the basis of our present knowledge the following facts can be accepted and applied. 1. Excessive body weight contributes to atherosclerosis and shortens life expectancy, particularly in males. 2. Eating excessive fat is not conducive to longevity. 3. Physical activity within capacity is helpful and beneficial in the maintenance of health, probably because of the effects of increased metabolism on carbohydrates and fats. 4. The sex differences in atherosclerosis have something to do with sex hormones. 5. Diabetes and hypertension speed up the process of atherosclerosis and increase the frequency of coronary and cerebrovascular accidents.

The final word on atherosclerosis has not yet been written. Until the problem is completely solved, the medical profession must have an open mind and await new discoveries. Meanwhile, our present knowledge is sufficient justification for careful control of dietary fats.

THE CARPAL TUNNEL SYNDROME.—Anything that narrows the carpal tunnel can and does compress the median nerve, and if abnormal pressure is allowed to continue, irreparable damage to the nerve and its function will occur. The snydrome of median-nerve compression in the carpal tunnel consists of painful paresthesias involving to varying degrees the thumb and first two or three fingers of one or both hands, or weakness and disability of the thumb, or both of these sensory and motor phenomena. . . . The diagnosis of the carpal tunnel syndrome is usually quite easily made if the diagnostician is aware of the condition and has reason to suspect its presence. . . . The onset usually is insidious and symptoms may be present for a long time before the patient consults a physician. On examination often the appearance of the hand, or both hands if the lesion is bilateral, is sufficient to justify a presumptive diagnosis. If the thenar muscles are wasted the depression in the thenar eminences will be obvious and pathognomonic of median-nerve disturbance. The absence of motor disturbance above the wrist will indicate the wrist as the site of the lesion.—J. G. Love, M.D., Median Neuritis due to Pressure in the Carpal Tunnel, *Medical Record and Annals,* July, 1959.

CONTROLLED TRIAL OF METHOXSALEN IN SOLAR DERMATITIS OF CHIPPEWA INDIANS

Robert R. Schenck, M.D., Redlake, Minn.

A markedly seasonal dermatitis, characterized by erythema, edema, vesiculation, and crusting, occurs among American Indians. The possibility of preventing it by administration of methoxsalen was studied in 13 members of a group of Chippewa Indians living in Minnesota. The course of the dermatitis during two-week periods of medication with methoxsalen was compared with its course during periods of placebo administration. The results showed that regardless of medication most patients improved under limited controlled exposure to sunlight whereas in outpatients methoxsalen, in a dosage of two 10-mg. capsules per day by mouth, caused a worsening of the condition in six of the nine patients evaluated. Lactose produced a variety of responses in 10 patients. Since the most important etiological factor in the dermatitis was exposure to sunlight, the wearing of wide-brimmed hats and other protective covering was advised as the logical method of prevention and treatment.

One of the challenging clinical problems seen among the Chippewa Indians in Minnesota is dermatitis actinica. Usually exposed areas, such as the cheeks, nose, lower lip, ears, dorsal surfaces of the hands, and the V-area of the neck are involved, the condition arising in the spring and lasting throughout the summer. Onset of cold weather, with less solar radiant energy per day and the tendency to spend more time indoors, is associated with improvement. The lesion constitutes an overreaction to sunlight, with erythema, edema, vesiculation, and crusting. Secondary infection, especially in the areas around the nose and the mouth is the rule. Many afflicted persons develop a chronic and severe impetigo, with brawny induration or atrophic scarring of the affected areas. It tends to recur year after year in the same persons. The presence of sensitivity to sunlight in persons with a moderate degree of pigmentation is a most fascinating phenomenon.

The properties of methoxsalen suggested that it might be of value in increasing skin tolerance to solar radiation in these patients. The report of Becker [1] clearly showed that the use of the drug combined with carefully measured exposure to ultraviolet rays promoted two epidermal changes of a protective nature. First, the stratum corneum became thickened and more dense than control areas, with formation of a stratum lucidum. Secondly, because of increased adherence of the cells of the epidermis, melanin pigmentation was more efficiently retained. These changes markedly increased the minimal erythema-producing dose of midultraviolet rays, and even six months later it required twice as much energy to induce erythema in the treated areas than was the case in the control sites. Further, Imbrie and co-workers [2] confirmed and extended Becker's report, by showing that persistent tolerance for sunlight which lasted for weeks would result from a single orally given dose of methoxsalen combined with solar exposure. In a well-controlled study Stegmaier [3] reported that a 20-mg. dosage regimen of methoxsalen compared to placebo caused increased tanning (98% confidence level) and decreased burning of the skin (90% confidence level). The *Medical Letter* [4] reported, "A trial of methoxsalen is warranted with albinos or light-complexioned persons who require protection from the harmful effects of sun rays because of occupation or habits." Although the Chippewa Indians appear to be of medium or dark complexion, it seemed to me that those with solar dermatitis were reacting more like light-complexioned persons. The final definition of why this should be so invites further study of the anatomic structure of the skin, comparing the skin of Indians (with and without dermatitis actinica) to that of similar groups of non-Indians.

Potential systemic toxicity was not a serious concern, for Sulzberger and Lerner [5] have pointed out that "the original fear that methoxsalen might cause liver damage has not been proved in a single case." Even more reassuring was the fact that psoralens are widely distributed in foodstuffs—for example, in parsley, celery, parsnips, huckleberry, cloves, figs, and some citrus fruits.[6]

Materials and Method

The Indian Hospital at Redlake provides medical and dispensary care for nearly 3,000 Chippewa Indians. During the summer months I regularly saw 20 or more patients with dermatitis actinica. During the months of July and August I studied 13 patients. Of these, 11 were induced to enter the hospital for initiation of treatment for one-week periods. This enabled controlled exposure to sun-

light. Two were treated exclusively as outpatients. The group ranged in age from 9 to 61 years and four of the patients were male.

Alternate patients were given two capsules of a medicament daily, two hours prior to solar exposures according to the schedule presented in table 1. The capsules, which were supplied under a numerical code, contained either methoxsalen, 10 mg., or were placebos (lactose) of identical appearance. Pretreatment 35-mm. color transparency photographs were taken of all subjects. Other photographs were taken at weekly intervals during and after the periods of drug administration, so that most patients had five photographs taken over a four-week period. In addition, "follow-up" photographs were taken of some patients.

Table 1.—*Schedule of Solar Exposure of Patients with Dermatitis Actinica Treated with Coded Medicament*

Treatment

12	90
13	120
14	180

At the beginning of the study, patients alternately received one of the two coded capsules for an initial two weeks of administration. During a second two-week period the remaining coded capsule was given. Thus each patient who completed participation in the study received a total of four weeks of treatment. The first and third week was spent in the hospital by 11 of the 13 subjects. During these periods the exposure to sunlight was accurately timed with watches by the nurses. Careful explanation and instruction was given to all patients for proper exposure while at home, for 2 were treated as outpatients while the remaining 11 were discharged during the second and fourth weeks of the study.

Results

Of the 13 patients, 7 received the placebo and 6 methoxsalen during the initial two weeks of treatment. During the third and fourth weeks, when the medication was switched, a few subjects would not continue participation in the study. Thus, only five received the placebo and three methoxsalen during the second course of medication. This enabled a total of 19 evaluations of two-week periods of treatment to be made. In addition, evaluations and photographs were made of the inpatients on their discharge from the hospital after one week of treatment. Altogether there were 12 trials with the placebo and 9 with methoxsalen, enabling 36 separate evaluations to be made at weekly intervals. Six scheduled evaluations were not done because of the patients' failure to return, at the end of one week in four instances and at the end of two weeks in two.

Three independent observers reviewed the serial kodachrome transparencies, and the findings of each were fairly consistent when compared. These results are found in table 2. It became apparent that 9 of 17 patients showed improvement after one week of hospitalization. However, seven of these had received the placebo. It was believed that the relative lack of exposure to sunlight while in the hospital under control conditions was responsible for this improvement.

After a week at home, the patients treated with placebo showed a variety of responses; the condition of two became worse while that of four improved. The condition of patients who received methoxsalen during the week at home became worse in six and remained unchanged in three instances; in none of the patients was there improvement with methoxsalen therapy during this period. Of the six patients whose condition deteriorated, several had manifestations or exacerbations of complicating impetigo.

Comment

The presence of solar sensitivity in Indians at first seemed unlikely because of the relatively dark color of exposed areas of skin. The natural course of the process, however, showed that exacerbation or improvement depended on exposure to the sun or protection from it. Exposure was, in general, excessive, because the typical small house is used primarily at times of eating and sleeping during the summer months. Protective clothing, such as wide-brimmed hats, was seldom worn. Further, most employment involved outdoor jobs. An earlier suggestion that dietary deficiencies might be involved is untenable, because the Chippewa Indians' diet is best in the summer, when such garden products as vegetables and blueberries are present. In the winter, when their diet is poorest, the dermatitis spontaneously clears. If indoor employment was obtained in the summer the condition was likewise found to improve.

Table 2.—*Results of Comparative Trial of Methoxsalen and Placebo Combined with Solar Exposure in Dermatitis Actinica*

	Therapy			
	Placebo		Methoxsalen

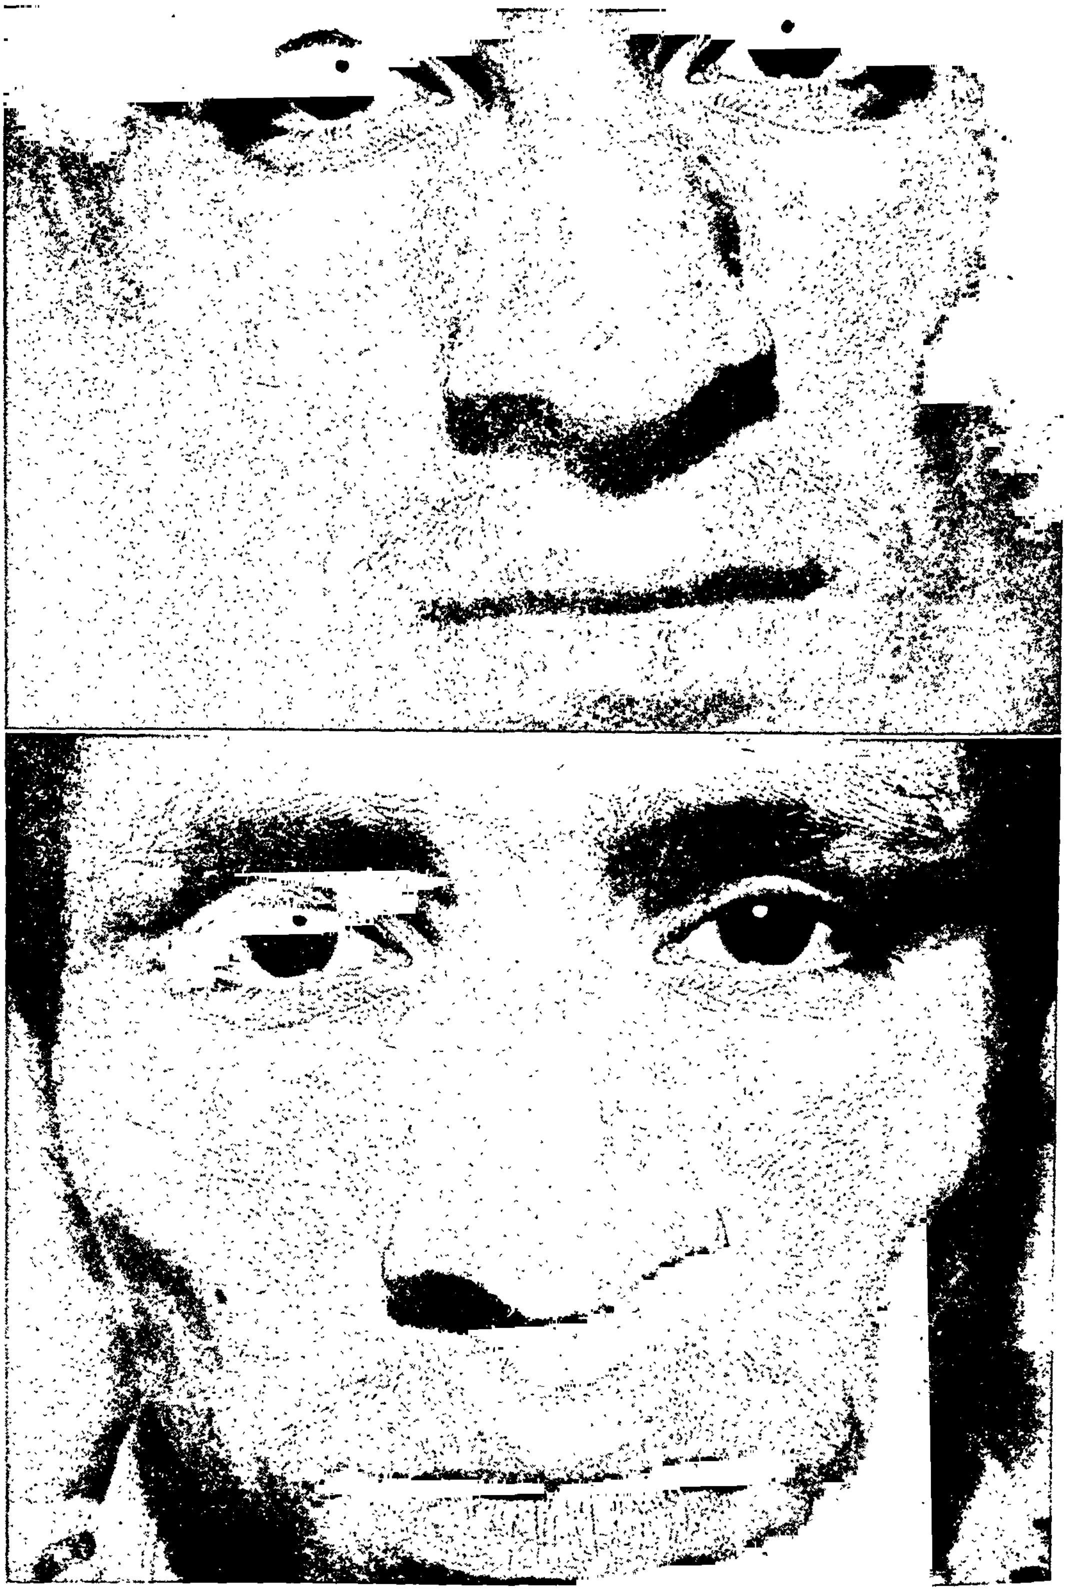
Worse	0	2	2	6
Unchanged	1	4	5	3
Improved	7	4	2	0

It is important that this situation become better known, for once the etiological role of sunlight is recognized, steps may be taken to minimize ex-



Patient treated for dermatitis actinica. *Top,* lesion covering bridge of nose and cheeks prior to hospital admission. *Bottom,* one week after administration of medicament (either methoxsalen or placebo) and solar exposure there is marked improvement in condition. When code was broken, it was found that patient had been given lactose placebo instead of methoxsalen.

posure. Although the entity is being diagnosed by a few dermatologists who treat Indians, many other practitioners have not considered the true etiology. It is also important not to confuse this entity with other, more serious, conditions. The patient shown in the figure, for example, had undergone extensive studies to rule out acute lupus erythematosus because of the butterfly distribution of his facial lesions.

As to the role of methoxsalen in preventing or ameliorating the condition, it seemed likely that carefully timed exposure to sunlight in early spring might induce the protective changes described by Becker. This could be of distinct help to those not already sensitized, although it may be possible that the skin has been irreversibly made prone to the lesion in those who have developed the syndrome.

This study would indicate that the use of methoxsalen in patients in whom the syndrome is already developed and presently active serves no useful purpose and is probably contraindicated. The increase in severity of the condition during the second week of therapy in six of the patients reported by me might in some ways be explained by the findings of Becker[7] that combined therapy with methoxsalen and ultraviolet light produced greater inflammation than the control medicament. This was manifested by a greater amount of infiltration about the superficial vessels of the dermis, as disclosed by biopsy specimens taken on the 14th day of short-term administration of methoxysalen. Undoubtedly another factor played a role in the adverse response to methoxsalen while patients were at home. For, despite the careful directions on the length of exposure to ultraviolet light, it is likely that the specified exposure of 30 minutes per day on the day of discharge (8th day of treatment) to 3 hours on the fourteenth day was not strictly observed. This can be explained by the mode of living of Chippewa Indians, and the usual lack in their homes of conveniences such as plumbing and indoor lavatories. In this respect the outpatient phase of treatment simulated more closely the usual field conditions met in medical practice.

It is possible that, if methoxsalen is given in early spring, prior to the activation of the dermatitis, the condition may be prevented or ameliorated. Because of the excessive solar exposure inherent in the Chippewa Indian's way of life, however, a more practical preventive might be to encourage or even to insist on the use, by those known to react excessively to sunlight, of wide-brimmed hats and other protective clothing during the sunny months.

Summary

A comparatively common sensitivity to sunlight was observed among Chippewa Indians in Minnesota. The lesions constituted an overreaction to solar energy, with erythema, edema, vesiculation, and crusting. Many such patients develop a chronic impetigo, with brawny induration of the affected areas. The areas usually involved are the cheeks, nose, lower lip, ears, dorsal surface of hands, and the V-area of the neck. The condition characteristically appears during the spring and summer months and improves or clears completely with the onset of cold weather.

Because of the secondary protective changes brought about in skin by the use of methoxsalen combined with exposure to solar energy, a controlled trial of the drug was carried out during the months of July and August.

The condition of most patients improved during the period of hospitalization, but seven of the nine who did so had received the placebo. After having been discharged one week, there was a clear-cut distinction between patients who had received the placebo and those who had received the active drug. The condition of patients on methoxsalen therapy became worse in six, remained unchanged in three, and improved in none. Thus methoxsalen was found to exacerbate an already active dermatitis actinica. This was initially probably due to the known skin-sensitization response to sunlight induced by methoxsalen, together with the subsequent factor of inadequate control of exposure to sunlight because of the Chippewa Indians' unavoidable mode of living.

A further trial of methoxsalen might be of value in patients in early spring, prior to the activation of the dermatitis, to prevent or ameliorate the condition. However, a more practical preventive might be to encourage or to insist on the use, by those known to react excessively to sunlight, of wide-brimmed hats and other protective clothing during the sunny months.

1713 W. 105th St., Chicago 43.

The methoxsalen, supplied as Meloxine, and the placebo used in this study and reimbursement for photographic supplies and secretarial help were provided by the Upjohn Company, Kalamazoo, Mich.

MANAGEMENT OF NONPENETRATING INJURIES OF THE CHEST

Claude C. Craighead, M.D.
and
Bertram A. Glass, M.D., New Orleans

In a series of 166 patients with nonpenetrating injuries of the chest there were 118 with fractures of ribs. Thirty-one of these were of the stove-in (flail chest) type, accompanied by paradoxical sinking-in of the chest wall during inspiratory contractions of the diaphragm. Sand bags sufficed to correct this dangerous condition in 9 patients, but in 19 it was necessary to apply traction either to the sternum or to the pectoral muscles. Immediate thoracotomy was resorted to on four occasions. Two patients with organized hemothorax and one with empyema required decortication. From this small number of complications it appears that early operation for nonpenetrating chest wounds is seldom indicated. Of eight deaths in this series only two were directly attributable to the injuries within the chest.

As various modes of travel are designed for higher and higher speeds, patients suffering blunt trauma to the chest, of frequent occurrence now, must be reckoned with in ever increasing numbers. It seems timely, therefore, to review the management and evaluate the results in an institution where many such injuries are seen. From July, 1954, through June, 1959, 166 patients having nonpenetrating injuries of the chest were admitted to the Thoracic Surgical Service, Louisiana State University Division, Charity Hospital, New Orleans.

Uncomplicated Fractures of the Rib

Patients with fractures of the rib treated in the outpatient clinic are not included in this study. However, 20 were admitted who had fractures of the rib without other complications. If an initial roentgenogram discloses no intrapleural complication, the patient is given analgesics and, frequently, intercostal nerve blocks to control pain. Another roentgenogram is made in six hours. If no intrathoracic lesion is demonstrable, the patient is usually sent home to return within 48 hours.

In one patient pneumothorax occurred two weeks after the initial injury and in one, hemothorax five days later. In three patients hemopneumothorax occurred after 2, 5, and 10 days respectively. Follow-up examination, therefore, is imperative.

Treatment of fractures of the rib by encircling devices is contraindicated. To splint a broken rib satisfactorily and relieve pain by strapping, the adhesive tape must be applied beyond the midline anteriorly and posteriorly. Respiratory excursion and, hence, efficiency are decreased, not only on the injured but also on the uninjured side. Complete encirclement of the chest by a belt decreases excursion on both sides. The sole benefit from such treatment is relief of pain. This can be more adequately controlled by intercostal nerve blocks repeated at 12-to-24-hour intervals, if necessary, without interfering with ventilatory function. Indeed, function is improved, since the patient is able to cough and breathe deeply without pain. The dangers of atelectasis and pneumonitis thus are minimized. Often the block affords prolonged relief from pain so that only a single injection is necessary. Rarely does a patient require more than four or five injections. It is advisable to inject two intercostal nerves above and two below the sites of fracture.

Although it is an infrequent sequel, pneumothorax may result from the needle puncture in carrying out the procedure. It is of minor significance if recognized and treated properly.

Subcutaneous Emphysema

Of interest in 13 patients with fractures of the rib was the occurrence of subcutaneous emphysema with neither pneumothorax nor hemothorax, a phenomenon sometimes difficult to interpret. In most instances previous pulmonary or pleural disease has been sufficient to cause visceral and parietal pleural symphysis. When an accident occurs, the jagged end of the rib penetrates underlying adhered lung to effect a small leak. The result would ordinarily be a pneumothorax. However, in cases in which adhesions underlie the site of injury, the air, having no pleural space to enter, escapes from the rent in the lung to dissect into the subcutaneous tissues. At times subcutaneous emphysema, without any other evidence of intrapleural injury, may be marked. Most instances resolve spontaneously but should be observed by serially performed roentgenography. Adhesions beneath the site of puncture may be thin and later tear to allow leakage of air and blood into the pleural space. Probably this mechanism obtained in several cases of delayed pneumohemothorax.

the Department of Surgery, Louisiana State University School
ine.

Subcutaneous emphysema is produced in yet another, and even more important, manner. Air escapes through an opening in a major bronchus, trachea, or esophagus, makes its way into the mediastinum, and progresses from there into the subcutaneous tissues. Thus evolves a critical situation, in which prompt discernment of the underlying disorder is demanded. If the leak is considered to be of sufficient magnitude to compress the great veins within the semiclosed mediastinal compartment and encroach on the return flow of blood to the heart, decompression is accomplished by opening the anterior mediastinum through a suprasternal approach. If the leak continues unabated and respiratory function is appreciably embarrassed, a large opening is present which calls for immediate surgical intervention to secure its closure.

Hemopneumothorax

Twenty-six patients had fractures of the rib associated with unilateral pneumothorax, 1 with bilateral pneumothorax, 30 with unilateral hemothorax, 23 with unilateral hemopneumothorax, and 1 with bilateral hemopneumothorax. Treatment in such cases must encompass one major goal, to rid the pleural space of fluid and air so that the visceral and parietal pleurae are apposed. The quickest way to stop the spill of air or blood from the lung is to secure contact of pleural surfaces, a principle long familiar to thoracic surgeons.

Blunt trauma rarely causes injury to major vessels. In any event, the few patients with bleeding from such sources will seldom live to be transported. Most intrapleural bleeding occurs from the peripheral lung, usually from puncture by a fragment of rib, and can be controlled by pleural apposition. Occasionally bleeding from an intercostal vessel cannot be checked by pleural coaptation. However, it is significant that open thoracotomy was undertaken only twice for uncontrolled bleeding, originating from intercostal vessels in both instances. Only two patients with clotted hemothorax required decortication.

The maintenance of a lung in collapse in order to seal a hole on its surface is not, in our opinion, to be countenanced. While it is true that the opening may eventually seal off and that the lung will reexpand as air is absorbed, there are several dangers. A pleural effusion of varying degree ensues. Unless the lung reexpands quickly, fibrinous exudate is deposited over its surface and soon organizes into a fibrous rind, entrapping the lung and preventing its reexpansion. Frequently the effusion becomes secondarily infected and empyema results. Empyema occurred in two patients with pneumothorax who were not seen until two or more weeks after their initial injury. One required decortication.

Pleural apposition may be accomplished in a variety of ways. A single aspiration served to accomplish this in 28 patients, while multiple aspirations were needed in 40. Use of tube thoracotomy was necessary in 47.

In pneumothorax alone, aspiration is the preferred method of treatment. An 18-gauge or 20-gauge needle is attached to a three-way stopcock; a large syringe is introduced into the second intercostal space in the midclavicular line and the air is drawn off. In a patient with pneumothorax with less than 15% collapse, aspiration is not done. Minimal pneumothorax will clear so rapidly that no pleural effusion develops. Conversely, complete collapse of the lung under obvious tension denotes a large leak. Treatment consists of immediate insertion of a catheter into the second intercostal space anteriorly and connected via a water trap to either the Emerson or Thoracic Gomco suction apparatus.

No single method is best for cases which fall between these two extremes. When possible, aspiration with a needle is preferable. Single or even multiple thoracenteses are less painful than insertion of an intercostal catheter which, although more efficient in emptying the pleural cavity, is invariably irritating to the pleura and causes pain on deep inspiration and coughing. Burdened with a tube, the patient breathes less deeply and coughs less. As a result atelectasis may develop. In addition, the danger of introducing infection into the pleural space, while slight in either case, is less with a needle than with a tube. There need be no hesitation, however, in use of a tube in those not responding quickly to aspiration.

In hemothorax, pneumothorax, or hemopneumothorax of moderate degree, an attempt is made to remove all air and fluid by performance of thoracentesis. If no negative intrapleural pressure develops after 500 cc. of air or more is removed and air continues to be drawn out, the leak is obviously large and an intercostal catheter is placed in at once. The pneumothorax machine is of value in determining intrapleural pressure in such cases. Similarly, if 500 cc. or more of blood is removed, or if the blood appears fresh some hours after injury, a catheter placed through the seventh or eighth intercostal space in the posterior axillary line affords the opportunity of a minute-to-minute check on the rate of bleeding, once the initial accumulation has been removed. The tube should never be placed more posteriorly than the posterior axillary line so that the patient may lie in comfort on his back.

In the patient on whom aspiration has been performed and who is thought free of fluid and air, an immediate portable roentgenogram is made with the patient in the upright position. If air persists, a tube is put in the second anterior interspace; if blood remains, it is placed in the seventh intercostal space at the posterior axillary line. If both air and blood are still accumulated, catheters may be placed anteriorly and posteriorly, or a multiperforated catheter may be introduced from the dependent portion and directed toward the apex.

If the roentgenogram is clear after thoracentesis, another is obtained in six hours. The degree of either pneumothorax or hemothorax at this time will decide whether thoracentesis is to be repeated or evacuation by catheter planned. During the period of observation, indicated diagnostic and therapeutic measures are carried out.

Performance of open thoracotomy was resorted to immediately on four occasions. Two patients with organized hemothorax and one with empyema required decortication. It would seem evident from this small number of complications, therefore, that early operation for nonpenetrating wounds is seldom indicated.

Other Injuries

Diaphragmatic Rupture.—Four patients with fractures of the rib and one with flail chest had associated diaphragmatic injury. Diaphragmatic rupture, per se, does not constitute an indication for emergency thoracotomy. Two patients, submitted to immediate thoracotomy, were considered to need emergency procedures because of associated conditions. One had severe respiratory distress and a massive diaphragmatic hernia, the left side of the chest being completely filled by abdominal viscera. His was one of the operative deaths and at autopsy the brain was extensively lacerated. This, no doubt, contributed more to the respiratory distress than did the diaphragmatic rupture. The second, operated on because of continued bleeding, had a herniation of the spleen through the diaphragm; the splenic pedicle was also lacerated.

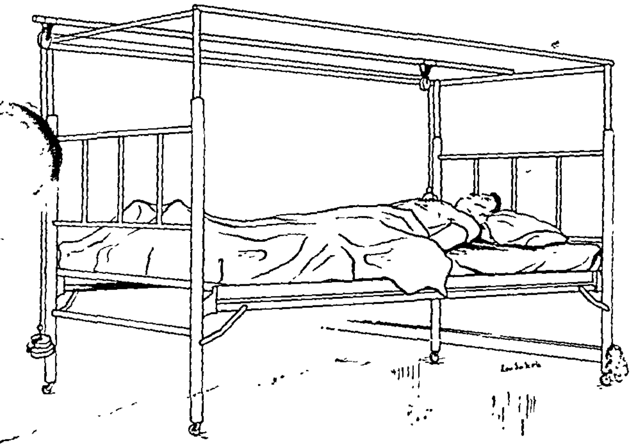

Fig. 1.—Stabilization of flail chest by sternal traction. Application of traction to sternum involves use of overhead frame.

Usually concomitant injuries such as pneumothorax or hemothorax can be treated and repair to the diaphragm delayed until the patient has recovered from the secondary injuries and his condition has been stabilized. Thee of five patients with ruptured diaphragm had synchronous craniocerebral trauma.

Mediastinal Injuries.—Four patients with fractures of the rib and two patients with flail chest had mediastinal damage. Three injuries involved the heart (definite myocardial infarct in two and questionable infarct in one) and one the tracheobronchial tree. In blunt injuries to the anterior chest wall, particularly those caused by steering wheels, the sternum is driven inward and presses the heart between it and the vertebral column. The myocardium is contused, and the clinical picture is that of a myocardial infarct. Consequently, any injured patient in whom the possibility of sternal compression exists should have serial electrocardiograms, and, if the myocardium is damaged, the patient should receive treatment as prescribed for myocardial infarction, as well as for his other injuries.

Sternal Fractures.—In 10 patients with fractures of the sternum, 2 also had hemothorax, 1 had myocardial injury, and 2 exhibited a marked paradoxical sinking-in of the chest wall during the inspiratory contractions of the diaphragm. In one patient the soft tissues overlying the sternum were contused without a demonstrable fracture of the sternum. Treatment of sternal fracture is similar to that of a broken rib. If no intrapleural or mediastinal injury exists, treatment is directed toward relief of pain.

Flail Chest.—More urgent than the previously described conditions, a crushing injury of sufficient magnitude to produce a flail chest demands an understanding of the resulting marked derangement of cardiopulmonary function for proper management. Of 31 patients with flail chest, 7 had associated hemothorax, 2 pneumothorax, 7 hemopneumothorax, 1 diaphragmatic rupture, and 2 myocardial injury.

It is of the utmost importance, when dealing with the stove-in (flail) chest, to stabilize the chest cage and to end the sinking-in of the injured part during each inspiration. Sand bags were used in 9, while traction from the sternum with Bigelow screws (fig. 1 and 2) [1] or from the pectoral muscles as described by Hudson,[2] or a combination of the two, was used in 19 patients. In the others the sinking-in was either minimal or else in a posterior location where rest in bed sufficed to splint the segment. Most of these cases have been reported elsewhere and treatment discussed in detail.[1]

Tracheotomy, of prime importance in the management of many thoracic wounds, is particularly advantageous in the management of patients with flail chest. While tracheotomy serves its most useful function as a means by which tracheobronchial secretions may be aspirated in the patient who cannot or will not cough, it also serves to lower the amount of dead air space and lessen the amount of physical work involved in respiration. Nasotracheal aspiration and bronchoscopy are frequently used to keep the tracheobronchial tract free of secretion.

Miscellaneous Injuries.—Other cases include one patient with mild intrapulmonary hemorrhage and one with hematoma of the chest wall, both of whom were treated symptomatically with good results.

Concomitant Injuries to Other Organs: Most concomitant injuries to other organs result from violent trauma and multiple injuries are frequent. Eleven patients had, in addition to the chest injury, injuries to the abdomen; 16 to the brain and spinal cord; 28 to bones and joints; and 4 to the genitourinary tract (table 1). Of the 59 concomitant injuries, 30 patients had involvement of one other system, 10 of two systems, and 3 of three systems (table 2). This points out the necessity of attention to all injuries. Treatment of the thoracic condition should not be emphasized to the point that care of other injuries is neglected (table 3).

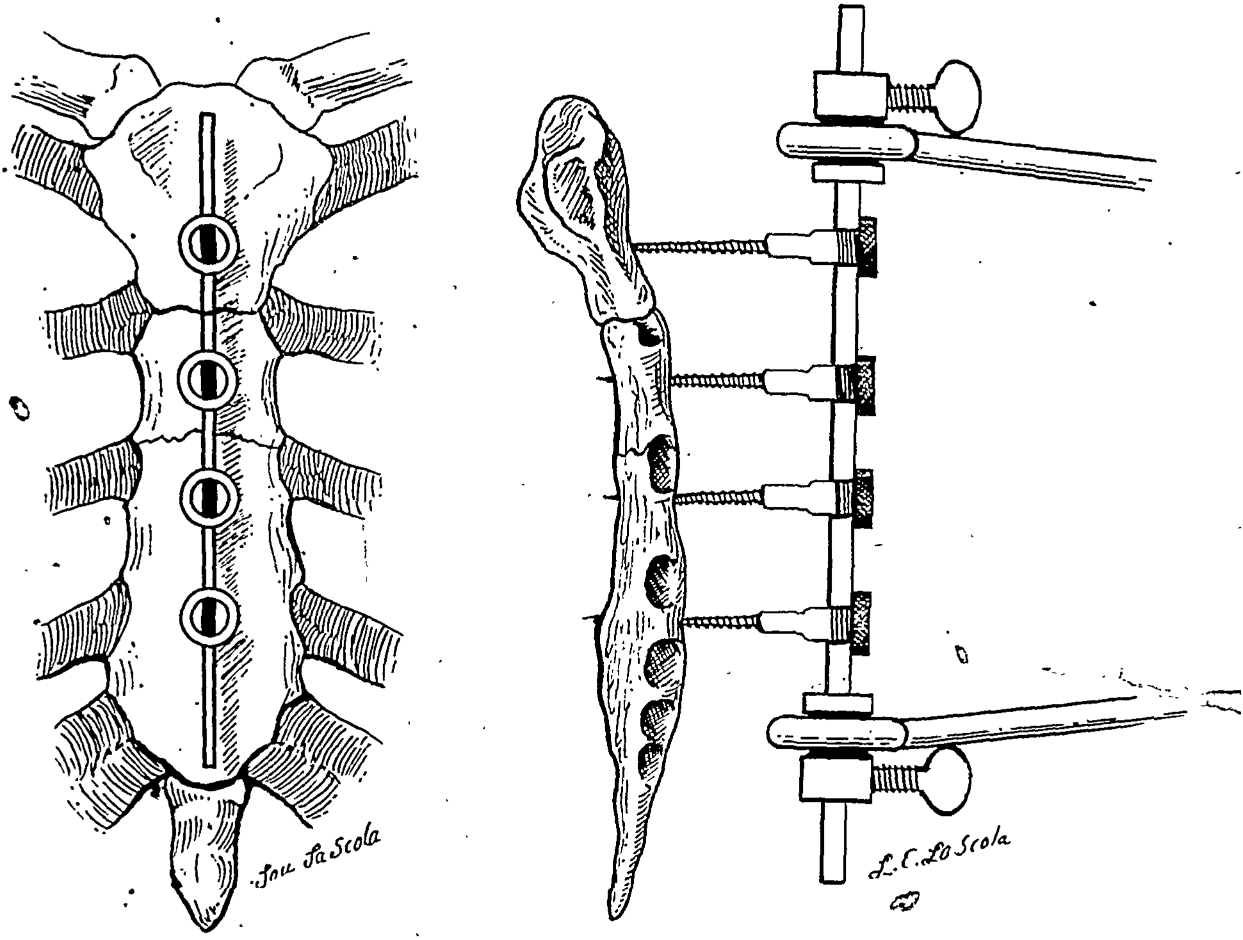

Fig. 2.—*Right,* diagrammatic sketch of fractured sternum with Bigelow screws and bar in place. Note two screws above and two below fracture site. *Left,* lateral view of sternum with Bigelow screws, bar, and traction clevis.

Deaths

Of the eight deaths, two were due to injury within the chest. The first was in a 55-year-old man with left hemopneumothorax and fractures of the femur and fibula, treated with repeated thoracenteses, tracheotomy, and closed reduction of the fractures. He developed acute pulmonary edema and died 48 hours after admission. Permission to perform autopsy was not obtained. The second was one of two operative deaths. A 28-year-old man was admitted after an automobile accident with multiple fractures of the rib, left hemopneumothorax, and intraperitoneal bleeding. Immediate treatment consisted of single thoracentesis followed by insertion of an intercostal catheter and tracheotomy. Thereafter, at exploratory celiotomy a ruptured spleen was removed and a contused kidney necessitated drainage of the renal fossa. The patient died 48 hours later as a result of, according to the findings at autopsy, acute myocardial infarction, presumably due to trauma and cerebral contusion.

Four deaths were ascribed to other injuries. Three were from cerebral lacerations, and fractures of the rib were incidental. The fourth was also adjudged due to cerebral laceration. This death was previously discussed in the section on diaphragmatic rupture.

Of the two other deaths, one occurred in a 65-year-old woman with fractures of the rib who died of a pulmonary embolus eight days after admission. The second occurred in an 87-year-old man with known cardiac disease. Admitted with fractures of the rib, he developed cardiac failure and died with acute pulmonary edema two weeks after admission.

Comment

Of 118 patients with fractures of the rib, 20 demonstrated no other lesion. Thirteen patients developed subcutaneous emphysema. The rest collected either air or blood, or both, in one or both of the pleural cavities. Four received, in addition, a tear in the diaphragm.

Ten patients suffered fractures of the sternum and one a contusion of the sternal region without evidence of fracture. Thirty-one patients exhibited, as a prominent feature, a flail chest. One patient had an intrapulmonary, and another a subcutaneous, hematoma.

Total	4

Complications immediately attributable to the thoracic injury included three instances of organized hemothorax and three of empyema; two patients with the former and one with the latter were treated by decortication. Atelectasis was severe enough in 16 patients to require use of bronchoscopy and in 9, of tracheal suction. Pneumonia occurred in seven patients. A myocardial infarct developed in one patient and pulmonary edema and electrolytic imbalance in another.

Treatment in 42 patients consisted solely of supportive care, including in many instances, intercostal nerve block. The less formidable thoracentesis sufficed for accumulations of air and blood in the pleural cavity in 68 patients, while the more efficient intercostal drainage was required for larger collections in 47 patients. To remove air, the needle or catheter was put in the second anterior interspace and to drain off blood, in the seventh posterolateral space. Some modification of these approaches was demanded in patients with pocketed accumulations.

DIAGNOSIS OF INTERMEDIATE STAGE OF ALCOHOLIC BRAIN DISEASE

Abram E. Bennett, M.D., Berkeley, Calif.

Between the acute, reversible forms of alcoholic brain disease and the chronic, irreversible forms exemplified in cortical atrophy, there is an intermediate group of forms in which severe disturbances of the personality are present, but permanent organic deterioration can still be prevented. This belief, based on clinical impressions, is strengthened by electroencephalographic studies in 227 patients. Of these, 81 were classified as intermediate by clinical criteria, and 64 of the 81 had abnormal electroencephalograms which reverted slowly to normal. Five case histories illustrate the type of personality change encountered, the difficulty of management, and the need of resolute treatment if patients still in the intermediate, reversible stage are to be saved from irremediable cortical atrophy.

Alcoholic brain disease has been classified as either acute alcoholic brain syndrome, acute intoxication, delirium tremens, and acute hallucinosis (reversible) or as chronic brain syndrome, cortical atrophy, and midbrain involvement (organic dementia or Korsakoff's or Wernicke's disease [irreversible]). From my studies I believe that large numbers of chronic alcoholics lie between these groups and have what I term the intermediate brain syndrome; this paper presents the evidence for this concept.

An increase in the incidence of alcoholic brain damage throughout the United States is shown by many indications; for example, the increasing number of admissions to state hospitals, of which about 20% are for alcoholism, either with or without definite psychoses. In electroencephalographic studies of 758 (512 male, 246 female) alcoholic patients admitted to the psychiatric department of a private general hospital over the past six years, I have found at least one-third with abnormal recordings, many of which reverted to normal only after many months of sobriety.[1] These patients are in either the intermediate or the chronic stage of organic brain disease, in both of which cortical cerebral atrophy is present. If the diagnosis can be made in the intermediate stage, permanent organic deterioration may be prevented. I believe that thousands of these cases go unrecognized.[2] The patients have reached the phase of the essential pathology of chronic alcoholism; namely, compulsive drinking with permanent loss of control over drinking.

Heretofore the symptoms in this group were largely considered to be emotional personality changes, either sociopathic or neurotic disorders, to be treated psychotherapeutically; whereas one can now demonstrate that these are signs of organically induced cortical damage, more like frontal lobe syndromes. In those patients with slow reversal of abnormal electroencephalograms (EEG's) or persistence of abnormal records, the organic basis has been confirmed by psychological testing and by pneumoencephalography which reveals cortical atrophy. The degree of cortical atrophy roughly parallels the clinical and electroencephalographic findings. To be sure, some persons with chronic cases and with severe atrophy have normal electroencephalographic patterns; the same thing was seen in the past in treated cases of advanced paretic dementia[3] and also in some hopeless cases of Korsakoff's disease.

Electroencephalographic Studies in 227 Patients with Alcoholism

The electroencephalographic findings in general are persistent mild generalized activity of 15 to 30 and 4 to 7 waves per second and at times paroxysmal slowing and spiking. Of the 227 patients studied 78, or 34.4%, had two or more electroencephalograms; 25, or 11%, had psychological tests; and 12, or 5.3%, had pneumoencephalograms. Findings on the repeat EEG's are shown in the table.

Acute Stage.—Of 98 patients with alcoholic brain disease in the acute stage, 37 had abnormal EEG's which reverted to normal. Psychological testing was done in eight cases and in three showed evidence of organic brain damage. The EEG's were normal in 53 cases.

Intermediate Stage.—Sixty-four (79%) of 81 patients with disease in the intermediate stage had abnormal EEG's, which usually reverted to normal slowly. On psychological tests, five of six patients showed organic brain damage, while three of four patients had pneumoencephalograms that showed cortical atrophy. EEG's were normal in 17 cases.

Chronic Stage.—There were 48 patients with disease in the chronic stage. Of these, 38 (79.2%) had abnormal EEG's. All 11 patients given psychological tests had evidence of organic brain damage. Pneumoencephalograms in seven of eight patients showed cortical atrophy. There were normal EEG's in 10 cases.

Presented as a Scientific Exhibit at the 107th Annual Meeting of the American Medical Association, San Francisco, June 23-27, 1958.

From the A. E. Bennett Neuropsychiatric Research Foundation and the Psychiatric Department of Herrick Memorial Hospital.

Of the two other deaths, one occurred in a 65-year-old woman with fractures of the rib who died of a pulmonary embolus eight days after admission. The second occurred in an 87-year-old man with known cardiac disease. Admitted with fractures of the rib, he developed cardiac failure and died with acute pulmonary edema two weeks after admission.

Comment

Of 118 patients with fractures of the rib, 20 demonstrated no other lesion. Thirteen patients developed subcutaneous emphysema. The rest collected either air or blood, or both, in one or both of the pleural cavities. Four received, in addition, a tear in the diaphragm.

Ten patients suffered fractures of the sternum and one a contusion of the sternal region without evidence of fracture. Thirty-one patients exhibited, as a prominent feature, a flail chest. One patient had an intrapulmonary, and another a subcutaneous, hematoma.

Hematuria	1
Total	4

Complications immediately attributable to the thoracic injury included three instances of organized hemothorax and three of empyema; two patients with the former and one with the latter were treated by decortication. Atelectasis was severe enough in 16 patients to require use of bronchoscopy and in 9, of tracheal suction. Pneumonia occurred in seven patients. A myocardial infarct developed in one patient and pulmonary edema and electrolytic imbalance in another.

Treatment in 42 patients consisted solely of supportive care, including in many instances, intercostal nerve block. The less formidable thoracentesis sufficed for accumulations of air and blood in the pleural cavity in 68 patients, while the more efficient intercostal drainage was required for larger collections in 47 patients. To remove air, the needle or catheter was put in the second anterior interspace and to drain off blood, in the seventh posterolateral space. Some modification of these approaches was demanded in patients with pocketed accumulations.

DIAGNOSIS OF INTERMEDIATE STAGE OF ALCOHOLIC BRAIN DISEASE

Abram E. Bennett, M.D., Berkeley, Calif.

Between the acute, reversible forms of alcoholic brain disease and the chronic, irreversible forms exemplified in cortical atrophy, there is an intermediate group of forms in which severe disturbances of the personality are present, but permanent organic deterioration can still be prevented. This belief, based on clinical impressions, is strengthened by electroencephalographic studies in 227 patients. Of these, 81 were classified as intermediate by clinical criteria, and 64 of the 81 had abnormal electroencephalograms which reverted slowly to normal. Five case histories illustrate the type of personality change encountered, the difficulty of management, and the need of resolute treatment if patients still in the intermediate, reversible stage are to be saved from irremediable cortical atrophy.

Alcoholic brain disease has been classified as either acute alcoholic brain syndrome, acute intoxication, delirium tremens, and acute hallucinosis (reversible) or as chronic brain syndrome, cortical atrophy, and midbrain involvement (organic dementia or Korsakoff's or Wernicke's disease [irreversible]). From my studies I believe that large numbers of chronic alcoholics lie between these groups and have what I term the intermediate brain syndrome; this paper presents the evidence for this concept.

An increase in the incidence of alcoholic brain damage throughout the United States is shown by many indications; for example, the increasing number of admissions to state hospitals, of which about 20% are for alcoholism, either with or without definite psychoses. In electroencephalographic studies of 758 (512 male, 246 female) alcoholic patients admitted to the psychiatric department of a private general hospital over the past six years, I have found at least one-third with abnormal recordings, many of which reverted to normal only after many months of sobriety.[1] These patients are in either the intermediate or the chronic stage of organic brain disease, in both of which cortical cerebral atrophy is present. If the diagnosis can be made in the intermediate stage, permanent organic deterioration may be prevented. I believe that thousands of these cases go unrecognized.[2] The patients have reached the phase of the essential pathology of chronic alcoholism; namely, compulsive drinking with permanent loss of control over drinking.

Heretofore the symptoms in this group were largely considered to be emotional personality changes, either sociopathic or neurotic disorders, to be treated psychotherapeutically; whereas one can now demonstrate that these are signs of organically induced cortical damage, more like frontal lobe syndromes. In those patients with slow reversal of abnormal electroencephalograms (EEG's) or persistence of abnormal records, the organic basis has been confirmed by psychological testing and by pneumoencephalography which reveals cortical atrophy. The degree of cortical atrophy roughly parallels the clinical and electroencephalographic findings. To be sure, some persons with chronic cases and with severe atrophy have normal electroencephalographic patterns; the same thing was seen in the past in treated cases of advanced paretic dementia[3] and also in some hopeless cases of Korsakoff's disease.

Electroencephalographic Studies in 227 Patients with Alcoholism

The electroencephalographic findings in general are persistent mild generalized activity of 15 to 30 and 4 to 7 waves per second and at times paroxysmal slowing and spiking. Of the 227 patients studied 78, or 34.4%, had two or more electroencephalograms; 25, or 11%, had psychological tests; and 12, or 5.3%, had pneumoencephalograms. Findings on the repeat EEG's are shown in the table.

Acute Stage.—Of 98 patients with alcoholic brain disease in the acute stage, 37 had abnormal EEG's which reverted to normal. Psychological testing was done in eight cases and in three showed evidence of organic brain damage. The EEG's were normal in 53 cases.

Intermediate Stage.—Sixty-four (79%) of 81 patients with disease in the intermediate stage had abnormal EEG's, which usually reverted to normal slowly. On psychological tests, five of six patients showed organic brain damage, while three of four patients had pneumoencephalograms that showed cortical atrophy. EEG's were normal in 17 cases.

Chronic Stage.—There were 48 patients with disease in the chronic stage. Of these, 38 (79.2%) had abnormal EEG's. All 11 patients given psychological tests had evidence of organic brain damage. Pneumoencephalograms in seven of eight patients showed cortical atrophy. There were normal EEG's in 10 cases.

Clinical Observations and Symptoms

Personality changes in persons with intermediate-stage brain damage include rationalization of drinking, pathological lying, infantile behavior, poor judgment, hostility, emotional lability, and lack of insight. The drinking pattern is addictive, dependent, or compulsive, usually with daytime and solitary drinking. Among physiological reactions are included blackouts, withdrawal reactions, and severe hangovers. There are delirious or convulsive episodes in about 50% of cases and systemic complications such as fatty liver, cirrhosis, and polyneuritis. On psychological tests the main findings are perceptual (visual) organization defect, intellectual and personality deterioration, and impaired power of abstraction.

Since I started my investigations I have discovered a study done in France by Lafon and others[4] that confirms my findings. They compared electroencephalographic and pneumoencephalographic studies in 100 cases of chronic alcoholism; the pneumoencephalograms revealed cerebral atrophy in 78 of the 100 cases. In 8% the atrophy was cortical, in 44% subcortical, and in 48% cortico-subcortical. No strict correlation between the degree of atrophy and the clinical manifestations was observed. Of the 100 patients, 80 had abnormal and 20 normal EEG's. In 58 patients the findings of pneumoencephalograms and EEG's could be definitely correlated. In 42 patients radiologic findings of atrophy were significant but the EEG's were within normal limits.

Increased abnormality	0	4	4
Totals	15	39	24

* Two or more repeat EEG's.

It is hard to determine accurately from the clinical picture alone just what phase of alcoholism the patient is in and what developing symptoms point to permanent brain damage. A significant early symptom is the appearance of blackouts or temporary periods of amnesia about happenings during drinking; this symptom usually means that brain disease from alcohol is either present or near. Irreversible brain change will begin possibly within a year or two after the development of recurrent blackouts. The phase of increasing dependency on alcohol and inability to control drinking forces the drinker into intricate rationalizations, alibis, and lies about his drinking, aptly called "alcoholic thinking" by Alcoholics Anonymous. Anyone in this phase should be considered to be suffering from progressive impairment of frontal lobe brain functioning. The drinking pattern is usually compulsive, with solitary and daytime drinking. Intellectual impairment continues, with poor judgment, emotional lability, infantile behavior, hostility, defiance and denial of illness, and complete lack of insight as part of the clinical picture. Too often these symptoms are considered to be due to the sociopathic personality of the alcoholic, whereas they are determined by the chronic toxic effects of the addictive drug ethyl alcohol and are organic symptoms of brain damage.

Report of Cases

Case 1.—A 45-year-old man, who had been a solitary drinker for the previous two years, drank up to a quart of vodka daily. He had lost 50 lb. (22.7 kg.) in one year and had had attacks of polyneuritis for the previous year. Personality change, general loss of interest, errors in business judgment, and occasional blackouts were his symptoms during the two years. An EEG and psychological tests were normal, spinal fluid findings were normal, there was 8% retention of sulfobromophthalein, and a pneumoencephalogram showed enlarged subarachnoid spaces and basilar cisterns, widened cortical pathways, and slight ventricular enlargement.

Case 2.—The patient, a man 50 years of age, had been an excessive, compulsive drinker for three years. At his first admission he had acute delirium followed by two convulsions. An electroencephalographic recording was distinctly abnormal, with slow activity, superimposed fast activity, and spike discharges; repeated records showed the same pattern. On a second hospitalization 18 months later for acute intoxication without delirium, his recording was still abnormal. He was given disulfiram and his drinking was controlled for the next two years, at the end of which his electroencephalographic pattern became normal. It has remained so for another four years.

Case 3.—A man, aged 45, had been a social drinker since college days. After discharge from the Army, after marital discord and divorce, he began excessive and compulsive secretive drinking. He had remarried, and for two years before his admission he had had temper outbursts and rages and had physically abused his wife. Even small amounts of alcohol produced blackouts and irrational periods, and his wife had to watch over him constantly. Psychotherapy was tried for months, and he joined Alcoholics Anonymous, but with little change in personality or behavior. He agreed to hospital care when his wife threatened to leave him. Two EEG's were normal. A battery of psychological tests was diagnostic of neurotic character disorder, with diffuse organic impairment defect in immediate memory, some concreteness in thinking, and a disturbance in his visual spatial organization. The pneumoencephalogram showed mildly dilated ventricles, dilated basal cisterns, and dilation of all the subarachnoid spaces—suggestive of brain atrophy. This patient now takes disulfiram daily and has remained abstinent for two years. He is successful in both his home life and his business.

Case 4.—A woman, aged 49, had drunk excessively for many years and had had violent episodes with extreme hostility toward her family. From time to time she would have convulsive seizures during her drinking. During her first hospitalization she denied having any problems and blamed her family entirely for all her difficulties. Three EEG's taken during her three weeks' stay in the hospital were all abnormal, with slow activity and moderately fast activity. The patient continued to drink after discharge, and on her second hospitalization two years later she was very demonstrative and euphoric or expansive; she had a grand mal convulsive seizure on the fifth day, followed by two days of delirium. An EEG taken at this time, just before the delirious episode, showed the same severe fast activity. Psychological tests during this period of hospitalization showed evidence of definite organic impairment. Pneumoencephalograms made elsewhere during a prior hospitalization showed evidence of brain atrophy.

Case 5.—A man, aged 49, had been a problem drinker for 20 years. Presumably his drinking contributed to marital difficulties, and in a few years his wife left him. He had lost many jobs because of drinking, but his father's influence had always helped him to find new work. After the father's death in 1954, the patient lived alone with his mother. He drank almost continuously except for periods when his mother took him on trips. He had been in contact with Alcoholics Anonymous since 1949, and in recent years had gone to meetings quite regularly but continued to drink. While living with his mother the patient tried to conceal his drinking from her, and she in turn acted constantly as a watchdog and nurse. During periods of drinking he would become ugly and sarcastic, telling his mother he despised her; on one occasion he physically abused her and almost killed her. In 1954, after he had lost a job because of drinking, he was committed to a state hospital for three months. On discharge, he took a trip abroad and impulsively, on short acquaintance, married again without having previously obtained a divorce.

At the insistence of his mother and through the influence of Alcoholics Anonymous, he was finally brought in for evaluation. The patient was an overly familiar, very pleasant, passive man. Although he admitted all of his difficulties with drinking, he minimized their importance and had no insight into the seriousness of his condition. He felt he could do all right if he could move to his own apartment away from his mother. He saw no reason why he should either stop drinking or attempt to find useful work. He readily agreed to go along with my recommendations but it was quite obvious that he could not carry them out.

An electroencephalogram revealed a distinctly abnormal record with a mixture of slow waves and fast activity. A variety of psychological tests showed a generalized deterioration of his personality functioning, with evidence of organic factors and defects such as confusion and memory impairment, all suggesting serious brain damage. On pneumoencephalographic study, it was found that he had almost twice the normal amount of cerebrospinal fluid and there was marked enlargement of the entire ventricular system and patchy evidence of brain atrophy. He made no improvement and had to be committed to a state hospital.

Therapeutic Implications

It is important to recognize the intermediate stage of alcoholic brain disease because the usual therapeutic program must be changed. These patients first need medical care until the organic features of brain damage clear sufficiently for them to be able to gain insight. In 50% of cases it usually means treating other systemic disease, such as liver damage, and may take from weeks to months. Education of relatives as well as of the patient is important, and the significance of brain damage must be explained. Relatives are more tolerant of patients' personality changes and unusual behavior if they understand that much of it is beyond their control but that through prolonged treatment the organic features will improve.

All of these patients require either restraining care, through prolonged hospital or institutional control, until some insight can be established or a combination of close supervision at home to prevent access to alcohol and the judicious use of disulfiram or calcium carbamide to prevent drinking. An inviolate principle in treatment must be that alcoholics with disease in this stage must abstain from use of alcohol absolutely and permanently.

Even though our patients are informed of the seriousness of alcoholic brain damage, they are especially difficult to treat and may continue drinking. Some die of intercurrent disease or by suicide or require permanent institutional care. If control can be established until the organic features clear and fairly normal judgment returns, the beginning of insight can be established and the motivation to learn to live without alcohol can be developed. Psychiatric evaluation to determine whether the alcoholism is symptomatic of a neurosis or psychosis must also be considered.

After the patient gains some insight, psychotherapeutic efforts may be fruitful, along with social and other supportive measures such as membership in Alcoholics Anonymous, to bring about effective rehabilitation. I have described my overall treatment program elsewhere.[5]

Conclusions

In the syndrome of the intermediate stage of alcoholic brain disease the electroencephalographic changes and the clinical and psychological findings lead to the diagnosis. Pneumoencephalographic examination will confirm the presence of cerebral atrophy. The organic features of these cases are often erroneously considered to indicate emotional personality disorders. The recognition of this stage is of extreme importance prognostically and therapeutically.

ADAMS-STOKES SYNDROME ASSOCIATED WITH CHRONIC HEART BLOCK

TREATMENT WITH CORTICOSTEROIDS

Charles K. Friedberg, M.D., Melvin Kahn, M.D., James Scheuer, M.D., Selvyn Bleifer, M.D.
and
Simon Dack, M.D., New York

The authors report on six patients in whom prednisone therapy either permanently or temporarily diminished or eliminated heart block and abolished the associated attacks of syncope. The attacks were eliminated within 24 hours after the beginning of corticosteroid therapy, whether or not the heart block was alleviated. The case histories illustrate the relief afforded by prednisone, the recurrence of heart block when dosages were reduced or interrupted, the occasional absence of symptoms in the presence of recurrent heart block, and the occasional failure of the patient to respond further to dosages of prednisone that had previously been effective. The drug was given in doses of 60 mg. per day initially, and it was not always possible to reduce the dosage to 30 mg. without a return of the syndrome. Prednisone sometimes was effective after atropine and isoproterenol had failed, and no untoward results followed the simultaneous administration of all three drugs.

Despite the availability of a variety of therapeutic agents, the treatment of Adams-Stokes syndrome associated with heart block is often unsatisfactory and the prognosis ominous. The sympathomimetic amines, isoproterenol hydrochloride and epinephrine,[1] and external or internal electrical artificial cardiac pacemakers[2] have been used most commonly and with variable degrees of success.[3] Although their use has often been lifesaving, their effectiveness is commonly of temporary duration. The sympathomimetic drugs must be given intravenously and the dosage carefully and continuously adjusted. The use of a cardiac pacemaker requires complex equipment which is not always readily available and has other disadvantages. Among other agents which have been used, atropine is generally ineffective, and the value of sodium lactate has not been adequately confirmed. The use of the latter is associated with the danger of serious arrhythmias and congestive heart failure. Because of the poor prognosis for patients with Adams-Stokes syndrome and the shortcomings of commonly used therapy, it appears desirable to call attention to additional therapeutic agents, the corticosteroids. The purpose of this report is to present some encouraging experiences with the use of the drugs in six patients with Adams-Stokes syndrome and heart block, in whom prednisone therapy was either permanently or temporarily capable of abolishing the seizures and of diminishing or eliminating the heart block.

From the Division of Cardiology, Department of Medicine, the Mount Sinai Hospital.

In single cases of heart block associated with acute myocardial infarction reported by Prinzmetal and Kennamer[4] and by Phelps and Lindsay[5] ACTH or cortisone therapy abolished the attacks and restored sinus rhythm within one to several hours. Rosenfeld and Segall[6] administered cortisone to two patients with Adams-Stokes syndrome and heart block. One died despite its use in conjunction with the external cardiac pacemaker, whereas in the other the attacks ceased soon after administration of cortisone. The use of an external pacemaker which previously had been necessary for 10 hours was no longer required. Tung and colleagues[7] terminated Adams-Stokes attacks in two patients with complete heart block within 24 hours after administering ACTH therapy. In three cases reported by Litchfield and co-workers[8] corticotropin controlled attacks in less than 24 hours. Jones[9] was able to prevent repeated attacks by the simultaneous administration of isoproterenol hydrochloride intravenously and 40 mg. of prednisone daily; the relative importance of the prednisone therapy is therefore uncertain.

Report of Cases

Case 1.—A 79-year-old man was admitted to the hospital on Sept. 26, 1958, because of a syncopal attack three weeks prior to admission and dizzy spells, dyspnea, and confusion since. The patient had mild diabetes of 30 years' duration. The night prior to admission there was an episode of acute pulmonary edema. An electrocardiogram revealed a varying 2:1 and 3:1 atrioventricular block (fig. 1*A*).

The patient was treated for congestive heart failure, and because of hemoptysis, possibly due to pulmonary embolism, therapy with anticoagulants was begun. Atropine, ephedrine, and isoproterenol (Isuprel) hydrochloride were ineffective in improving the degree of heart block. On the patient's 15th hospital day treatment with prednisone, 15 mg. four times daily, was begun. Thirty-six hours later, after the patient had received 90 mg. of prednisone, normal atrioventricular conduction was restored with the ventricular rate averaging 75 per minute (fig. 1*B*). Mental clarity returned and the patient became asymptomatic. On the 18th hospital day the administration of prednisone was abruptly stopped because of increased glycosuria. Seven days after therapy with prednisone had been discontinued there was a syncopal episode and an electrocardiogram revealed 1:1 and 2:1 atrioventricular conduction with the ventricular rate varying between 44 and 72 per minute (fig. 1*C*). Prednisone was again given and normal atrioventricular conduction was restored within 24 hours (fig. 1*D*). The patient was finally discharged from the hospital after 29 days, receiving 5 mg. of prednisone four times daily.

While the patient was at home complete heart block with Adams-Stokes attacks occurred three times concomitantly with an abrupt reduction in the prednisone dosage. Regular sinus rhythm was restored on each occasion within 24 hours after the reinstitution of prednisone therapy. The patient eventually died at home during an episode of acute pulmonary edema.

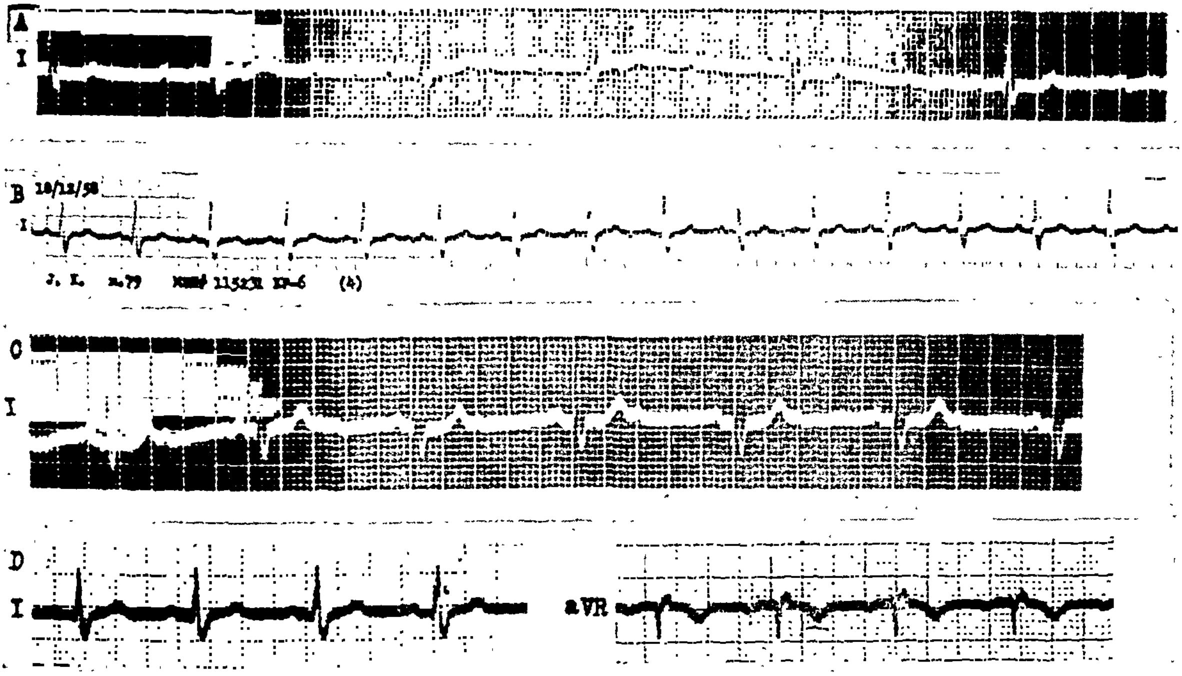

Fig. 1.—Electrocardiograms of patient in case 1. *A*, on admission of patient 2:1 and 3:1 atrioventricular conduction was present. *B*, 36 hours after the initiation of prednisone therapy normal atrioventricular conduction was present. *C*, seven days after cessation of prednisone therapy 2:1 atrioventricular conduction was present. *D*, 24 hours after reinstitution of prednisone therapy normal atrioventricular conduction was present.

Comment.—This case illustrates the prompt abolition of Adams-Stokes syndrome and the restoration of normal atrioventricular conduction within 12 to 36 hours on repeated occasions with prednisone therapy and reversion to heart block within several days after the cessation of therapy.

Case 2.—A 57-year-old woman was admitted to the hospital on May 5, 1958, because of syncopal attacks during the week prior to admission. She had been known to have hypertension for one year prior to admission for which she was treated with mild antihypertensive drugs. An electrocardiogram revealed a 2:1 atrioventricular block and periods of complete heart block and was suggestive of left ventricular hypertrophy. Roentgenographic examination disclosed enlargement of the heart.

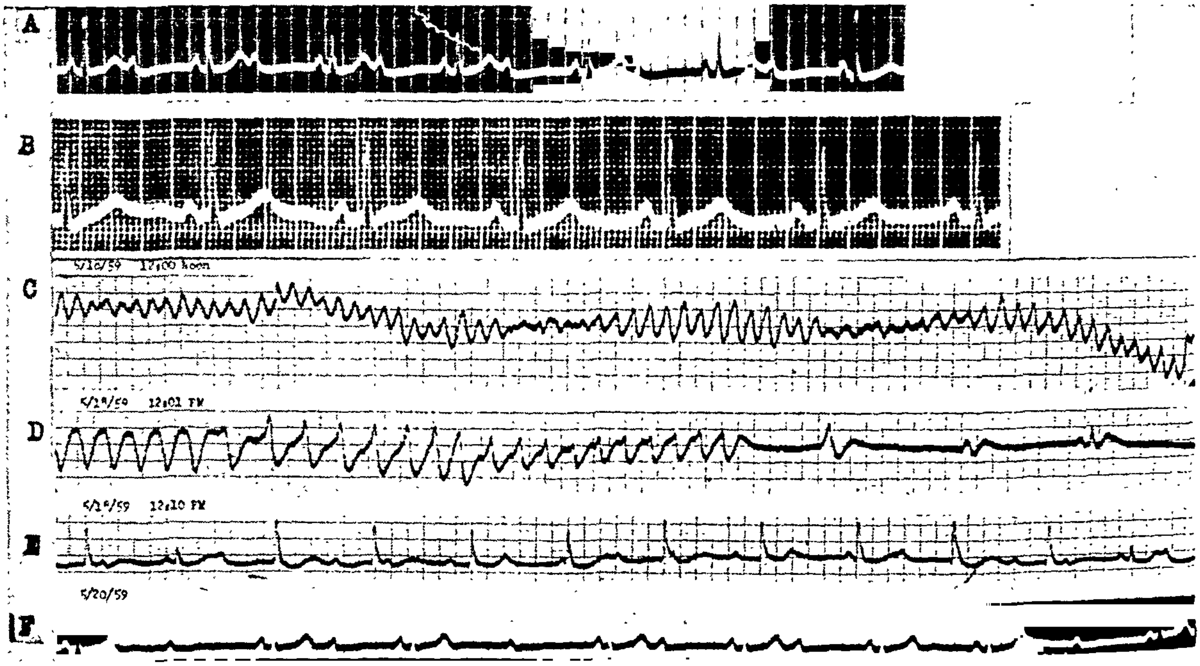

Fig. 2.—Electrocardiograms of patient in case 2. *A,* on patient's second admission to hospital 2:1 atrioventricular conduction was present. *B,* 16 hours after initiation of prednisone therapy normal atrioventricular conduction was present. *C* and *D,* shortly after patient received isoproterenol ventricular flutter, fibrillation, and tachycardia were present. *E,* 10 minutes after ventricular arrhythmia, complete heart block with occasional conducted beats was present. *F,* after episode of ventricular arrhythmia second degree heart block persisted.

On the second hospital day there was a generalized convulsive seizure which was associated with a slow heart rate and was treated with intramuscularly injected isoproterenol, atropine, and ephedrine. There were no further Adams-Stokes attacks, and after the patient was discharged she was given a long-acting isoproterenol preparation, but a 2:1 heart block still persisted. She was again admitted to the hospital Jan. 26, 1959, because of two syncopal attacks. An electrocardiogram revealed a 2:1 atrioventricular block (fig. 2*A*). With sublingual isoproterenol and atropine therapy the ventricular rate remained at 40 per minute. On the second hospital day there was a syncopal attack, and an electrocardiogram revealed a complete heart block, with a subsequent 2:1 atrioventricular block.

On the third hospital day therapy was started with 10 mg. of prednisone four times daily, and 16 hours later there was normal atrioventricular conduction (fig. 2*B*). Administration of atropine and isoproterenol was discontinued, and during the next several days there were occasional periods of 2:1 atrioventricular block and complete heart block but no syncopal attacks. On two occasions reduction of dosage of prednisone was followed by 2:1 heart block, and there was a return to normal conduction after the dosage was again increased. For the next 10 days there was alternation between 1:1 and 2:1 atrioventricular conduction, but the patient was asymptomatic. Therapy with prednisone was then discontinued and 2:1 and 3:1 atrioventricular block predominated. After therapy with long-acting isoproterenol but without prednisone 2:1 and 1:1 conduction remained the predominant rhythm and the patient was discharged.

On June 19, 1959, the patient was readmitted because of a syncopal attack. The electrocardiogram revealed complete heart block. Therapy was started with intravenously given hydrocortisone, atropine, and prednisone, 15 mg. four times a day. The next day there was an episode of ventricular arrhythmia shortly after the patient had received intramuscularly given isoproterenol (fig. 2*C, D,* and *E*). This reverted spontaneously to a normal sinus rhythm, followed by 2:1 and complete heart block. Thereafter the rhythm varied from normal atrioventricular conduction to second degree heart block (fig. 2*F*), and there were no further syncopal attacks. Administration of prednisone and atropine was discontinued and the patient was discharged on the 15th hospital day.

Comment.—This case illustrates the effectiveness of treatment with prednisone in abolishing syncope and restoring normal atrioventricular conduction after treatment with sympathomimetic amines had failed. Despite continued use of prednisone there was gradual reversion to a partial heart block, but syncope did not recur. One of the dangers (ventricular tachycardia or fibrillation) of sympathetic amine therapy was encountered.

Case 3.—A 58-year-old man was admitted to the hospital on July 16, 1958, because of several attacks of syncope during the preceding two weeks. There was no history of heart disease. The electrocardiogram showed a sinus arrhythmia at a rate of 70 per minute with 1:1, 3:2, and 2:1 atrioventricular conduction and a left bundle-branch-block pattern.

Despite large doses of atropine, isoproterenol, and ephedrine there was no change in the cardiac rhythm by the 10th hospital day. Use of all these medicaments, except isoproterenol, was discontinued. Administration of prednisone, 10 mg., three times a day, was begun. After two doses of prednisone normal atrioventricular conduction was present. The isoproterenol therapy was discontinued and the dosage of prednisone decreased to 5 mg. three times a day. On the 13th hospital day the patient was discharged on this regimen with normal atrioventricular conduction and without symptoms.

Administration of prednisone was discontinued three days after discharge, and normal conduction persisted for four months, until Nov. 11, 1958, when again episodes of dizziness without syncope were noted by the patient. An electrocardiogram showed complete heart block with occasional conducted beats and a ventricular rate of 40. Despite therapy with isoproterenol, atropine, prednisone, and molar lactate, complete heart block persisted. All medication was stopped and the patient was discharged with complete heart block. This rhythm persisted after discharge, but the patient remained asymptomatic.

Comment.—This case illustrates the effectiveness of prednisone therapy in restoring normal atrioventricular conduction and preventing Adams-Stokes attacks after treatment with the usual sympathomimetic amines had failed. In contrast to the preceding case, in this case the effect was long lasting. The refractoriness of the heart block to prednisone on a subsequent trial is also illustrated.

Case 4.—A 55-year-old man was admitted to the hospital on March 10, 1959, because of syncopal attacks. For the two years prior to admission he had been known to have partial heart block, and there were occasional episodes of syncope. For the week prior to admission there was a slowing of the pulse rate and more frequent syncopal attacks. The electrocardiogram showed a sinus rhythm with 2:1 and 3:1 atrioventricular conduction and a right-bundle-branch block pattern.

There was no change in the cardiac rhythm during therapy with isoproterenol and ephedrine. Treatment with these drugs was discontinued and administration of prednisone, 15 mg. four times a day, was begun. Sixteen hours after the first dose of prednisone was given 1:1 and occasional periods of 2:1 atrioventricular conduction were noted. On the seventh hospital day the dosage of prednisone was reduced to 40 mg. per day, and ephedrine, 25 mg. four times a day, was added. On the ninth hospital day the predominant conduction was 1:1 and the ventricular rate was 65. There were no further syncopal attacks and the patient was discharged on a regimen of 30 mg. of prednisone and atropine. The pulse rate soon decreased to between 32 and 40 per minute and the electrocardiogram showed 2:1 and 3:1 atrioventricular block. The patient remained asymptomatic, however. One month later, without any change in medication, the pulse rate became 80 and 1:1 atrioventricular conduction was noted. Despite the periods of varying atrioventricular conduction the patient had no Adams-Stokes attacks for the three months during which he received prednisone. For the previous two years there had been no period free of syncopal attacks of greater than one month's duration.

Comment.—This case illustrates the effectiveness of prednisone in abolishing Adams-Stokes attacks and in restoring normal atrioventricular conduction. There was a reversion to a partial heart block when dosage of prednisone was decreased but there was no recurrence of symptoms.

Case 5.—A 64-year-old man was admitted to the hospital on Dec. 22, 1958, because of syncope. Attacks had begun in May, 1958, and recurred with increasing frequency. An electrocardiogram revealed sinus rhythm with 2:1 and 3:2 atrioventricular block, a P-R interval of 0.22 seconds, and a right-bundle-branch block pattern.

With use of ephedrine and atropine therapy, normal atrioventricular conduction was restored. On the 10th hospital day the patient developed bronchopneumonia with a temperature of 104 F (40 C). This was followed by several Adams-Stokes attacks and complete heart block. From this time on the patient was monitored by a pacemaker (Electrodyne model PM-65). Electrical stimulation was used during the syncopal attacks, which were all due to periods of asystole. With antibiotic therapy the fever had abated but the attacks continued despite isoproterenol therapy. On the 16th hospital day there was a syncopal episode during micturition. Therapy with isoproterenol was discontinued and administration of prednisone, 60 mg. per day in divided doses, was begun. No further syncopal attacks occurred. The next day 2:1 atrioventricular block was the predominant cardiac rhythm, and after four days normal atrioventricular conduction was present.

Three attempts were made to abruptly reduce the steroid dosage to less than 60 mg. per day. Each attempt was soon followed by Adams-Stokes attacks, and these were promptly abolished by reinstitution of the original dosage level. After several weeks, however, the patient developed complete heart block with rare Adams-Stokes attacks despite continued prednisone therapy.

Comment.—This case illustrates the repeated effectiveness of prednisone therapy in the abolition of Adams-Stokes attacks; an apparent dosage dependence for these effects; and the development of refractoriness to dosages of prednisone that were previously effective.

Case 6.—A 57-year-old woman was admitted to the hospital on June 8, 1958, because of a convulsion. An electrocardiogram revealed complete heart block with multifocal ventricular contractions and a ventricular rate of 36 to 40 per minute. Therapy with large doses of atropine and isoproterenol for three weeks failed to significantly reduce the frequency of Adams-Stokes attacks.

She was then given hydrocortisone, 50 mg. intramuscularly, and prednisone, 10 mg. every six hours. The other medications were continued without change. During the 36 hours after the administration of hydrocortisone she had four mild syncopal episodes with convulsions, but thereafter she was free of symptoms. The complete heart block persisted with an unchanged regular idioventricular rhythm. On July 9 the dosage of prednisone was reduced to 30 mg. daily, and the next day the patient had a short syncopal episode. She was discharged from the hospital on July 11 receiving prednisone, 40 mg. daily, atropine sulfate, 0.4 mg. three times daily, and isoproterenol, 5 mg. sublingually every four hours. At the time of this writing she has had regular sinus rhythm without heart block, and the dosage of prednisone has been diminished to 15 mg. daily.

Shortly after the patient's discharge the dosage of predisone was decreased to 30 mg. daily. She had occasional giddiness without loss of consciousness. Subsequently, on three occasions when the dosage of prednisone was decreased, she experienced dizziness and syncope. On each occasion after an increase in the dosage of prednisone the patient became asymptomatic, although complete heart block persisted.

Comment.—Prednisone therapy was effective on numerous occasions in preventing Adams-Stokes attacks without any change in atrioventricular conduction. Complete heart block persisted and the ventricular rate was unchanged, but asystolic intervals were prevented. This effect was apparently related to the dosage of prednisone.

Comment

In these six patients with chronic heart block, the amelioration of symptoms after administration of prednisone was characterized by a variety of responses. There was restoration of normal atrioventricular conduction on the initial trial of prednisone therapy in five of the six patients. All of them had been receiving isoproterenol, ephedrine, and/or atropine without effect immediately prior to the institution of prednisone therapy. Within 8 to 36 hours after the onset of therapy there was electrocardiographic evidence of improvement of atrioventricular conduction. When there was complete heart block at the time of prednisone therapy a period of partial heart block preceded the conversion to normal conduction, which usually occurred within 48 hours. Paralleling the improvement as revealed by electrocardiogram there was a marked clinical benefit with diminution and subsequent cessation of Adams-Stokes seizures.

In one patient (case 3) normal atrioventricular conduction persisted for several months after the cessation of prednisone therapy, but when heart block subsequently recurred, prednisone in the same dosage was ineffective. In another patient (case 1) normal atrioventricular conduction lasted only 12 days after cessation of therapy, but whenever complete heart block recurred normal conduction was always restored after prednisone therapy. It is apparent that the effectiveness of prednisone therapy varies from patient to patient and in any single patient from time to time. Although a reversion to normal conduction often occurs with the initial trial, subsequent usage may be without effect.

One patient (case 5) clearly demonstrated a dosage dependence during prednisone therapy. Reversion to normal conduction was accomplished on several occasions when prednisone was given in a dosage of 60 mg. per day. When the dosage was decreased to 30 mg. daily heart block and Adams-Stokes seizures recurred. When the dosage was raised to the original level, normal conduction again was restored. Normal conduction could be maintained with 60 mg. of prednisone but not with lower doses. This effect could not be maintained permanently, however, and despite large doses of prednisone complete heart block recurred.

In two patients (cases 2 and 4), although normal atrioventricular conduction was restored with use of prednisone, partial heart block recurred while they were on therapy without a change in dosage. These patients did not have a recurrence of Adams-Stokes attacks, however, and were clinically improved.

One patient (case 6) exhibited a response to therapy with prednisone which was qualitatively different from responses in the preceding cases. Repeated Adams-Stokes seizures occurred while this patient was receiving atropine, ephedrine, and isoproterenol. Within 8 to 24 hours after starting therapy with prednisone the patient was asymptomatic in spite of the persistence of complete heart block. The ventricular rate remained slow, but there were no longer asystolic periods. Every attempt to decrease or discontinue use of prednisone was followed by a recurrence of Adams-Stokes attacks.

Relationship Between Steroid Therapy and Clinical Results.—It is necessary to consider, first, whether corticosteroid drugs are actually to be credited with the clinical results after their use and, second, the possible mechanisms by which these effects might have been accomplished. The variable and unpredictable course of Adams-Stokes attacks is a noteworthy obstacle to distinguishing between their spontaneous and drug-induced cessation. Nevertheless, both in the cases here reported and those in the literature, in view of the frequency, severity, and duration of the attacks prior to corticosteroid therapy, the speed with which they disappeared after the start of treatment is sufficiently impressive to suggest that the beneficial effect was due to the use of corticosteroids. Furthermore, the attacks tended to recur with discontinuation of the drug therapy or reduction below a critical dosage, whereas the attacks were prevented when the drug was again administered in adequate dosage.

In the case reported by Prinzmetal and Kennamer[4] reversion of complete heart block to sinus rhythm occurred within a few hours after administration of ACTH, and when heart block recurred it promptly disappeared after further ACTH therapy. In the case reported by Phelps and Lindsay[5] Adams-Stokes attacks of increasing frequency for about 12 hours were occurring every few minutes, but only one last attack occurred soon after cortisone was given, and the heart block disappeared sometime within the next nine hours. Despite this time relationship, the association of the heart block with acute myocardial infarction raises the possibility of spontaneous disappearance of the heart block with subsidence of the acute infarction. This possible objection does not apply to the other cases culled from the literature or to the cases here reported.

In one of the cases reported by Tung and associates[7] there had been 23 Adams-Stokes attacks in a period of 48 hours preceding corticotropin therapy. Not a single syncopal attack occurred after treatment was started with ACTH, and within 24 hours complete atrioventricular block was replaced by regular sinus rhythm. In the second of their cases there had been eight Adams-Stokes attacks in 48 hours prior to treatment, three brief seizures soon after completing an intravenous infusion of ACTH, and three more seizures 12 hours later, but none thereafter. But in these cases complete heart block persisted.

In one of the cases reported by Litchfield and others,[8] the patient had been suffering Adams-Stokes attacks from 1 to 40 times daily for many weeks, but the attacks ceased within a few hours after corticotropin therapy was begun. In another case the patient had been suffering such attacks for eight weeks, and within six hours after the beginning of corticotropin therapy the attacks ceased. Similarly, in the cases reported here, Adams-Stokes attacks promptly ceased, and in some cases the attacks recurred when the prednisone therapy was discontinued and were repeatedly eliminated when prednisone therapy was resumed. As a rule normal conduction was restored within 12 to 36 hours. It was difficult to avoid the conclusion that the cessation of attacks and improvement in atrioventricular conduction was related to the treatment with prednisone.

Mechanisms of Beneficial Effect of Steroids.—Any explanation for the mechanism of the beneficial action of the corticosteroid drugs in these cases must account both for the improvement in atrioventricular conduction and for the control of the Adams-Stokes attacks. When atrioventricular conduction is improved and the ventricles respond to the sinus pacemaker the prevention of the Adams-Stokes attacks is obviously due to restoration of normal conduction. But it is apparent that incomplete and complete heart block may occur without Adams-Stokes attacks, and in our patients as well as the others to whom we have referred, the Adams-Stokes attacks were often eliminated before normal conduction was restored, and in some cases even though incomplete or complete heart block persisted.

That corticosteroids may accelerate or improve atrioventricular conduction is indicated by studies of the P-R interval in patients with adrenal cortical hypofunction (Addison's disease) and those with adrenal cortical hyperfunction (Cushing's disease). Lown and associates[10] found that the mean P-R interval in patients with adrenal cortical hypofunction was longer than that of normal controls and that 20% of the former had first-degree heart block during their illness. In most of those who received cortisone therapy there was a significant shortening of the P-R interval. Conversely, patients with adrenal cortical hyperfunction had a mean P-R interval which was shorter than the mean of normal controls; in a high percentage of the former the P-R interval was 0.12 seconds or less. After adrenalectomy had been performed the P-R intervals lengthened. The effect on the P-R interval was attributed to the glucocorticoid and not to mineralocorticoid adrenal secretion, because desoxycorticosterone acetate therapy had no effect on the P-R interval and because addisonian crisis which is associated with electrolyte disturbance likewise did not affect the P-R interval.

The mechanism by which the corticosteroids may accelerate atrioventricular conduction is unknown. Although the corticosteroids may tend to produce slight potassium depletion and alkalosis and although alkalosis accelerates atrioventricular conduction[11] there is no evidence to support such a mechanism to account for improved conduction in heart block after corticosteroid therapy. Sympathetic stimulation accelerates atrioventricular conduction.[1] Although there is no direct evidence that treatment with corticosteroids may increase the responsiveness of the atrioventricular conduction system to sympathetic stimuli, it is of interest to note that there are observations indicating an increase in vascular sensitivity (vasoconstriction) to norepinephrine after the administration of corticonteroids.[12] The anti-inflammatory action has generally served as the rationale for the use of corticosteroids in patients with heart block. This was the basis of its use in patients with acute myocardial infarction and the explanation of its effectiveness. Similarly in the cases reported by Tung and co-workers[7] these drugs were used because of the assumption of persistent rheumatic inflammation in the conduction system. However such an explanation is difficult to invoke in the cases here reported.

It is noteworthy that after therapy with corticosteroids the attacks of Adams-Stokes syndrome often ceased before there was any apparent improvement in atrioventricular conduction and even when complete heart block persisted. This indicates that the arousal and stabilization of ventricular pacemakers is an independent action and may occur earlier than any effect on atrioventricular conduction. There is no basis for attributing this important effect on idioventricular pacemakers to any anti-inflammatory action of the corticosteroids.

This report of encouraging results after corticosteroid therapy in cases of heart block and Adams-Stokes syndrome should not be regarded as necessarily representative of the effectiveness of these drugs in a much larger all-inclusive series of consecutive cases of this disease. We know of two other patients not under our care in whom the use of prednisone alone, in apparently adequate dosage, was ineffective in causing either symptomatic or electrocardiographic improvement. Undoubtedly favorable results are more likely to be reported than unfavorable ones. Furthermore, it is apparent that patients who appear to respond favorably at one stage of the disease may later become refractory to the same treatment. Similar variability of response has been noted with the other accepted and generally used methods of therapy.

In the six cases reported here the favorable response from administration of prednisone occurred after therapy with the other drugs had failed. The seriousness of the disease, the ready availability and simplicity of administration of corticosteroids, and the uncertainty of response of other therapies justify the prompt use of the corticosteroids at the onset of attacks of Adams-Stokes syndrome with heart block. Sympathomimetic drugs and artificial pacemakers, which usually cannot be used as promptly, can be used in conjunction with corticosteroids if the latter are ineffective.

Summary

Prednisone therapy was effective in abolishing Adams-Stokes attacks in six patients. In five of these atrioventricular conduction was improved or restored to normal. The frequency and duration of the seizures prior to treatment and the speed with which they were controlled after treatment suggest that the prednisone therapy was responsible for the beneficial effects. The Adams-Stokes seizures were abolished in some patients even when heart block persisted, suggesting that prednisone arouses and stabilizes idioventricular pacemakers as well as improves atrioventricular conduction. The use of adrenal glucocorticoids appears warranted in view of their immediate availability and simplicity of administration. Sympathomimetic drugs and an artificial pacemaker can be used simultaneously, if available, or added later if therapy with corticosteroids is ineffective.

1125 Fifth Ave. (28) (Dr. Friedberg).

Dr. Harry Jaffe supplied information on the patient in case 3, Dr. Arthur Grishman in case 4, and Dr. Howard Moscovitz in case 6.

CLINICAL NOTES

ARTIFICIAL EMBOLIZATION OF CEREBRAL ARTERIES

REPORT OF USE IN A CASE OF ARTERIOVENOUS MALFORMATION

Alfred J. Luessenhop, M.D.
and
William T. Spence, M.D., Washington, D. C.

It has been the theoretical and technical consideration of one of us (A. J. L.) that certain large arteriovenous malformations of the brain can be treated by artificial embolization. The major feeding arteries are greatly enlarged compared to the arteries to the surrounding brain.[1] Because of the reduced peripheral resistance there is a far greater flow of blood to the malformation than to the surrounding brain.[2] The main arterial feeders arborize into considerably smaller, "arteriole-like" vessels before entrance into the larger channels which constitute the bulk of the lesion.[3] Therefore, an embolus of predetermined size and configuration, introduced even far proximal to the malformation, will always find its way to it. By its size the embolus will be excluded from passage into the smaller branches to the brain and will ultimately come to rest at a site proximal to the malformation where normal and abnormal vessels are seen to be clearly separate (fig. 1).

Herewith is the first reported case of an arteriovenous malformation of the brain treated by embolization according to the above considerations.

Report of a Case

On Sept. 11, 1959, a 47-year-old woman, referred by Dr. Bruce Mallett, was admitted to the Georgetown University Hospital about four hours after the rapid onset of a severe generalized headache, drowsiness, and impairment of vocal expression.

Since early childhood she had had frequent episodes of syncope. For 15 years prior to admission she had had occasional episodes of transient numbness and weakness of the right arm and leg, a slight loss of skilled movements of her right fingers, and periods during which she had difficulty in finding "the right word."

Initial examination revealed the following pertinent findings. The blood pressure was 100/80 mm. Hg, with a pulse rate of 80 per minute. She was drowsy and in moderate distress because of a headache. She showed a mild expressive dysphasia, slight nuchal rigidity, and mild right hemiparesis, with greatest involvement of the face, wrist, and fingers. There was a soft, blowing systolic bruit over the left eye. There was no evidence of cortical sensory loss.

A lumbar puncture revealed an initial pressure of 300 mm. of cerebrospinal fluid which was dark pink and without evidence of xanthrochromia. A percutaneous carotid angiogram on the left side was made 10 hours after admission, and one was made on the right side two days later. As shown in fig. 2, the angiogram on the left side revealed a large arteriovenous malformation intimately involving the areas of motor, speech, and the lower portion of the motor strip. The angiogram of the right side showed filling of both anterior cerebral arteries, with virtually no contribution to the malformation. The middle cerebral trunk on the left side was increased in diameter to about 5 mm. up to its point of division. More distally, there were many large trunks but precise measurements could not be made.

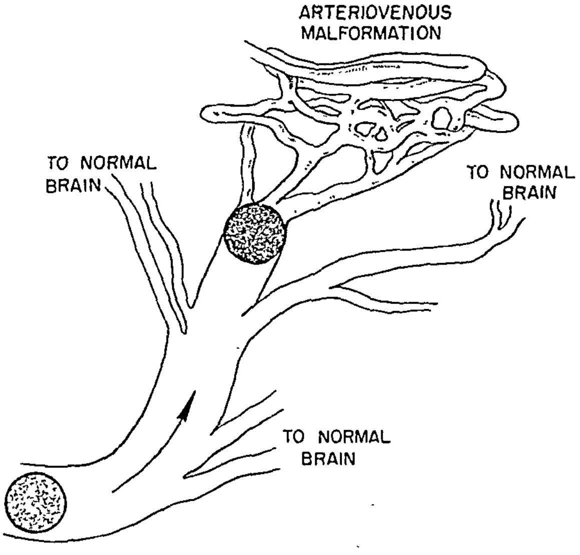

Fig. 1.—Embolus in main arterial channel, excluded from smaller branches to normal brain and forced to arrest at point proximal to malformation.

After eight hours of hospitalization the patient's headache subsided, but her expressive dysphasia in-

---

From the Department of Surgery (Neurosurgery), Georgetown University Medical School, Washington, D. C.

creased, causing her to omit or alter at least one word per sentence. The paresis of her right hand, fingers, and face improved somewhat.

Operation was performed on Sept. 18, 1959, seven days after admission. With the patient under local anesthesia the left common carotid bifurcation was exposed. Four spherical emboli, made of methyl methacrylate,[4] were introduced at intervals of about 15 minutes. They measured successively about 2.5, 3.0, 4.0, and 4.2 mm. in maximum diameter. After introduction of each embolus, strength of the right arm and speech were tested and x-rays were taken to determine the site of arrest. Immediately after introduction of the fourth embolus the patient became drowsy and showed increasing weakness of the right hand but no alteration of speech. The angiogram made shortly thereafter is shown in fig. 3. The malformation was reduced to a slight stain, and for the first time normal filling of the anterior and middle cerebral arteries was evident. The emboli, identifiable by metallic fragments within the plastic coating, had come to arrest at the beginning of the malformation.

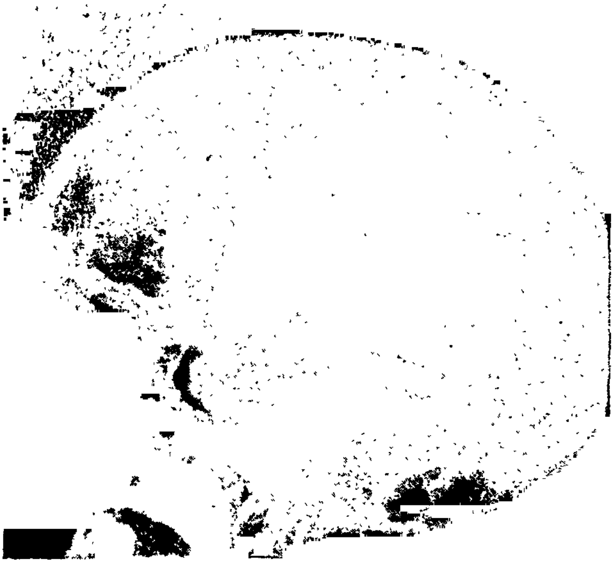

Fig. 2.—Lateral view of preoperative arteriogram, showing malformation.

The weakness of her right hand progressed over the next 14 hours until there was but feeble extension and flexion of the wrist and fingers. Thereafter the strength rapidly returned. Seven weeks after surgery she was able to write legibly with her right hand. At no time during her postoperative course was there any recurrence of her dysphasia or loss of cortical sensory function.

Roentgenograms of the skull taken five days after surgery was performed showed that the fourth embolus, represented by the large round fragment in fig. 3, had moved to a position closer to the malformation. This embolus, being larger than the others, had temporarily lodged too far proximal to the malformation and had thereby caused her transient neurological defect. The follow-up angiogram of the left carotid artery, made 26 days afte surgery, is shown in fig. 4. There is excellent fillin of the normal arteries and only a remnant of th malformation persists.

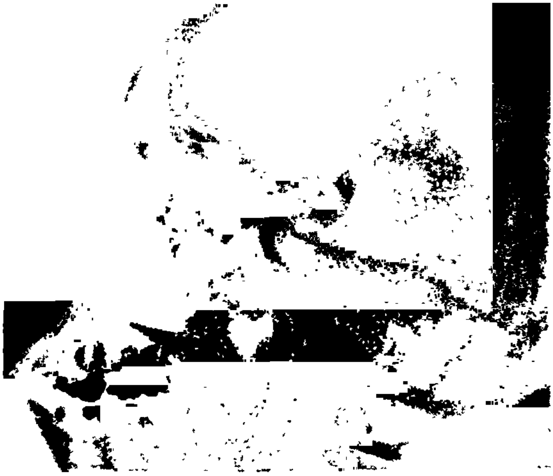

Fig. 3.—Immediate postoperative arteriogram, showin nearly complete obliteration of malformation and filling normal arteries.

Comment

Because this initial case was, to a large degre a trial of the theoretical considerations describe above, the emboli were made from material no likely to promote thrombosis. With further confirmation of the applicability of this method this safeguard need not be adhered to.

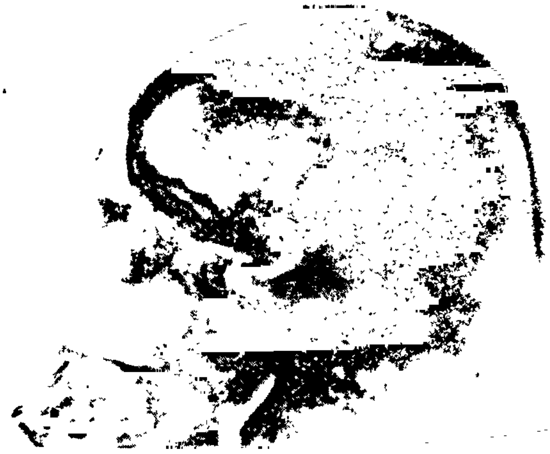

Fig. 4.—Arteriogram made 26 days after surgery; remnant of malformation persists.

Most large arteriovenous malformations are supplied primarily or solely by the middle cerebral artery.[1] This artery, being the natural continuation of the internal carotid, forms the route the emboli will naturally seek. However, with large malforma-

tions situated in the middle of the hemisphere and generously supplied by both the middle and anterior cerebral systems, prior embolization of the middle cerebral contribution will leave direct intracranial occlusion of the anterior cerebral feeders to effect a satisfactory result. Important cortical areas over the surface of the hemisphere will thereby remain undisturbed.

If the emboli can be retrieved by attachment of sutures or wire, an adaptation of this technique for the treatment of saccular aneurysms is possible. If the distance the embolus can ascend in the internal carotid artery is limited, it can be held in a position to occlude temporarily the intravascular orifice of the aneurysm. After thrombosis has occurred, recovery of the embolus is effected.

Summary

Theoretical considerations suggest that the differential in blood flow between an arteriovenous malformation and the surrounding brain, plus the differential in size among the arteries directly feeding the malformation, the branches to the brain, and the small arteries at the beginning of the malformation, will always lead an embolus of proper size to a site of arrest at the beginning of the malformation. A patient with large, inoperable malformation was satisfactorily treated by embolization.

The methyl methacrylate emboli used in this study are available from the L. D. Caulk Company, Milford, Del.

PHOTOSENSITIVITY DUE TO TETRACYCLINE DERIVATIVE

William E. Morris, M.D., Corpus Christi, Texas

Dermatological manifestations have been reported from the use of many drugs, particularly antibiotics. With the widespread use of antibiotics, particularly the tetracycline derivatives, it is likely that photosensitivity will be found in the ordinary practice of medicine, particularly when warmer weather comes and more persons are exposed to sunlight. A single case of a severe reaction to demethylchlortetracycline hydrochloride was noted in September, 1959.

Report of a Case

A 30-year-old woman was suffering from a generalized ache, a sore throat, and a respiratory infection. She had a slightly elevated temperature and pulse rate; otherwise, physical findings were normal. On Sept. 1 she was put on therapy with demethylchlortetracycline (Declomycin) hydrochloride, 150 mg. four times daily, for four days. On Sept. 5 the patient went surf fishing and was exposed to sunlight over the arms, hands, neck, and face. Within 30 to 40 minutes she began to develop a severe tingling of the tips of the ears and the backs of the hands. She thought that she might be getting too much sun and immediately put on a shirt, but within another 30 minutes she was most uncomfortable and discontinued the fishing.

By the evening she was quite red over the dorsal surfaces of the hands and the tops of the ears, and a butterfly distribution of redness was noted over both cheeks. On Sept. 6 she had an extreme edema of the dorsal surfaces of the hands, across the bridge of the nose, over the cheeks, and over the ears, but none on the shoulders. She had ordinary sunburn on her shoulders but no edema or pain. At this time laboratory indexes showed a circulating eosinophil count of 2,331 per cubic millimeter. She was given ACTH in reducing doses and chlorprophenpyridamine (Chlor-Trimeton) by mouth, to which she began to respond in about 24 hours. On Sept. 18 she had 33 circulating eosinophils per cubic millimeter and an otherwise perfectly normal hemogram.

After the patient's condition had cleared completely, we decided to attempt to reproduce this situation and evaluated her condition Oct. 13; her circulating eosinophil count was 251 per cubic millimeter, with normal white and differential blood cell counts. She was given one capsule only of demethylchlortetracycline, 150 mg., on Oct. 31, without any subsequent symptoms. On Nov. 1 the patient began taking one capsule four times a day, which she took for four days. The next blood cell count showed an eosinophil count of 155 per cubic millimeter, with a platelet count of 160,000 per cubic millimeter and a normal hemogram. She was exposed to sunlight at noon on Nov. 4 and, within 20 minutes, she developed a typical erythema over the ears and the dorsal surfaces of the hands; the circulating eosinophil count had risen to 255 per cubic millimeter and the number of platelets had risen to 208,000 per cubic millimeter. She was

---

From the Thomas-Spann Clinic.

immediately given diphenhydramine (Benadryl) hydrochloride by injection and by mouth and the condition cleared in four hours.

It is my purpose to exhibit a photosensitive rather than a phototoxic reaction to the offending antibiotic. I believe that, had the patient been left longer in the sunlight on Nov. 4, her condition might have progressed to more serious results; therefore the patient was not exposed to the full hazard of this situation. Demethylchlortetracycline has been used on 56 other patients without adverse reactions.

Summary

In a patient with photosensitivity to a new antibiotic, demethylchlortetracycline (Declomycin) hydrochloride, a considerable rise in the number of circulating eosinophils occurred after exposure to sunlight and a significant elevation in the count of circulating eosinophils after moderate exposure to sunlight after four days of treatment with this drug. Administration of antihistamines and steroids may be useful in the control of this condition.

LIGHT SENSITIVITY DUE TO DEMETHYLCHLORTETRACYCLINE

REPORT OF FOUR CASES

Mortimer S. Falk, M.D., Reno, Nev.

Demethylchlortetracycline (Declomycin) is a recently introduced, broad-spectrum antibiotic produced by a mutant strain of Streptomyces aureofaciens. It is chemically closely related to the other known tetracyclines. Recent studies indicate that it may have an advantage over other tetracyclines, because comparable orally given doses produce greater and more prolonged serum activity against certain test organisms (Streptococcus 98, Staphylococcus 209P, and Bacillus cereus).[1] It is possible, therefore, that smaller and more widely spaced doses of demethylchlortetracycline may be at least comparable in clinical antibacterial activity to larger and more closely spaced doses of other tetracyclines.

In view of the relative effectiveness of the tetracyclines in controlling some cases of cystic and pustular acne, it was decided to use demethylchlortetracycline in a series of patients with this and other pyogenic dermatoses. The antibiotic was obtained in gelatin capsules containing 150 mg. (the unit dosage for the other tetracyclines is usually 250 mg.). It was given to 27 ambulant office patients in doses varying from 150 to 900 mg. per day for periods of from 3 to 128 days. Those who took the antibiotic for prolonged periods were on relatively small maintenance doses (150-300 mg.) during most of this period.

It is not the primary purpose of this paper to report the clinical results observed from use of demethylchlortetracycline. Moreover, the course of acne is such that the results of drug therapy, reported in exact quantitative statistics, are disputable. In general, however, the results were classified as follows: excellent six, good nine, fair (some improvement) eight, and poor four.

Four patients in this series experienced photosensitivity while taking the antibiotic. The reactions were manifested by erythema and edema of exposed portions of the skin. None were taking other medicaments concurrently. These reactions are cited in the following case histories.

Report of Cases

Case 1.—A 15-year-old, medium-complexioned high-school girl had moderately severe papulopustular acne of about two years' duration. On Sept. 10, 1959, she was given 24 demethylchlortetracycline capsules to be taken in a dosage of 300 mg. twice daily. When she was seen again, on Sept. 18, there was a pronounced erythema over the areas that had been exposed to sunlight, i. e., the face, neck, dorsal surfaces of the hands, lower legs, and dorsal surfaces of the feet. There were sharp lines of demarcation at the wrists, lower edge of the neck, and at the edge of her shoes. There was also edema and tenderness of the hands and feet. She was afebrile and had no complaints other than discomfort in the areas with solar erythema. She stated that she had not experienced prolonged exposure to the sun at any time during the week. As usual she had walked to and from school. The edema subsided in about one week, but the erythema persisted for one month after cessation of therapy with demethylchlortetracycline. It was followed by increased pigmentation of the involved areas.

Case 2.—A 25-year-old white male rancher had a grouped papular and folliculopustular eruption for at least five months, which involved the periorbital areas, the bridge of the nose, and the perioral region. The clinical and histological diagnosis was lupus miliaris disseminatus faciei, although results of the tuberculin test were negative. Treatment with demethylchlortetracycline was started on Sept. 16, 1959, with a dosage of 300 mg. twice daily. When he was seen on Sept. 29, he had taken 40 capsules (6 Gm.). There was a marked reddening of the face and neck, with sharp lines of demarcation in the nasolabial folds and submental region, indicative of a solar erythema. He was afebrile, and his only subjective complaint was a burning sensation in the involved areas. This man had worked outdoors for years, including the past summer, without ever having experienced a solar erythema of this intensity. Treatment with demethylchlortetracycline was discontinued, but it took about three weeks for the erythema to subside.

Case 3.—A 12-year-old girl, who had had a moderate papulopustular acne for about one year, was given 150 mg. of demethylchlortetracycline twice daily on Sept. 30, 1959. When she was seen on Oct. 7, after having taken 1.8 Gm. of the antibiotic, her face and neck were erythematous, and she complained of burning and itching. She had no other symptoms and was afebrile. The erythema subsided gradually over the next two and one-half weeks.

Case 4.—A 35-year-old woman had a mild papular acne, with a tendency toward premenstrual exacerbations. She also had tender subcutaneous nodules in the lower extremities which were compatible with a histological diagnosis of erythema induratum (Bazin's disease). On May 29 she was given demethylchlortetracycline, with instructions to take 150 mg. four times per day. From this date until June 15 she took 44 capsules (6.6 Gm.). On June 8, after having taken 4.2 Gm. of the antibiotic, no untoward reaction was apparent when she was seen in the office. The next week, after having taken an additional 2.4 Gm., she had a pruritic erythematovesicular eruption involving the nose and paranasal region, the chin, the dorsal surfaces of the hands and forearms, and sharply demarcated areas on the dorsal surfaces of the feet and toes corresponding only to portions of the skin which had been exposed to sunlight while she was wearing strap sandals and supportive elastic bandages which covered the middle and posterior part of her feet. She stated that she experienced a burning sensation in the involved areas after she had worked in her garden for about one-half hour during the previous week. Within the next few hours and the next day the areas became more erythematous and vesicles appeared on the hands and forearms. There were no other complaints. On June 26 the involved areas were still erythematous but the vesicles had subsided. By July 10 there was residual pigmentation on all the involved areas, and on Dec. 9 (six months later) pigmentation was still evident on the feet although the other areas appeared normal.

Comment

On the basis of this experience it appears that demethylchlortetracycline has photosensitizing properties. Four of 27 ambulatory patients developed sunburns on exposed areas while taking the antibiotic. None of the patients was taking another medicament which could be incriminated. Each of the four denied having experienced more prolonged exposure to sunlight than he or she ordinarily was accustomed to. It is of interest that one of the patients who exhibited this sensitivity to sunlight was a rancher (case 2) who had been outdoors daily throughout the previous summer and could therefore be expected to have built up a considerable tolerance to the erythema-producing portions of the ultraviolet rays. Nevertheless, in mid-September he developed a marked erythema which was sharply limited to exposed areas of the face and neck while taking demethylchlortetracycline. Three of the four patients who experienced reactions did so within a week, while one showed no evidence of photosensitivity until she had taken the antibiotic for more than two weeks. The daily dosage at the time the reactions occurred was 600 mg. for three of the patients but only 300 mg. for the fourth, the 12-year-old girl. Another interesting observation was the fact that the erythemas persisted longer than would ordinarily be expected, requiring from two and one-half to over four weeks to subside. One patient still had areas of pigmentation, corresponding to the reaction sites, on the dorsal surfaces of the feet, six months later.

Summary

Of 27 ambulatory patients 4, whose case histories are given, exhibited skin reactions indicative of photosensitivity while being treated with demethylchlortetracycline (Declomycin) for pustular acne and other pyogenic dermatoses.

505 S. Arlington Ave.

The demethylchlortetracycline used in this study was provided as Declomycin by Lederle Laboratories, Division of the American Cyanamid Co., Pearl River, N. Y.

COMMITTEE ON MEDICOLEGAL PROBLEMS

Rh-Hr BLOOD TYPES—PRESENT STATUS

Alexander S. Wiener, M.D., Brooklyn, N. Y., Lester J. Unger, M.D., New York City
and
Milton S. Sacks, M.D., Baltimore

Recently a third report on the subject of medicolegal applications of blood-grouping tests was published by the Committee on Medicolegal Problems.[1] This report reviewed the available information about the human blood groups and their heredity, from the point of view of their applications in medicolegal problems of disputed parentage. It also summarized the facts concerning the fundamental problem of Rh-Hr nomenclature and on the basis of the available evidence recommended that "unless and until some other convention can be agreed upon, the original Rh-Hr notations be kept as the standard and sole nomenclature for preparing approved medicolegal reports on Rh-Hr types." Soon after this report and recommendation appeared, a protest was published by 33 well-known workers in the field of blood-grouping,[2] but their protest offered no evidence in support of their position nor did it attempt to refute the evidence on which the American Medical Association report was based. Accordingly, this protest cannot be taken seriously and, in fact, has been answered in detail.[3]

The wisdom of the recommendation regarding Rh-Hr nomenclature has been further demonstrated by recent observations on the Rh-Hr types. These findings cannot be fitted into the C-D-E triple-inheritance scheme of notations, though they fit readily into the Rh-Hr nomenclature and were indeed anticipated by the serologic concepts on which the Rh-Hr symbols are based. The Rh-Hr terminology takes into account the sharp distinction between agglutinogens and their serologic attributes (or blood factors), and a notable feature of it is the use of regular type for symbols representing agglutinogens, phenotypes, and blood group systems, while **boldface** type is used for symbols for blood factors and their corresponding antibodies and *italics* for symbols for genes and genotypes. Some workers have attempted, without success, to adapt these important conventions to the C-D-E symbols. As has been pointed out, however, those who use the C-D-E notations unwittingly accept as facts the erroneous implications of the symbols and thus are led into serious misconceptions, which, when applied to serologic or even medicolegal problems, may lead to an erroneous conclusion. This consideration was one of the chief reasons for the A. M. A. Committee's recommendation regarding Rh-Hr nomenclature, since in scientific matters accuracy always takes precedence over mere simplicity and convenience.

The purpose of the present report is to detail the advances in knowledge concerning the Rh-Hr types which have occurred since the publication of the report and particularly to discuss their medicolegal implications, including the problem of Rh-Hr terminology.

Blood Factors Associated with Factor $\mathbf{Rh_0}$

Blood Factors $\boldsymbol{Rh^A}$, $\boldsymbol{Rh^B}$, $\boldsymbol{Rh^C}$, $\boldsymbol{Rh^D}$.—It is well established that blood factor $\mathbf{Rh_0}$ holds a special central position in the Rh-Hr blood group system. For one thing, it is the most antigenic of the Rh-Hr blood factors, and the one to which the clinician must pay the most attention if he wishes to avoid hemolytic post-transfusion reactions and neurological sequelae in erythroblastotic babies, with their unpleasant medicolegal repercussions. Moreover, the $\mathbf{Rh_0}$ blood factor seems to be located in a special part of the surface of the Rh-Hr agglutinogen molecule, as shown by the fact that red cells can be coated or blocked with univalent $\mathbf{Rh_0}$ antibodies without interfering in their reactions with other Rh-Hr antibodies. Recent observations have further demonstrated the special nature of the $\mathbf{Rh_0}$ portion of the Rh agglutinogen molecule and have disclosed the existence of previously unrecognized serologic complexities.

The new Rh factors were discovered through the study of clinical problems in which $\mathbf{Rh_0}$-positive patients had become isosensitized and had antibodies in their serum seemingly identical in specificity with anti-$\mathbf{Rh_0}$. This seeming paradox was resolved by the demonstration that the antibodies in question failed to react with the patient's own $\mathbf{Rh_0}$-positive cells as well as with cells of certain other rare $\mathbf{Rh_0}$-positive persons. This proved that these antibodies, although *simulating* anti-$\mathbf{Rh_0}$, were actually different from anti-$\mathbf{Rh_0}$ in specificity. This made it necessary to assign special symbols to the antibodies. The first such case recognized was one involving a patient with $\mathbf{Rh_0}$ variant red blood cells; a similar case was reported in detail a few years later. One of the most striking cases was that reported by Wiener and Geiger[1] involving a woman with "standard" Rh$_o$-positive cells who was isosensitized to the Rh factor and had an erythroblastotic baby as a result. The authors showed that the antibody in this patient's serum was not only different from anti-Rh$_o$ but also different from the Rh antibody of patients in previously reported cases, as well as in a case reported about the same time by Rosenfield and co-workers.[5] Wiener and Geiger postulated and predicted that in "standard" Rh-positive cells, associated with blood factor Rh$_o$, there occur multiple other blood factors, Rh^A, Rh^B, Rh^C, etc., but that in certain rare Rh-positive persons one or more of these factors may be lacking, so that if an antibody is formed for the missing blood factor these Rh-positive persons will seem to be sensitized to the Rh$_o$ factor.

The serum from the first patient reported on is no longer available, and no symbol has been assigned to the antibodies of his case or those reported later or of the patient of Rosenfield and co-workers.[5] Wiener has assigned the symbol anti-Rh^A to the antibody of the patient studied by Wiener and Geiger and to the corresponding blood factor the symbol Rh^A. Unger and Wiener[6] then encountered another similar antibody in an Rh-positive patient who had a hemolytic post-transfusion reaction, and since it was shown to be different from anti-Rh^A, they assigned to it the symbol anti-Rh^B and to the corresponding blood factor the symbol Rh^B. A third such antibody was next found by Unger and Wiener[7] in the serum of a mother of a pair of erythroblastotic twins, to which they assigned the symbol anti-Rh^C. More recently a fourth such antibody, anti-Rh^D, was found by Sacks and co-workers.[8]

Table 1 summarizes the results of investigations carried out by Unger and others on the distribution of blood factors Rh^A, Rh^B, Rh^C, and Rh^D among Rh-positive caucasoid and negroid persons. As the table demonstrates, almost every person with Rh-positive blood has, in addition to blood factor Rh$_o$, the four blood factors Rh^A, Rh^B, Rh^C, and Rh^D. Persons with blood giving the reaction characteristic of standard Rh$_o$ and which lacks one or more of the associated factors (Rh^A, Rh^B, Rh^C, and Rh^D) are quite rare.

TABLE 1.—*Incidence of Persons with Rh-Positive Blood Lacking Blood Factors Rh^A, Rh^B, Rh^C, and Rh^D**

		Blood Factor Tested for							
		Rh^A		Rh^B		Rh^C		Rh^D	
Racial Group		Total	Negative	Total	Negative	Total	Negative	Total	Negative
Caucasoid	No.	1,293	0	1,104	2	730	2	542	0
	%		0		0.18		0.27		0
Negroid	No.	1,170	8	1,037	0	658	1	511	5
	%		0.68		0		0.15		0.98

* Data modified from those of Unger and others.[9]

Nomenclature.—Since typical "standard" Rh-positive blood has, in addition to factor Rh$_o$, all the associated factors, Rh^A, Rh^B, Rh^C, etc., there is no need to indicate this fact in the symbol. Only the rare atypical Rh-positive bloods which lack one or more of these associated blood factors require a special distinctive symbol. For this purpose it has become conventional to insert a small superscribed letter to indicate the missing blood factor or factors; for example, blood of type Rh$_1^{ab}$rh gives all the expected reactions of Rh$_1$rh except that it fails to react with anti-Rh^A and anti-Rh^B.

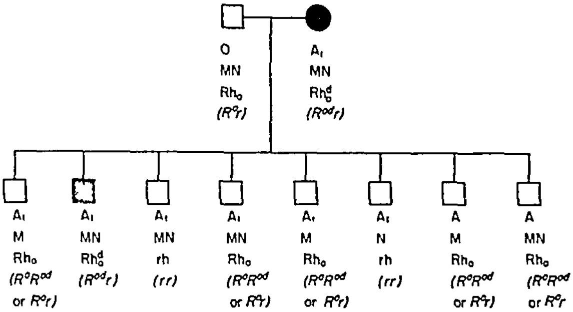

Fig. 1.—Family tree of patient, demonstrating hereditary transmission of agglutinogen Rh$_o^d$ by corresponding gene R^{od} (reprinted, with permission, from Sacks and others[8]).

Genetics.—It is reasonable to assume that the unusual varieties of Rh-positive blood which have been described are due to corresponding unusual Rh-Hr agglutinogens. For example, a person with blood of type Rh$_o^d$ presumably has in his blood an agglutinogen Rh$_o^d$ hereditarily transmitted by a corresponding allelic gene, R^{od}. That such is the case was proved by carrying out a family study, and the pedigree reported by Sacks and others[8] is shown in fig. 1. Since standard Rh genes, such as R^o, R^1, R^2, and R^z, each determine a corresponding agglutinogen, with all the blood factors Rh$_o$, Rh^A, Rh^B, Rh^C, and Rh^D inherited as a block, it is evident that the presence of agglutinogen Rh$_o^d$ can be detected only in persons of genotypes $R^{od}R^{od}$, $R^{od}r$, $R^{od}r'$ $R^{od}r''$, and $R^{od}r^y$ but not in persons of genotypes $R^{od}R^o$, $R^{od}R^1$, $R^{od}R^2$, etc., in whom the standard Rh agglutinogen will mask the presence of the atypical agglutinogen. This is illustrated by the pedigree shown in fig. 1.

An even more instructive pedigree was found earlier by Unger and Wiener[7] and is shown in fig. 2. In this case the unusual agglutinogen was designated $\mathfrak{R}h^c_2$, and the corresponding gene $\mathfrak{R}^{2c}$. The use of a Germanic capital $\mathfrak{R}$ was necessary to indicate that the Rh$_o$ factor in this case was not standard but a variant. In other respects, the pedigree shown is self-explanatory.

$\mathfrak{R}$h$_o$-Positive (Rh$_o$ Variant) Blood

Soon after the discovery of the Rh$_o$ factor, the existence of occasional bloods which reacted only weakly with the anti-Rh$_o$ agglutinating serum available at that time was observed. Because of the weak reaction of such bloods, they were said to have an intermediate Rh_0 factor. In tests on a large series of blood specimens from caucasoid and negroid persons, it was found that these unusual bloods were four to five times as frequent among negroid as among caucasoid persons. When the newer methods of testing by the conglutination, antiglobulin, and enzyme techniques became available, it was found that a graded series of bloods exist, ranging from typical Rh-positive to Rh-negative. The intermediate bloods are now known as Rh_0 variants ($\mathfrak{R}h$), the presence of an Rh_0 variant factor being indicated in the symbol by the use of a Germanic capital letter $\mathfrak{R}$. The original intermediate bloods first described would now probably be classified as "high-grade" Rh_0 variants. Modern techniques make possible the identification also of so-called medium and low-grade Rh_0 variant bloods. Such bloods fail to react at all with saline agglutinating anti-Rh_0 but react distinctly, by the antiglobulin technique, with univalent anti-Rh_0 serum. Thus, the symbol $\mathfrak{R}h$ includes a heterogeneous group of agglutinogens and blood types having in common the property of reacting atypically with anti-Rh_0 serum. Further light has been thrown on the nature of Rh_0 variants by the recent work on blood factors Rh^{A}, Rh^{B}, Rh^{C}, and Rh^{D}.

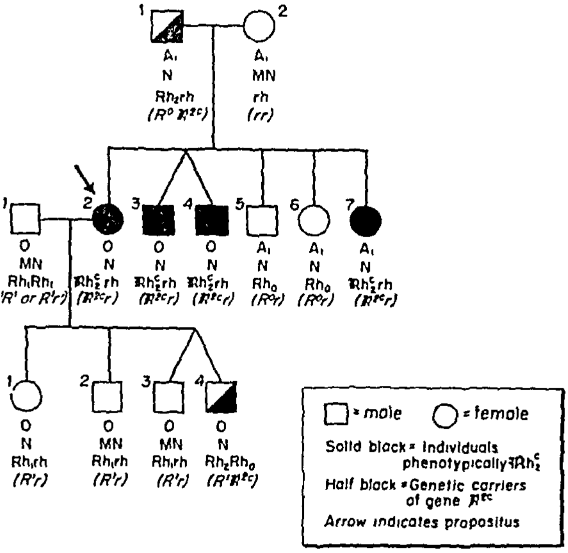

Fig. 2.—Family study, showing hereditary transmission of rare gene $\mathfrak{R}^{2c}$ (modified from Unger and Wiener[7]).

Tests carried out by Unger and others[9] *on a* series of more than 150 $\mathfrak{R}h$-positive bloods showed that most of these bloods lacked one or more of the blood factors Rh^{A}, Rh^{B}, and Rh^{C}; examples of all eight theoretical possibilities $\mathfrak{R}h$, $\mathfrak{R}h^{a}$, $\mathfrak{R}h^{b}$, $\mathfrak{R}h^{c}$, $\mathfrak{R}h^{ab}$, $\mathfrak{R}h^{ac}$, $\mathfrak{R}h^{bc}$, *and* $\mathfrak{R}h^{abc}$ *were encountered. More*over, when $\mathfrak{R}h$-positive blood had the factors Rh^{A}, Rh^{B}, *or* Rh^{C}, or any combination of these, these factors were almost always variants. By means of absorption experiments on pooled and selected anti-Rh_0 serum with Rh_0 variant blood specimens, *the existence of numerous serologic differences among such* Rh_0 *variant bloods* has been demonstrated. These findings become intelligible in the light of the findings of Unger and co-workers,[9] if it is assumed that the anti-Rh_0 serum used in the absorption experiments was polyvalent and contained, *in addition to* anti-Rh_0, anti-Rh^{A}, anti-Rh^{B}, and *anti-*Rh^{C}, *etc. and that the various absorbing* cells differed in their antigenic makeup. Thus, after absorption, different fractions of antibodies remained in the serums.

Medicolegal Implications

From the point of view of clinical medicine, Rh-positive persons who are sensitized to blood factors Rh^{A}, Rh^{B}, Rh^{C}, etc., should be treated like Rh-negative sensitized persons. Thus, if they require *blood transfusions, they may be given Rh-negative blood, and if such a female patient has an erythro*blastotic baby, Rh-negative blood should be used when the baby is treated by exchange transfusions. Failure to recognize the situation may lead to disaster, with medicolegal repercussions, *just as when sensitized Rh-negative patients are incorrectly trans*fused with Rh-positive blood. *Since the majority of* Rh_0-variant persons lack one or more of the factors Rh^{A}, Rh^{B}, Rh^{C}, etc., the problem is especially apt to arise with such patients. Therefore, this possibility *must be borne in mind, when patients with* Rh_0 *variant blood are treated, and for reasons presented* this problem will probably arise more frequently among negroid than among caucasoid persons.

From the point of view of disputed parentage, tests for Rh^{A}, Rh^{B}, Rh^{C}, Rh^{D}, etc., will yield useful results only in rare instances, because persons with Rh-positive (or $\mathfrak{R}h$-positive) bloods lacking one or more of these factors are rare. Paternity would be excluded in a mating such as rh × Rh_1rh, with a type Rh_1rh child, if it could be *shown that the Rh-positive parent* lacks one of the blood *factors* Rh^{A}, Rh^{B}, Rh^{C}, ... etc. but the blood factor in question is present in the blood of the child. On the other hand, in a mating such as Rh_0 × rh, with a type Rh_0 *child, if, for example, the Rh-positive parent and the child* both lack blood factor Rh^{D} (type Rh_0^{d}), this could be considered circumstantial evidence in favor of parentage, because blood type Rh_0^{d} is rare.

Blood Factors hr and rh_i

The recently discovered blood factors hr and rh_i have, on occasion, proved useful in resolving problems of disputed parentage. Blood factor *hr is a serologic attribute shared only by the agglutinogens rh and* Rh_0 *determined by the genes r and R'* respectively. On the other hand, according to the latest information, in caucasoid persons, factor rh_i is limited to the agglutinogens Rh_1 and rh' determined by the genes R^1 and r' respectively. Anti-rh_i, therefore, simulates anti-rh′ in specificity because of the low incidence of agglutinogens rh_y and Rh_z with which only anti-rh′ reacts (table 2).[9]

These two serologic reagents, anti-hr and anti-rh_i, are useful in resolving parentage disputes involving type $\mathrm{Rh}_z\mathrm{Rh}_0$ putative parents or children. For example, a type $\mathrm{Rh}_z\mathrm{Rh}_0$ person with a type rh or type Rh_0 child (or vice versa) would be excluded if he belonged to the common genotype R^1R^2 (or R^1r'' or R^2r') but not if he belonged to one of the rare genotypes R^zr or R^zR^0 or R^0r^y. Therefore, if the blood of such a putative father is hr-negative, he is excluded, but if it is hr-positive he is not. Similarly, if the blood of such a person is rh_i-positive, he is excluded, while if it is rh_i-negative he is not.[10]

From the points of view of serology, genetics, and nomenclature, blood factors hr and rh_i may be considered as additional associated blood factors of previously identified Rh-Hr agglutinogens, as in the case of factors Rh^A, Rh^B, Rh^C, Rh^D, etc. For example, at the present stage of knowledge agglutinogen rh is known to have a total of at least 4 blood factors: hr′, hr″, hr, and Hr_0; while agglutinogen Rh_1^w has a total of at least 10 blood factors: Rh_0, Rh^A, Rh^B, Rh^C, Rh^D, rh′, rh_i, rh^w, hr″, and Hr_0. (Anti-Hr_0 is presently defined as the antibody produced by sensitized persons homozygous for so-called double bar genes, i. e., persons of type $\bar{\bar{\mathrm{Rh}}}_0$, type $\bar{\bar{\mathrm{Rh}}}^w$, etc. "Double bar" Rh agglutinogens [e. g., type $\bar{\bar{\mathrm{Rh}}}_0$] are defined as those characterized by absence of the two pairs of contrasting blood factors rh′-hr′ and rh″-hr″. "Single bar" Rh agglutinogens [e. g., type $\bar{\mathrm{Rh}}_0$] are defined as those which lack only one pair of contrasting factors, namely rh″-hr″; recent work has shown that in chimpanzees, the Rh-Hr agglutinogen resembles the "single bar" human Rh agglutinogen.) The end is still not in sight, since as Wiener has predicted the number of blood factors characterizing an agglutinogen is limited only by one's energy and ingenuity in searching for and identifying antiserums of new specificities. At any rate, the blood factors which make up the serologic attributes of each agglutinogen are inherited as a block and transmitted by corresponding allelic genes, so that the individual blood factors do not represent separate agglutinogens inherited in three's or any other fixed number, as erroneously implied by the C-D-E notations.

Persons with blood of types $\bar{\bar{\mathrm{Rh}}}_0$ and $\bar{\bar{\mathrm{Rh}}}^w$ have been shown by family studies to be homozygous for the genes $\bar{\bar{R}}^0$ and $\bar{\bar{R}}^w$ respectively. These two genes are extremely rare, so that persons with blood of types $\bar{\bar{\mathrm{Rh}}}_0$ and $\bar{\bar{\mathrm{Rh}}}^w$ are generally the result of consanguineous marriages. The medicolegal importance of genes $\bar{\bar{R}}^0$ and $\bar{\bar{R}}^w$ is that, unless the expert takes their existence into account, he may misinterpret the results of blood tests and incorrectly exclude paternity or maternity. For example, a medicolegal case of disputed paternity, in which the mother belonged to type Rh_0 and the child to type $\mathrm{Rh}_2\mathrm{Rh}_2$, thus seemingly excluding maternity, was described in 1952. In this case, the mother was presumably genotype $\bar{R}^0r$, as shown by the weak reaction of her cells with anti-hr″ serum, and the child's genotype $R^2\bar{R}^0$. In an even more striking recent case, the putative father was found to be type $\mathrm{Rh}_1^w\mathrm{Rh}_1$, the mother type Rh_0, and the child type $\mathrm{Rh}_1^w\mathrm{Rh}_1$, so that the maternity of the child appeared to be excluded. Further tests showed that the mother's blood gave a "single-dose" reaction with *anti-hr′ and anti-hr″ serums*, while the child's blood cells gave a single-dose reaction with anti-hr″ serum and reacted much more weakly with anti-rh′ serum than the father's cells. Therefore the mother's phenotype was corrected to read $\bar{\bar{\mathrm{Rh}}}_0\mathrm{rh}$, and the child's $\mathrm{Rh}_1^w\bar{\bar{\mathrm{Rh}}}_0$, so that maternity was not excluded. In this case, considering the low frequency of gene R^{1w}, the findings instead provided circumstantial evidence that the accused man was the actual father of the child.

TABLE 2.—*The Eight "Standard" Rh Genes, Their Corresponding Agglutinogens, and the Major Blood Factors of Each Agglutinogen*

			Reactions of Three "Standard" Rh Serums			Reactions of Two Hr Serums		Reactions of Two "Special" Serums		
Genes	Agglutinogens	Frequency Among Caucasoid Persons in New York City, %	Anti-Rh_0	Anti-rh′	Anti-rh″	Anti hr′	Anti-hr″	Anti-rh_i	Anti-hr	Blood Factors Present
r	rh	38.0	—	—	—	+	+	—	+	hr′, hr″, and hr
r'	rh′	0.6	—	+	—	—	+	+	—	rh′, rh_i, and hr″
r''	rh″	0.5	—	—	+	+	—	—	—	rh″ and hr′

R^0	Rh_0	2.7	+	—	—	+	+	—	+	Rh_0, hr′, hr″, and hr
R^1	Rh_1	43.0	+	+	—	—	+	+	—	Rh_0, rh′, rh_i, and hr″
R^2	Rh_2	15.0	+	—	+	+	—	—	—	Rh_0, rh″, and hr′
R^z	Rh_z	0.2	+	+	+	—	—	—	—	Rh_0, rh′, and rh″

Rh-Hr Consultation Laboratories

The newer findings point up the need for additional consultation laboratories having available reagents of unusual specificities and panels of donors of rare Rh-Hr types, not only for clinical purposes but also for their research value. For example, there is need for laboratories to which blood specimens can be sent to resolve unusual clinical problems, notably cases of Rh-positive sensitized patients with Rh antibodies in their serums. It would also be of interest to have available persons of rare Rh-Hr types, such as rh'rh″, rh_yrh, $\text{rh}'^{w}\text{rh}$, Rh_1^{ab}, Rh_0^{a}, etc., whose blood is useful for testing Rh antiserums in order to determine their specificities.

Summary

Supplementing previous reports on the medicolegal applications of blood-grouping tests, the present report surveys developments of the past few years. New Rh-Hr factors Rh^A, Rh^B, Rh^C, Rh^D, etc., hr, and rh_i are discussed and their clinical and medicolegal importance explained.

PRELIMINARY COMMUNICATIONS

METHAMINODIAZEPOXIDE

Titus H. Harris, M.D., Galveston, Texas

A new drug, with a broad range of pharmacological activity, gives promise under current clinical testing of having diverse therapeutic applications. Methaminodiazepoxide (7-chloro-2-methylamino-5-phenyl-3H-1,4-benzodiazepine-4-oxide hydrochloride), one of a new class of compounds, exerts three primary actions, namely, (1) tranquilization, (2) muscular relaxation, and (3) anticonvulsant effect. According to Randall[1] it is unlike other tranquilizers in that it calms laboratory animals without inducing sedation or motor inhibition. While possessing the tranquilizing properties of chlorpromazine and reserpine, it lacks their autonomic blocking effects. It is more active than meprobamate, chlorpromazine, and phenobarbital in antagonizing pentylenetetrazol (Metrazol)-induced convulsions; more potent than the first two in preventing electroshock convulsions, and different from phenobarbital in that it does not induce hypnosis. It blocks spinal reflexes at lower dosages than meprobamate, a property which accounts for its stronger muscle-relaxant effects.

Its unique action on vicious, agitated monkeys, dingo dogs, and other wild animals stimulated the first clinical trials with the drug. At a recent symposium (University of Texas Medical Branch Symposium on Newer Antidepressants and Other Psychotherapeutic Drugs; Their Use in Psychiatry and Other Branches of Medicine, Nov. 13 and 14, 1959), investigators in a number of medical specialties, including internal medicine, cited impressive results obtained from use of methaminodiazepoxide *in a variety of conditions and a freedom from side-*effects at therapeutic dosage levels. These investigations confirm my findings that the drug reduces anxiety and agitation but does not cloud consciousness or impair intellectual function. My experience with its use in all types of anxiety, convulsive disorders, tension states, obsessive-compulsive conditions, agitated depressions, and jitters in alcoholics

---

Chairman and Professor, Department of Psychiatry and Neurology, University of Texas Medical Branch.

indicated that methaminodiazepoxide is one of the most interesting drugs of its type that has been developed. Of special interest is its apparent effectiveness in obsessive-compulsive neuroses, which have thus far defied chemotherapeutic management. It has been shown to have a margin of safety greater than meprobamate, and it approaches the activity of the phenothiazines, without their potential toxicity, in decreasing anxiety, mainly in neurotic patients. In certain patients the compound has a calming effect, while in others it has an elevating effect and increases drive; there are no extrapyramidal complications. A site and mode of action have not been delineated.

Methaminodiazepoxide has been subjected to extensive clinical study in general hospitals, where it was used in patients whose primary disorders were complicated by a psychoneurotic component. Breitner[1] reported successful results from its use, chiefly in patients with obsessional states. Kinross-Wright[1] found the drug to be most helpful in neurotic patients exhibiting anxiety and tension. Bowes[1] used it successfully in clinic outpatients with "long-standing anxiety and phobic reactions and in some obsessional states." Excellent results were also achieved in reactive depressive patients. Constant[1] observed that the drug shortened the course of electroconvulsive therapy (ECT) in private patients and made the agitated depressive patients more accessible to treatment with monoamine-oxidase inhibitors and psychotherapy. Sussex[1] reported success in the treatment of patients with "chronic mixed neurotic states with a neurasthenic, hypochondriacal, passive-dependent depressed symptom pattern."

Kaim[1] reported that methaminodiazepoxide demonstrated both tranquilizing and anticonvulsant properties in a group of epileptics with a long history of seizures. The frequency of seizures was reduced, and, in some instances, the electroencephalographic patterns were completely normalized. Favorable results with use of the drug have been reported in the management of alcoholics during the acute withdrawal phase. Thomas[1] noted a positive response in about 70% of ambulant patients with functional and psychophysiological disturbances that were referable chiefly to the gastrointestinal tract. Robinson[1] used the drug adjunctively in the treatment of dermatoses associated with emotional reactions, such as trichotillomania parasitophobia and neurotic excoriations, and in dermatoses which may precipitate anxiety states or depressions, i. e., severe acne with scarring, psoriasis, alopecia, and lupus erythematosus. Relief of emotional tension, control of anxiety states, and elimination of the need for bedtime sedation were observed after therapy with methaminodiazepoxide.

In human tolerance studies of the drug under controlled conditions, there was no evidence of cardiovascular disturbances and no significant changes were observed in hematocrit values, red and white blood cell counts, or kidney or liver function. The only important side-effects were drowsiness and ataxia. Drowsiness frequently subsided spontaneously after a day or two, and always with a slight decrease of the dose. Ataxia is a clinical sign of excessive dosage and disappears with smaller doses. Increased appetite and weight gain, which may be desirable effects in tense, anxious patients, have been reported.

The onset of action of methaminodiazepoxide is prompt, usually within one day, sometimes within a few hours. Evidence of habituation or postmedication depression has not been observed. Usually methaminodiazepoxide is administered orally, but it has been given in single intravenous doses as an aid to diagnosis in acutely agitated patients.

The methaminodiazepoxide used in this study was supplied as Librium by Hoffmann-La Roche, Inc., Nutley 10, N. J.

BERYLLIUM POISONING.—The metal, beryllium, is of great importance in building and operating atomic reactors. It seems likely that metallurgists will succeed in making it ductile and workable, which will greatly extend its use as it is the lightest metal known. Our first toxic troubles from beryllium came from fluorescent lamp manufacture where a complex beryllium silicate was used as a phosphor lining for the fluorescent tubes. Acute poisonings occurred and soon a number of chronic poisonings, many of which were of long duration and fatal. All of them, acute and chronic, probably resulted from breathing beryllium compounds sometimes in concentrations ordinarily considered as "trace amounts." . . . The precautionary measures now being applied in the processing of beryllium are comparable in severity to those used in handling very toxic gases or radioactive materials. There are still poisonings from exposures of some years ago, but it is felt that control is at last becoming effective, while advances in the medical management of Be poisonings have been very great.—P. Drinker, Industrial Hygiene and Air Pollution, *The Royal Society for the Promotion of Health Journal*, July-August, 1959.

LINOLEIC ACID CONTENT OF FATS AND OILS

IT IS accepted generally that specific alteration in the diet will lower the concentration of cholesterol in the blood. The most effective results to date have been achieved by increasing consumption of polyunsaturated fatty acids, particularly linoleic acid. However, indefinitive and conflicting information has left much to the imagination of some food processors. Some of the largest vegetable oil processors in the United States have implied in advertisements that the cholesterol level can be lowered merely by adding polyunsaturated fatty acids to the diet. This selling campaign has created confusion among lay people, making it increasingly important that the physician clarify for his patients the conditions under which changes in the diet will be effective.

The patient should understand that if he increases his consumption of polyunsaturated fatty acids without reducing his intake of other fats, little is gained save for additional calories which could lead to obesity. A particular regimen will be effective only if polyunsaturated fatty acids are responsible for an appreciable percentage of the total fat calories. That is, they must replace rather than supplement some of the saturated fats and oils already in the diet.

The physician may find it difficult to evaluate the actual therapeutic value of various products sold by food processors. He may prescribe drugs with the knowledge that they are essentially as the manufacturer states them to be, but he cannot recommend food products with the same sense of security. They are not regulated as closely by the federal government and their claims must be interpreted with caution and understanding.

Many vegetable fats and oils contain appreciable amounts of the polyunsaturated fatty acids and if used properly will lower the blood cholesterol level. Some of these oils, like cottonseed and corn oil, are plentiful. Others, like peanut, safflower, and soy oil are available only in limited supplies. Sour cherry seed, watermelon seed, sesame seed, walnut, wheat germ, and sunflower seed oils are esoteric in origin and in limited supply.

Contrary to statements sometimes made, not all animal fats are low in the polyunsaturated fatty acid content nor are all vegetable oils high in this quality. The depot fat of chicken is an excellent source of linoleic acid. Coconut oil, a vegetable product, has an extremely low concentration of linoleic acid. Fish and marine oils are reputed to be uniformly rich in polyunsaturated fatty acids. The position of the marine oils is debatable, as these oils frequently contain fatty acids of the C_{20}, C_{22}, and C_{24} series. The influence of these longer length molecules has not been evaluated fully.

Claims for various hydrogenated vegetable oils must be assessed with the knowledge that the hydrogenation process converts polyunsaturated fatty acids into monounsaturated fatty acids or completely saturated compounds. Commercial hydrogenation solidifies liquid oils and increases their storage time without rancidity. The sequence of events, though controllable to some extent, usually is polyunsaturate → monounsaturate → saturate. A product may be derived from 100% cottonseed or corn oil, but when it is hydrogenated, it loses most or all of its polyunsaturated qualities. Heating vegetable oils to the usual cooking temperatures does not significantly impair their polyunsaturated quality. Vegetable oil is converted to solid margarine by one of two procedures. In one method, a solidifying agent such as a measured amount of a saturated or hydrogenated high melting fat is mixed with pure oil. The only resulting loss of polyunsaturated fatty acids is by dilution. In the other method, direct hydrogenation is used to raise the melting point. This process significantly reduces polyunsaturated fatty acid content.

Some manufacturers cite the "iodine number" of a fat or oil as evidence of the unsaturated fatty acid content of their product. This number is not a reliable indicator of therapeutic value because it measures monounsaturated and polyunsaturated fatty-acid content at the same time. A monounsaturated acid, like oleic, takes up two iodine atoms but does not affect the cholesterol concentration of the blood. A polyunsaturated acid, like linoleic, takes up four iodine atoms. In a product containing large amounts of oleic acid and small amounts of linoleic acid, the iodine number is nearly the same as it would be for a product containing little oleic acid and a modest amount of linoleic acid. Cottonseed oil has an iodine number of 110 and corn oil a number of 127; yet they each have about the same amount of linoleic acid.

At one time, some physicians advocated the "low fat, low cholesterol" type of diet as a means of lowering the cholesterol level of the blood. Though this recommendation reappears from time to time, it is now generally believed that dietary cholesterol, within the limits of the average mixed diet, plays little part in raising the cholesterol concentration in the blood. Total exclusion of certain animal products from the diet to achieve a low cholesterol intake rarely is justified. In fact, many cholesterol-containing foods are important sources of valuable protective nutrients.

Low-fat diets will not reduce the concentration of circulating cholesterol and lipoproteins as effectively as will diets containing an adequate percentage of polyunsaturated fatty acids. Weight-reduction regimens are basically low in fat, and if a lowered cholesterol level is necessary, planning must be done to maintain the proper ratio of saturated to unsaturated fats. When caloric requirements are above 3,000 a day, the diet still can include many food items containing saturated fats, but caloric intakes under 2,500 require specialized attention. The invisible fat inherent in the American high meat diet is largely of the saturated type and a most meticulous replacement for visible fats is necessary. When chicken or fish is the source of invisible fat, greater latitude can be had. Pork products, which contain about 10% linoleic acid, allow for some latitude. Many nuts and grain products contain appreciable amounts of linoleic acid (except coconut, cashew, and macadamia) and may be included in the diet for variety. Because of widespread misinformation in this field, the physician must carefully evaluate new developments so that he can effectively advise his patients about dietary changes with the same knowledge and confidence he draws on when prescribing drugs.

CYTOLOGICAL SCREENING TECHNIQUES

The cervix is the second commonest site for cancer in women in the United States; in women of some other countries it is the commonest site. However, if treated adequately, cancer of the cervix has the best prognosis of all major forms of malignancy. The most important single factor influencing prognosis is the extent of the disease. The combination of cytological study of vaginal fluid and biopsy of the cervix results in a nearly perfect diagnostic score. This procedure could reduce significantly cancer of the cervix as a cause of death, if it were applied regularly to all women, or at least to all past 35 years of age.[1] The experience of the Strang Cancer Prevention Clinic at Memorial Hospital in New York City, together with studies being completed on 108,000 women in Memphis, Tenn., under the auspices of the United States Public Health Service, substantiates this assumption. The screening of presumably healthy women by the Papanicolaou method of exfoliative cytology is practical and leads to the discovery of many curable cancers of the cervix.

The opinion has been voiced that qualified cytologists are in short supply and that it is grossly impractical to plan for the periodic cytological study of a majority of women 35 years of age and older. However, technical cytologists can be trained to perform a portion of the job that is expected now of certified pathologists. The statement of Shields Warren, made a decade ago, remains: "It is a special advantage of the method that a large part of the diagnostic work may be done by one who has been trained in the technique. No broad background in pathology and cytology is required to recognize many types of cells. Competence in diagnosis depends mainly on experience with vaginal smears."

In spite of this evidence too few women throughout the nation undergo regular cytological examination. This deficiency is related in part to the lack of cytological services for physicians who are not affiliated with relatively large hospitals. General practitioners whose offices should be the front line of cancer detection often hesitate to make use of cytology centers geographically remote.

The U. S. Public Health Service reports in publication 671, January, 1959, that "a mass cytologic screening for uterine cancer is equally effective whether carried out entirely by private physicians on a mail order basis or by large, public, metropolitan clinics." This finding is based on a 10-year study by William Stoval and Paul Calabresi of the Wisconsin State Laboratory of Hygiene at Madison, Wis., who completed an effective case-finding program, carried out by private physicians, in which specimens were mailed to a central screening laboratory. In this screening survey 705 of the 805 malignancies present in 65,163 women were discovered. It is thus possible for most physicians, no matter how remote their practice may be from a medical center, to offer their patients the benefit of periodic vaginal cytological examinations. Furthermore, it may not be many months before an automatic cytoanalyzer is perfected which will expand

2. Cameron, C. S.: Truth About Cancer, Prentice-Hall, New Jersey, 1956.

the scope of such a program. If these technical developments are to be paralleled by an intensive educational program, then the hope expressed by Cameron[2] that periodic cytological examination "should make death from cancer of the cervix a rare event instead of the first cause of death from cancer among women" will indeed be realized.

Whatever the techniques used for preliminary screening, the basic concept in the diagnosis of disease and the particular medium must not be overlooked, i. e., that the procedure discussed is a screening technique and nothing more. The pathologist and the physician are not released from any ultimate responsibility. The pathologist, with his trained eye and judgment, should always counsel the physician for subsequent steps of professional action when smears show positive or doubtful results.

THE LAST OF THE HOPKINS FOUR

The publication of the biography of Dr. Howard C. Kelly[1] completes the tetralogy of the illustrious men of Johns Hopkins University School of Medicine who built an institution with enviable accomplishments. Kelly was the last of the four to join the distinguished group. His biography has been the last to be published. Harvey Cushing[2] was awarded the Pulitzer prize in biography in 1926 for his two-volume recounting of the "Life of Sir William Osler." The story of William H. Welch, the pathologist, who was largely responsible for the design of the Hopkins concept, was told by the Flexners[3] in 1941. William Stewart Halsted, surgeon and the most controversial member of the quartet, owes his biography to a one-time pupil and academic associate, Samuel J. Crowe.[4] And now, Audrey W. Davis, friend and confidante of Howard C. Kelly for two decades, has prepared the first full-length biography of this brilliant general surgeon and gynecologist who was as devoted to Christianity as he was dedicated to his profession.

Kelly was born in 1858 in Camden, N. J., and lived his 85 years in the environs of Philadelphia and Baltimore. He inherited a deep spiritual insight from his maternal grandfather, a clergyman, and a lifelong interest in the natural sciences from his mother. His father's contributions were spiritual and material—the latter because of his interest in the sugar industry. The University of Pennsylvania claimed Kelly as an undergraduate as well as a medical student. Summers afforded him leisure time for the pursuit of biology and other phases of natural science. A great many hours and days were spent in the out-of-doors. One summer was spent on a ranch in Elbert County in the Colorado Rockies. A physician who attended the construction crew charged with drilling a tunnel through the Continental Divide was numbered among hi professional friends. The doctor, George H. Simmons, was appointed editor of THE JOURNAL a decade later.

Fame and responsibility came to Howard C Kelly at an early age. He was scarcely 31 years o age when he was invited by President Gilman o Johns Hopkins University to head the departmen of obstetrics and gynecology in the medical schoo Simultaneously he was appointed chief of the clinical departments at the Johns Hopkins Universit Hospital. Until he relinquished his academic pos at the age of 60 years, his professional days wer prolific in writing, stimulating in developing youn men, bountiful in honors, and professionally frui ful as a skilled disciple of Asclepius. He shared common belief that a gynecologist should be qualified abdominal surgeon first. This is born out by the publication in 1905 of his monograp on the vermiform appendix. This followed only few years his two-volume treatise on operativ gynecology. Max Broedel, the medical artist o renown who had been invited to Johns Hopkin from Germany in 1894, illustrated these works.

The Flexner report on medical education appeared in the midst of Kelly's brilliant career. Th strong recommendation in support of full-tim clinical departments provoked much discussion a Hopkins as it did in many medical schools. Osle as well as Kelly was opposed to the full-tim system, although it is debatable whether the opportunity to collect consultation fees from privat patients interfered seriously with the scientifi contributions of either teacher. Kelly relinquishe his academic post at Hopkins in 1919 and concentrated his professional activities in private practice. His ancillary activities included philanthrop —medical, religious, and academic—motivated b a capacity to raise money from friends and patient for each of these three areas when the need arose

Kelly's interest in the out-of-doors continue until late in life. At the age of 71 years he expresse keen disappointment in being thwarted from goin down the Colorado River by boat, following the pattern of Powell and Dellenbaugh, a half centur earlier. The Colorado River is navigable over th treacherous runs late in the spring for a few week only. At the time selected for Kelly's party the rive was swollen beyond a dangerous level, and th trip was abandoned.

Many honors came to the "Prince of Gynecology." Probably the most distinguished was the degree of Doctor of Laws *honoris causa*, given b Johns Hopkins. He died in his 85th year, precedin by only a few hours the death of Mrs. Kelly.

ORGANIZATION SECTION

STATEMENT TO HOUSE OF REPRESENTATIVES COMMITTEE ON VETERANS' AFFAIRS ON H. R. 7966

January 28, 1960

Honorable Olin E. Teague, Chairman
Committee on Veterans' Affairs
House of Representatives
Washington 25, D. C.

Dear Mr. Chairman:

I should like to take this opportunity on behalf of the American Medical Association respectfully to submit for your consideration our views on H. R. 7966, 86th Congress, a bill which we understand is now pending before your Committee.

This bill would amend the definition of "medical services" in Section 601(6) of Title 38, United States Code to include the services of optometrists. This is general terminology and might be interpreted to include the diagnosis of eye diseases, the consideration of problems dealing with the prevention of blindness and the conservation or restoration of vision. Inasmuch as these activities constitute the practice of medicine, it is our considered opinion that they should be performed exclusively by qualified doctors of medicine.

We believe, as I am sure the Committee does, that veterans with service-connected conditions, of all people, are entitled to the highest quality of medical care. We do not, however, believe that this objective can be realized if the providing of eye care by optometrists is authorized by Congress.

The granting to optometrists of the right to perform eye examinations for veterans may result in a failure to administer necessary sight-saving medical treatment and rehabilitative care. Unfortunately, in too many cases proper treatment has been delayed or possible rehabilitation or cure denied because of a diagnosis rendered by others than qualified medical practitioners. On the other hand, the exercise of medical skills by qualified physicians insures the early detection and successful treatment of the organic and systemic causes of blindness.

For the reasons stated above the American Medical Association is opposed to the enactment of this legislation.

It is my hope that this statement can be made a part of the record of your hearings. If we can be of service to your Committee in any way, you may be assured of our willingness to cooperate.

Very truly yours,
F. J. L. Blasingame, M.D.
Executive Vice-President.

STATEMENT TO HOUSE OF REPRESENTATIVES COMMITTEE ON VETERANS' AFFAIRS ON H. R. 2412

January 25, 1960

Honorable Olin E. Teague, Chairman
Committee on Veterans' Affairs
U. S. House of Representatives
Washington 25, D. C.

Dear Mr. Chairman:

The purpose of this letter is to submit for the consideration of the Committee on Veterans' Affairs the official position of the American Medical Association on H. R. 2412, 86th Congress, which we understand will be the subject of hearings by your Committee today. H. R. 2412 would grant veterans of the Spanish-American War, the Philippine Insurrection and the Boxer Rebellion unlimited eligibility for hospital care from the Veterans' Administration for any disability by establishing the presumption that any disability of such a veteran would be held to be a service-connected disability incurred or aggravated in a period of war.

The American Medical Association is, and always has been, in complete agreement that the Federal Government has a duty to care for any person who has a physical or mental disease or disability caused or aggravated by military service. We believe, however, that the provision of medical care and hospitalization by the Federal Government for veterans with non-service-connected disabilities is unsound. This position was reaffirmed by the House of Delegates of the American Medical Association as recently as December, 1959, when it stated that federal responsibility for the provision of hospitalization and medical care should be limited to veterans with service-connected diseases and disabilities. It is the belief of the Association that the care of veterans with non-service-connected conditions should be the responsibility of the individual or his family or, if he is indigent, of the community or state government.

Therefore, we are opposed to H. R. 2412 which would expand the provision of medical care and hospitalization by the Federal Government for veterans with non-service-connected conditions. This bill would be particularly unacceptable since it would arbitrarily categorize the disabilities of this group of veterans as service connected without the requirement of proof or in spite of convincing evidence to the contrary. This device would negate completely the statutory and regulatory safeguards that do exist in the wholesale provision of medical and hospital care in non-service-connected cases.

Further, we oppose this legislation because it would constitute a precedent which in later years could lead to the Federal Government providing medical care for all veterans regardless of the cause of their illness or injury. The provision of such care for Spanish-American War veterans and other beneficiaries under this legislation would soon lead to pressure to provide the same care for veterans of World War I, World War II, and the Korean conflict.

We will appreciate your arranging to have this letter made a part of the record of your hearings.

Sincerely yours,
F. J. L. Blasingame, M.D.
Executive Vice-president.

STATEMENT TO SENATE INTERSTATE AND FOREIGN COMMERCE COMMITTEE ON S. 1283

January 27, 1960

Senator Warren G. Magnuson, Chairman
Interstate and Foreign Commerce Committee
United States Senate
Washington 25, D. C.

Dear Mr. Chairman:

On August 13, 1959, the American Medical Association submitted a statement outlining its position on S. 1283, 86th Congress, for inclusion in the record of the hearings on this bill. The statement recommended the following modifications:

1. Extension of the scope of the bill to include all hazardous substances "distributed as packaged chemicals for non-manufacturing purposes."
2. Application of the proposal to hazardous substances intended for export to any foreign country.
3. Inclusion of warning symbols for extremely dangerous substances.

Later testimony presented to your Committee raised questions concerning two important provisions of the bill. For this reason, we would like to supplement our original statement.

A recommendation was made by Doctor Emil Klarman, representing the Chemical Specialties Manufacturers Association, which in our opinion if accepted would seriously dilute the effectiveness of the proposed legislation. He advocated the omission of toxicologic tests in determing the necessity for the signal word "danger" and recommended that the term be applied only to very toxic substances which would also be labelled "poison." The reasons given for this proposed modification are that the present provisions would require "an enormous amount of laboratory work" and, in the words of a subsequent witness (Mr. Nicholas Walker), "would tax laboratory facilities. . . ."

The American Medical Association does not believe that these recommendations are sound. Objection to toxicity standards, because they overta testing facilities, is a recurring but unfounded fear This fear has been expressed during the consideration of every legislative improvement in the regulation of chemicals from the Federal Caustic Poiso Act of 1927 to the current legislative debate ove the regulations of chemical additives to food Admittedly, the provisions of S. 1283 would requir more toxicity testing than has heretofore been undertaken for these products. However, improve protection for consumers against bodily inju necessitates and justifies the additional work. I addition, experience with older laws indicates th the economics of the problem will insure faciliti and personnel to meet the demand. We strong recommend maintaining the toxicity standards f "danger" set forth in S. 1283; furthermore, w recommend serious consideration be given to e panding the toxicity standards to a degree co parable to those set forth in Article 173, the hazar ous substances provision of the New York Ci Health Code.

The other provision of S. 1283 on which we wi to comment concerns the scope of the bill. O original statement recommended that it include hazardous substances "distributed as packag chemicals for non-manufacturing purposes" rath than those "intended or suitable for househo use." At the hearing, Mr. Nicholas Walker, repr senting the Manufacturing Chemists Associatio implied that it is not feasible to include househol commercial, and industrial chemicals in the sa bill because their labels will vary. However, admitted that the principles used in preparing pr cautionary labelling for these three types of chem cals are the same. The argument against combini labelling for these chemicals in one bill is no mo valid here than it would be if applied to the Fe eral Food, Drug and Cosmetic Act which regulat three different types of chemical containi products.

The phrase, "suitable for household use," to defi the scope of the proposed legislation maintains th same inherent weakness which brought criticism the Federal Caustic Poisons Act. The restricti scope and language of this statute is the basis f the dissatisfaction with Caustic Poison Laws. T continue it under the guise of new and improve legislation is hardly a step forward and certain will not meet the compelling need for better co trol of hazardous substances.

If the American Medical Association can be further assistance to you or your Committee in yo consideration of S. 1283, 86th Congress, please fe free to call on us.

Sincerely yours,
F. J. L. Blasingame, M.D.
Executive Vice-President.

MEDICINE AND THE LAW

QUESTIONS AND ANSWERS ON INCOME TAX

Q. I plan to attend three medical meetings in Europe on May 15, May 28, and June 10. These meetings involve my medical specialty. Since it is more economical for me to remain in Europe during the interim between these meetings than to make separate trips, I will spend the open periods in sightseeing. What expenses may I deduct?

A. If a taxpayer travels to a destination and while at such destination engages in both business and personal activities, traveling expenses are deductible only if the trip is related primarily to the taxpayer's business or the practice of his profession. The Internal Revenue Service has taken the position that whether a trip is related primarily to the taxpayer's business or profession or is primarily personal depends on the facts and circumstances in each case. The amount of time during the period of the trip which is spent on personal activity compared to the amount of time spent on activities directly related to the practice of the traveler's profession is an important factor in determining whether the trip is primarily personal. The staggered dates of the meetings are an important consideration in establishing that your trip is primarily for business and not for personal reasons since most of your time in Europe will not be devoted to attending meetings. However, under no circumstances will you be allowed to deduct your sight-seeing and other personal expenses. Deductible traveling expenses include travel fares, meals, lodging, tips, and such other traveling expenses as are reasonable and necessary in your business travel.

Q. I am a medical specialist and my patients are frequently referred to me by other physicians. For business reasons, I sometimes entertain these physicians. To what extent are my entertainment expenses deductible?

A. A physician may deduct the costs of entertainment, provided he can establish, by appropriate evidence, that such expenses are ordinary and necessary business expenses and clearly related to the production of business income. You must be able to show the business benefit reasonably expected from the expenditure. The general statement that you hope to get referrals as a result of the entertainment is not enough. The following are typical criteria which I. R. S. uses in determining the deductibility of entertainment expenses by a physician: (1) the nature of your practice, (2) the names of the individuals entertained, as shown by your records, and the reason why additional income could reasonably be expected by entertaining these persons, (3) whether or not referrals were actually received from the doctors entertained, (4) the number of times individual doctors were entertained during the year, inasmuch as repeated entertainment indicates, in the opinion of I. R. S. a personal motive, and (5) whether or not other doctors in the same type practice in the locality have entertainment expenses.

Q. I have two automobiles. One automobile I use exclusively in my practice, and the other my wife and I use for personal travel. Is the I. R. S. correct in disputing my claim for 100% of the expense of the automobile which I use in my practice?

A. To the extent that you use your "business" automobile for commuting to and from "work" this constitutes a personal and not a business use. This is the same rule which prohibits your secretary or office nurse from deducting her transportation costs to and from work. If, for example, you drive your business automobile 10,000 miles during the year and 1,000 miles is estimated as attributable to commuting between your home and office, you would be entitled to deduct 90% of the cost of operation as a business expense. Commuting includes the first trip away from home and the last trip home each day.

Q. My health does not permit me to drive an automobile when I make house calls. After school hours, my son works for me as a chauffeur and I pay him for his services. Is his salary deductible?

A. A physician may employ a member of his family as a chauffeur, nurse, etc., in his practice and deduct the compensation paid provided that there is a genuine employer-employee relationship. The deduction should not exceed the amount that would have been paid to a stranger for similar services. A Treasury ruling holds, however, that if the father requires the child to purchase his own clothing or other necessities which the father is obligated to purchase, the deduction of the child's earnings should be disallowed to that extent.

Q. What is the current status of the tax law with regard to postgraduate courses?

A. A practicing physician may deduct his expenses in taking courses in order to maintain the existing kind of practice in which he is engaged, as contrasted with those courses taken for the purpose of beginning specialty practice. Expenses involved in taking the latter courses do not constitute a deductible expense. If your purpose in taking a course is primarily to keep abreast of new developments so as to maintain your existing practice, the expenses incurred are deductible. These expenses include tuition, travel, meals, and lodging while away from home.

Q. Occasionally, I see patients at my home. I have also set aside a room as a study for keeping up-to-date on medical literature. What portion of my household expenses may I deduct?

A. Under these facts it is doubtful whether any portion of your household expenses would constitute a legitimate deduction. If you use part of your residence as your principal office or a bona-fide second office, you are entitled to a business deduction for those expenses, on a pro-rata basis, which are properly attributable to the portion of your residence which is used as an office. For example, if one room in a seven-room rented house is used as your office, you would be entitled to deduct one-seventh of your rent, heat, light, fire insurance, etc. If your household maid also cleans your office, you may estimate the portion of her working time which is devoted to cleaning your office and deduct this portion of her wages. In the event that you own your residence you may similarly take a depreciation deduction on a pro-rata basis. In the event that you are questioned by a government agent as to whether you maintain a bona-fide second office in your residence, you must be prepared to show that you regularly see patients and maintain adequate treatment facilities at your home.

Q. I plan to take my wife with me to the A. M. A. Annual Meeting in Miami this June. May I deduct her expenses?

A. The I. R. S. has held such expenses to be personal and therefore nondeductible.

Q. Am I entitled to deduct my wife's expenses as a member of my medical association's women's auxiliary?

A. In a Tax Court case, a physician was denied a deduction for the expenses incurred by his wife as a member and officer of a medical association's women's auxiliary on the basis that he could not establish a positive economic benefit to his practice as a result of her membership.

Q. I am planning to take a "medical" cruise in the Caribbean which will feature a daily program of discussions and lectures on medical topics. Are my expenses deductible?

A. Treasury agents are prone to scrutinize such deductions carefully. The opportunities for recreation on a cruise of this nature are obvious and it is most difficult to convince an agent under these circumstances that the primary purpose is educational rather than personal. As a practical matter, agents will frequently compromise and permit partial deductions not exceeding 50% of the cost.

Q. In order to take advantage of the long-term rate, I purchased a three-year fire insurance policy covering my office equipment. Is the total premium deductible this year?

A. The I. R. S. has taken the position that the deduction for the premium paid for a long-term policy must be spread proportionately over the term of the policy. Therefore, you may deduct only the earned portion of the premium this year and the remaining premium cost in the years that it is earned by the insurance carrier. However, the premium covering insurance for a term of one year or less may be deducted in the year paid even though the policy may expire the following year.

Q. My professional liability insurance carrier, the British Commercial Insurance Co., is now in liquidation and it appears that I may have to contribute toward the settlement of a claim against me which is now being negotiated. Is this deductible?

A. You are entitled to deduct as a business expense, in the year paid, any payments made for the purpose of settling or paying a professional liability claim or judgment. If any portion of the payment is later recovered by you from the liquidators of the company, this will have to be reported as income.

Q. During the year, I paid a number of fines for parking. These were incurred while I was making house calls. Are they deductible?

A. Traffic fines are not deductible.

Q. Is the cost of an air conditioner or a special mattress deductible as a medical expense?

A. Portable room-type air-conditioning units installed on the advice of a physician for the purpose of alleviating allergies, respiratory, or similar ailments, may be deducted as a medical expense. However, air-conditioning systems which are built into the premises as permanent improvements may not be deducted. The cost of a special mattress, prescribed by a physician and intended to relieve an arthritic or similar condition, is a valid medical deduction.

Q. My wife's illness has made it necessary for me to employ a housekeeper so that she may have the rest necessary for her recovery. Is this a deductible expense?

A. The wages of a housekeeper employed to relieve your wife of household chores is not a deductible item. However, if your housekeeper's duties also include nursing services to your wife, a portion of her wages may be deducted on a reasonable pro-rata basis as a medical expense.

Q. One of my patients is so handicapped that it is necessary for him to commute to and from work in a taxi. Is the fare deductible either as an expense of his employment or as a medical expense?

A. Commuting to and from work is not deductible as a business expense even though the physical handicap of your patient does not permit him to use normal transportation. However, a recent court decision holds that where the employment is solely for therapeutic reasons, the transportation costs may be deducted as a medical expense.

MEDICAL NEWS

COLORADO

Dr. Kempe Studying Smallpox in India.—Dr. C. Henry Kempe, head, department of pediatrics, University of Colorado School of Medicine, Denver, has gone to Madras, India, where he will continue his studies on the prevention of smallpox under the auspices of the World Health Organization for a six-week period beginning March 1. His research will be conducted at the King's Institute, a medical research center near Madras, and will include a continuation of his work with hyperimmune vaccinal gamma globulin. Dr. Kempe, a consultant on smallpox to the World Health Organization, conducted similar studies in India six years ago. He will return to the University of Colorado Medical Center on April 15. Joining Dr. Kempe at Madras for the research program will be Prof. Allan W. Downie, University of Liverpool, Liverpool, England; Miss Cynthia Bowles, recently graduated registered nurse, of Connecticut, daughter of U. S. Representative Chester Bowles, former Ambassador to India; and Mrs. Leone St. Vincent, research associate, University of Colorado School of Medicine, department of pediatrics. When Dr. Kempe leaves Madras early in April he will be replaced by Dr. Gordon Meiklejohn, head of the department of medicine, University of Colorado School of Medicine, and Dr. Trygve Berge of Walter Reed Army Medical Center, Washington, D. C., who will continue the smallpox research program for four weeks.

CONNECTICUT

Establish Department of Science History.—President A. Whitney Griswold of Yale University announced Feb. 19 that a new department of history of science and medicine will be established and will offer both undergraduate and graduate courses beginning next September. Faculty appointments to the new department include Dr. John F. Fulton, Sterling Professor of the History of Medicine, as chairman; Mr. Derek J. deSolla Price, British scientist and historian, to the newly-created professorship of the history of science and also as curator of scientific instruments; and Mr. Leonard G. Wilson, appointed assistant professor of the history of medicine. The new department will be part of both the Yale Graduate School and the School of Medicine, and will replace the present history of medicine department which operates chiefly within the medical school.

FLORIDA

Hospital Seminar in Miami.—The 10th annual postgraduate seminar, conducted by the Mount Sinai Hospital of Greater Miami, will be held May 12-14 at the Hotel Fontainebleau. Guest speakers include Drs. Sol Sherry, St. Louis; Harold L. Israel, Philadelphia; Philip Thorek, Chicago; Edward R. Woodward, Gainesville; Jack E. Berk, Detroit; Edward A. Gall, Cincinnati; Robert B. Greenblatt, Augusta, Ga.; and David E. Zion, Los Angeles.

ILLINOIS

Cancer Congress Held in Springfield.—On March 9-11 the first Illinois Cancer Congress was presented in Springfield by the Illinois Department of Public Health in cooperation with the American Cancer Society, Illinois Division, the Illinois Academy of General Practice, and the Illinois State Medical Society. Speakers at the general sessions included the following: Dr. Warren H. Cole, Chicago; Dr. Leona Baumgartner, New York City; Dr. Donald L. Paulson, Dallas, Texas; Dr. Edward L. Burns, Toledo, Ohio; Dr. Nathan N. Crohn, Chicago; Dr. I. Phillips Frohman, Washington, D. C.; Dr. Emerson Day, New York City; and Dr. Lloyd M. Graves, Memphis, Tenn. Eight clinical conferences were held concerning the early detection of cancer of the skin, mouth, lungs, breast, uterine cervix and corpus, genital and urinary organs, rectum and colon, and thyroid. Information concerning the meeting may be obtained from the Illinois Department of Public Health, Division of Hospitals and Chronic Illness, Room 518, State Office Building, 400 S. Spring St., Springfield, Ill.

Chicago

Dr. Pinkus to Give Pusey Lecture.—Dr. Herman K. B. Pinkus, Monroe, Mich., will give the annual William Allen Pusey Lecture of the Chicago Dermatological Society on Wednesday, March 16, at the Illini Union, 715 S. Wood St., at 7 p. m. Preceding the lecture, dinner will be served at 6 p. m. at the Illini Union. The title of the lecture will be "Four-Dimensional Histopathology."

Personal.—Dr. Edward J. Beattie Jr., chairman, department of surgery, Presbyterian-St. Luke's Hospital, was named vice-chairman of the medical and nursing services of the Chicago Chapter of the American Red Cross. Dr. Beattie will be in charge of recruiting doctor-nurse teams for disaster operations in the area.——Dr. Charles B. Huggins, director of the Ben May Laboratory for Cancer Re-

---

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education, and public health. Programs should be received at least three weeks before the date of meeting.

search, University of Chicago, was elected honorary fellow of the Royal College of Surgeons, England, on Dec. 10.

MARYLAND

Dr. Romansky to Lecture.—The Phi Delta Epsilon Graduate Medical Fraternity will hold its annual Aaron Brown Lectureship at the Gordon Wilson Hall in University Hospital, Baltimore, Monday, April 4, 8:30 p. m. Dr. Monroe J. Romansky will deliver a lecture, "Basic Principles in the Use of Chemo-Therapeutic Agencies." Dr. Romansky is professor of medicine, George Washington University School of Medicine, Washington, D. C. He is a diplomate of the American Board of Internal Medicine.

Program for Research in Mental Retardation.—A grant of $1,261,448 to the Johns Hopkins Medical Institutions to establish a research program into the causes of mental retardation and to aid in the construction of the Children's Medical Center was announced Feb. 20 by the president of the Joseph P. Kennedy Jr. Foundation. The grant provides one million dollars for a period of 10 years for research into the etiology of mental retardation, including financial support of up to $15,000 annually for each of five senior research scholars; $150,000 toward the construction of 10 beds and their related hospital facilities in the Children's Medical Center; and $111,448 toward construction of a laboratory floor in the Children's Medical Center to be known as the Lt. Joseph P. Kennedy Jr. Laboratories for Research in Mental Retardation. Dr. Robert E. Cooke, professor of pediatrics and pediatrician-in-chief at the Johns Hopkins Hospital, will head the Kennedy research program. The Kennedy Foundation was established about 15 years ago by Joseph P. Kennedy, former ambassador to Great Britain, in memory of his son, Lt. Joseph P. Kennedy Jr., who was killed in action in World War II.

MASSACHUSETTS

Break Ground for Health Center.—Informal groundbreaking ceremonies for the 10-story University Health Center and office building for Harvard took place Feb. 17 in the parking lot on the corner of Holyoke and Mount Auburn Streets, Cambridge. The Building is scheduled for occupancy in the fall of 1961. Dr. Arlie V. Bock, who directed student health service from 1935 to 1954, broke ground for the new structure. He is Henry K. Oliver, Professor of Hygiene, Emeritus. The structure is the first phase of a planned rebuilding of the block near Harvard Square.

MISSOURI

Hospital Alumni Meeting.—The St. Louis City Hospital Alumni Association will hold its 72nd annual meeting on Wednesday, March 16, at the Le Chateau Restaurant, 10405 Clayton Road, St. Louis County. The Missouri State Medical Association will be meeting in St. Louis at the same time, so alumni of the hospital will be able to attend this annual dinner party. For information, write Dr. Shale M. Rifkin, Suite 830, 3720 Washington Blvd., St. Louis 8.

Annual State Meeting in St. Louis.—The 102nd annual meeting of the Missouri State Medical Association will be held at the Sheraton-Jefferson Hotel, St. Louis, March 13-16. The program includes refresher courses, March 14, and a clinical pathological conference, March 15. Papers to be presented by out-of-state speakers include the following:

Newer Concepts in Therapy of Diabetes, Dr. Franklin B. Peck, Indianapolis.
Surgery of the Common Bile Duct, Dr. George A. Hallenbeck, Rochester, Minn.
Estimation and Measurement of Blood Loss at Delivery Dr. Michael Newton, Jackson, Miss.
Pulmonary Emphysema, Dr. Hurley L. Motley, Los Angeles.
Indications for Open Heart Surgery in Adults, Dr. Ormand C. Julian, Chicago.

Two panel discussions are planned: "Medical Insurance, To Whom Does the Fee Belong?" and "Peripheral Vascular Disease." On March 16 a seminar "Accidents in Children," and a symposium, "Modern Concepts of Treatment of Arteriosclerotic Heart Disease," will be held concurrently. At the annual banquet 7:30 p.m., March 15, Congressman Bruce Alger, of Texas, will be the speaker.

NEBRASKA

Regional Meeting of Physicians.—The 14th annual regional meeting of the American College of Physicians for Nebraska will be held March 19 at the Cornhusker Hotel, Lincoln. Dr. Howard P. Lewis, Portland, Ore., president of the college, will present "The Role of the College in the Progress of Medicine" at the banquet, 6:30 p.m., and will speak on "Some Interesting Features of the Differences in Human Constitution" during the afternoon. The program includes the following papers:

Sodium Chloride and Potassium Losing Syndrome in Surgically Induced Diabetes Insipidus, Dr. William J. Dickerson, Omaha.
Experience with Phenformin, Dr. Maurice L. Pepper, Omaha.
Drug Induced Hemolytic Anemia, Dr. James A. Mailliard, Omaha.
Chromogen Infection of Lung, Dr. Orest J. Parillo and Dr. Morris Meiberger, Omaha.
A Comparison Between Peritoneal *Dialysis* and Hemo-Dialysis (Artificial Kidney), Dr. Charles F. Gutch, London.

Governor of the college for Nebraska is Dr. Edmond D. Walsh. For information, write the American College of Physicians, 4200 Pine St., Philadelphia 4.

NEW YORK

Program for Hospital Administrators.—A four-week Hospital Administrators Development Program will be offered at Cornell University, Ithaca, from July 11 to Aug. 5. The program will "offer hospital administrators an opportunity to add to their professional knowledge, explore new developments in hospital administration, and broaden their points of view." About 25 hospital administrators will be selected on the basis of applications received. The brochure and application blank may be obtained by writing to the Sloan Institute of Hospital Administration, Graduate School of Business and Public Administration, Rand Hall, Cornell University, Ithaca, N. Y.

New York City

Symposium on Fibrinolysis.—A symposium on fibrinolysis sponsored by Sloan-Kettering Institute will be held on March 25-26 at the Waldorf-Astoria Hotel. The program will cover the basic work on plasminogen, the activators and inhibitors of the fibrinolytic system, animal and physiological studies, and clinical experience with these materials. For information, write Dr. Eugene E. Cliffton, Sloan-Kettering Institute for Cancer Research, 410 E. 68th St., New York 21.

Clinic for Hearing and Speech.—A hearing and speech clinic was formally opened at the Kings County Hospital Center, Brooklyn, Feb. 24 by the department of hospitals of the City of New York. The clinic, under the supervision of Dr. Ira A. Polisar, director of otorhinolaryngology at the hospital and head, division of otorhinolaryngology, State University of New York Downstate Medical Center, will be open five days a week for the diagnosis and treatment of hearing and speech problems in patients of all ages. Services will include the diagnosis of hearing disorders, the prescription and evaluation of hearing aids, surgical correction of hearing loss if indicated, evaluation of disorders of speech, audiometric training, and speech therapy. A research program is also anticipated.

NORTH CAROLINA

Establish Neurology Department at Bowman Gray.—A new department of neurology for the Bowman Gray School of Medicine of Wake Forest College has been established. Dr. Martin G. Netsky, professor of neurology and neuropathology and associate in physiology and pharmacology, was named director of the department. Prior to becoming a separate department, neurology was a division of the combined department of psychiatry and neurology. In announcing future plans for the new department, Dr. Netsky lists its primary objectives as follows: (1) to train neurologists for further academic work; (2) to create a base for research in neurology; and (3) to develop a broad program of neurological sciences in all of the phases of medical instruction throughout the medical school. This will include neurology, neuropathology, neuropharmacology, and other areas.

OHIO

Law-Medicine Institute in Cleveland.—The Western Reserve University Law-Medicine Center in Cleveland will hold a two-day institute, "Alcohol Intoxication and Influence," May 12 and 13. The institute will emphasize the civil and criminal aspects of the topic and will consider such areas as the physiological effects of alcohol on the human body, the history and theory of chemical tests, and the scientific equipment available to perform chemical tests. Also under discussion will be the preparation of civil and criminal cases involving the issues of intoxication and influence. A segment of a criminal trial involving the intoxication issue in a traffic manslaughter charge is planned. The lectures and demonstrations will be provided by members of the Western Reserve University faculty and the professional staff of the Cuyahoga County Coroner's Office along with public officials. The enrollment fee is $25. For registration or information, contact Oliver Schroeder Jr., Director, the Law-Medicine Center, 2145 Adelbert Road, Cleveland 6.

WYOMING

Report on Births.—The Wyoming Department of Public Health in its monthly *Good Health for Wyoming* announced that 8,019 new births were reported in the state in 1959, an increase over the 7,950 births registered in 1958. This reverses a trend of decreasing births which started in 1955. The 2,644 deaths reported in 1959 also exceeded the 2,572 registered in 1958. Only in 1957 has this number been exceeded in Wyoming, the number being 2,666.

GENERAL

Conference on Vascular Disease of the Brain.—On Saturday afternoon, April 30, and Sunday morning and afternoon, May 1, the American Academy of Neurology is sponsoring an International Conference on Vascular Disease of the Brain. The conference will be held immediately following the close of the regular scientific sessions of the academy and will be open to the medical profession. This conference is being supported by the National Institute of Neurological Disease and Blindness and will be divided into three sections dealing with experimental studies, diagnostic procedures, and therapy. The conference will be held at the Eden Roc Hotel, Miami, Fla., headquarters for the academy meetings.

Meeting of Neuropsychiatric Hospital Association.—The 1960 annual meeting of the Central Neuropsychiatric Hospital Association will be held Thursday and Friday, March 17-18, at the Bismarck Hotel, Chicago. There will be medical, business, and social-work sections. The guest speaker for the main luncheon will be Dr. Lewis L. Robbins, medical director, Hillside Hospital, Glen Oaks, N. Y., whose topic will be "The Acting-Out Patient in the Private Psychiatric Hospital." For information, write Dr. Ralph S. Green, The Haven Sanitarium, Inc., Rochester, Mich., Secretary-Treasurer.

Meeting of Northwest Psychiatrists.—The North Pacific Society of Neurology and Psychiatry, in conjunction with the Northwest District Branch of the American Psychiatric Association, will hold its annual scientific meeting at the Benjamin Franklin Hotel, Seattle, April 8 and 9. Guest speakers will be Dr. Douglas D. Bond, chairman, department of psychiatry, Western Reserve School of Medicine, Cleveland, and Horace Magoun, Ph.D., head, department of anatomy, University of California, Los Angeles. For information, write Dr. Thomas H. Holmes III, Department of Psychiatry, University of Washington, Seattle 5, Secretary-Treasurer.

Aerospace Meeting in Miami Beach.—Dr. Ludwig G. Lederer, Washington, D. C., president, Aerospace Medical Association, announced that Detlev W. Bronk, Ph.D., president of the Rockefeller Institute and of the National Academy of Sciences, will present the sixth Louis H. Bauer Lecture at the association's 31st annual meeting at the Americana Hotel, Miami Beach, Fla., May 9-11. More than 100 papers, "covering all aspects of aerospace medicine and research," comprise the scientific program of the meeting. Dr. Lederer is medical director of Capital Airlines and physician-in-chief of the Washington National Airport. At the close of the 1960 meeting the association will install as its new president Dr. George J. Kidera, of Chicago, medical director of United Air Lines. For information, write Dr. Robert J. Benford, 4200 Cathedral Ave., N. W., Washington 16, D. C.

Increase in Contributions to Education Foundation.—The conclusion of the 1959 year found "a marked increase" in funds contributed by physicians to medical education through the American Medical Education Foundation. The foundation closed the 1959 books on Jan. 31, 1960, with a total of $1,195,824.79, an increase of $75,780.10 over the 1958 total which included a gift from the American Medical Association of $100,000. The total increase in contributed money is $175,780.10, or a 17.2% increase over the contributed amount of the preceding year, not including the A. M. A. grant. The two-year increase in the actual amount of contributions, discounting A. M. A. grants, is 36.7%. Forty-one state and Puerto Rico increased their total contribution during 1959 over that of 1958. The total number o contributors increased from 49,729 in 1958 t 55,399 in 1959.

Intermountain Pediatric Meeting.—The annual clinical convention of the Intermountain Pediatric Society will be held at the Stardust Hotel, Las Vega Nev., March 28-29. Dr. Lloyd G. Veasy, Salt Lak City, president of the society, will open the progra with an address. Each of the following three gues speakers will present two papers: Dr. Robert Cooke, professor of pediatrics, Johns Hopkins Un versity School of Medicine, Baltimore; Dr. Lou K. Diamond, associate professor of pediatrics, Ha vard Medical School, Boston; and Dr. Frederic Silverman, associate professor of radiology an pediatrics, University of Cincinnati College Medicine. Round-table discussions will be co ducted at the luncheon sessions both days. Regi tration fee is $25, and the meeting is open to a interested physicians. A ladies' luncheon is planne for March 29. For information, write the Inte mountain Pediatric Society, 2000 S. 9th East Stree Salt Lake City, Utah.

Public Relations Institute for Health Personnel. A first-time Public Relations Institute for healt and welfare agency personnel will be held in Ne York City June 2 and 3 by the National Publici Council for Health and Welfare Services. Geared agency administrators as well as to public relatio and education staffs and volunteers on the loca state, and national levels, the institute will de with the public relations problems of administrato and others having major public relations respons bility and with the "latest thought and practice" i public relations planning and evaluation. Progra speakers will be drawn from both the nonprofit an commercial public relations fields. Registration fe for the two-day institute, which will be held at th Hotel Belmont Plaza, is $10 for persons in membe agencies of the National Publicity Council, and $1 for others. Advance registration is required. Alon with the National Publicity Council, the institute i being sponsored by two-score national and loca health and welfare agencies, all sustaining membe of the council. For information or advance registration, write the council at 257 Fourth Ave., Ne York 10.

Plural Births.—Statisticians of the Metropolitan Lif Insurance Company report that plural births are relatively uncommon occurrence. Of the abou 27,700,000 confinements in the United States durin the seven-year period 1951-1957, less than 300,00 resulted in a plural birth in which at least one infant was born alive, a frequency of a little more than 10 per 1,000 confinements. For every million confinements in the period under review, there were 10,539 pairs of twins, 93 sets of triplets, and only about 1 set of quadruplets. The likelihood that a confinement will result in a plural birth varies with the age of the mother. The chances are smallest for teen-age mothers—6 per 1,000—and increase with advance in age to a maximum of about 16 per 1,000 at ages 35-39. Women in this age group accounted for little more than 8% of all confinements, but for 13% of the twins and 17% of the triplets born during 1951-1957. The chances that the confinement of a woman aged 40-44 will result in a plural birth are nearly 13 per 1,000 and for those at the end of the reproductive period the chances are about 8 per 1,000. The relative frequency of plural births are 14 per 1,000 for nonwhite and 10 per 1,000 for white women.

Report on Venereal Disease.—The Annual Joint Statement on Today's Venereal Disease Control Problem, sponsored by the American Social Health Association, the Association of State and Territorial Health Officers, and the American Venereal Disease Association, and developed from information provided by the health departments of all 50 states, 3 counties, 91 cities with population over 100,000, and the District of Columbia, was released Feb. 23. The number of early infectious syphilis cases reported increased from 6,661 in 1958 to 8,178 in 1959, or 22.8%. Gonorrhea cases rose from 220,191 in 1958 to 237,318 in 1959, or 7.8%. First quarter reports for fiscal 1960 show 42% more cases of early infectious syphilis than for the same period last year. Data received from the British Isles also indicated a "significant rise" in venereal disease. The British Cooperative Clinical Group reports increases in all ages for males through 59, and in all ages except 35-49 for females.

Venereal disease is up 14.3% in the 10-14 age group over 1958 and 11.4% in the 15-19 group. The statement points out the greatest concentration of reported venereal disease in all age groups is in cities having populations over 100,000. In New York City, early infectious syphilis is up 59.6% in the 10-14 age group and 78.3% in the 15-19 group. The statement indicated that syphilis kills a minimum of 4,000 persons a year, and costs $12,000,000 a year to maintain the syphilitic blind and $46,000,000 for hospitalization of syphilitic psychotics. Of untreated syphilitics, 1 in 200 will become blind; 1 in 50 will become insane; 1 in 25 will become crippled or incapacitated to some extent; and 1 in 15 will become a syphilitic heart victim.

General Practice Meeting in Philadelphia.—The American Academy of General Practice annual scientific assembly will be held March 21-24 in Philadelphia. The four-day scientific program, in Convention Hall, will feature 35 prominent speakers, 127 scientific and 219 technical exhibits. A complete modern office building will be erected inside Convention Hall and will contain complete examination and diagnostic facilities, laboratory equipment, two offices, and a waiting room. The building will be erected by the Sears Roebuck Foundation as part of its program to help find doctors for small rural communities, A mid-19th Century doctor's office, will be located adjacent to the Sears Foundation building. The academy's policy-making Congress of Delegates will meet at 2 p. m., March 19, in the Bellevue-Stratford Hotel. The scientific program will open at 1:30 p. m., March 21, with a panel discussion of the doctor-patient relationship and the related role of the doctor's wife. Two geriatric sessions will follow. Sessions will include the following topics; antibiotic therapy, preventive pediatrics, old and new concepts of the origin of disease, gynecologic surgery, occupational health, cardiac emergencies, traumatic cerebral emergencies, hematology, and mental health. Social activities include the president's reception and dance and a ladies' program. Twenty $1,000 general practice residency training awards will go to interns or young physicians who have completed their military training. The assembly is combined with the Philadelphia Postgraduate Institute. For information, write the American Academy of General Practice, Volker Boulevard at Brookside, Kansas City 12, Mo.

FOREIGN

Meeting of German Otorhinolaryngologists.—Prof. Meyer zum Gottesberge, Secretary, Deutsche Gesellschaft der Hals-Nasen-Ohrenärzte, Düsseldorf Moorenstr, 5, Germany, announced that the German Society of Otorhinolaryngologists will hold their annual meeting May 25. The chief subjects are allergy from the viewpoint of the otolaryngologist, the malignant tumors of the mesopharynx, and the irradiation of malignant tumors of the mesopharynx.

Neuropathology Congress in Munich.—The fourth International Congress of Neuropathology will be held in Munich, Germany, Sept. 3-8, 1961. The main themes are histochemistry and related biochemistry of diseases of the central and peripheral nervous systems (Sept. 4); electron microscopy of the central and peripheral nervous systems and of the myoneural junction (Sept. 5); cell biology and cell culture of nervous tissue (Sept. 6). Deadlines for abstracts for these themes is June 1, 1960. There will also be groups of papers on perinatal neuropathology and free papers. Those wishing to attend should notify the chairman of the American committee, Dr. Orville T. Bailey, Neuropsychiatric Institute, 912 S. Wood St., Chicago 12.

CORRECTIONS

Diagnostic Approach to the Infant with an Enlarging Head.—In the article entitled "Diagnostic Approach to the Infant with an Enlarging Head" in The Journal, Feb. 6, page 538, an error appeared. The illustration on page 540 was printed upside down. The legend, to be meaningful, must be placed on the opposite side of the illustration.

Hypothermic Coma.—In the letter from the United Kingdom, "Hypothermic Coma from Chlorpromazine," in The Journal, Jan. 23, page 367, it was stated that a patient was immersed in a water bath at 98 C. This should have read 98 F. The reference cited should have been the *British Medical Journal* and not *Lancet*.

Annual Lecture in Chicago March 30.—Dr. Joseph H. Kiefer, chairman of the Committee on the Annual D. J. Davis Memorial Lecture on Medical History has reported that the news item published in The Journal for Feb. 13 under Chicago announcing the Davis Lecture should have read March 30 as the date of the lecture. Also the room number should have been 106 of the Dental-Medical-Pharmacy Building of the University of Illinois, 1853 W. Polk St., Chicago.

EXAMINATIONS AND LICENSURE

MEDICAL SPECIALTY BOARDS

American Board of Anesthesiology: *Written.* Various locations, June 24. Final date for filing application was January 10. *Oral.* Miami Beach, April 25-30. Applications already on file. Sec., Dr. Forrest E. Leffingwell, 217 Farmington Ave., Hartford 5, Conn.

American Board of Dermatology: *Written.* Various locations, June 5, 1961. Final date for filing application is March 1, 1961. *Oral.* Philadelphia, Oct. 13-16. Sec., Dr. Beatrice M. Kesten, One Haven Ave., New York 32, New York.

American Board of Internal Medicine: *Oral.* San Francisco, March 30-April 1; New York City, Nov. 14-17. Closing date for filing application: Jan. 2 and July 1. *Written.* Oct. 17. Closing date for filing application is May 1. *Oral. Gastroenterology.* Philadelphia, March 11-12. Final date for filing application was January 15. Sec.-Treas., Dr. William A. Werrell, One West Main St., Madison 3, Wis.

American Board of Neurological Surgery: Examination given twice annually, in the spring and fall. St. Louis, April 10-12. In order to be eligible a candidate must have his application filed at least six months before the examination time. Sec., Dr. Donald D. Matson, 300 Longwood Ave., Boston, Mass.

American Board of Obstetrics and Gynecology: *Part II Oral and Clinical.* Chicago, April 11-16. Final date fo filing application was August 1. Applications for certification in Part I, new and reopened, and requests for reexamination in Part II are now being accepted. Deadlin for receipt of applications is August 1, 1960. After July 1 1962 a minimum of three years of approved progressiv residency training will be required. Training by preceptorship will no longer be acceptable. The initiation o preceptorships will not be approved after July 1, 196 Sec., Dr. Robert L. Faulkner, 2105 Adelbert Road, Cleveland 6.

American Board of Ophthalmology: *Written.* Jan. 2 1961. Deadline for filing applications is July 1. *Oral.* Sa Francisco, May 9-13; Chicago, Oct. 3-7. Sec., Dr. Merri J. King, Box 236 Cape Cottage Branch, Portland, Main

American Board of Orthopaedic Surgery: *Part I,* Nashville, Denver and Philadelphia, Apr. 13-14. Deadline f receipt of applications was Nov. 30. *Oral and Writte Part II.* Miami Beach, Jan. 3-5, 1961. Final date for filin application is July 1. Sec., Dr. Sam W. Banks, 116 Sout Michigan Ave., Chicago 3.

American Board of Otolaryngology: *Oral,* Chicago, Oc 3-6. Final date for filing application is April 1. Sec., D Dean M. Lierle, University Hospitals, Iowa City.

American Board of Pathology: Memphis, April 21-2 Final date for filing application was March 7. *Examination in Forensic Pathology.* Memphis, April 22. Final da for filing application was March 7. Sec., Dr. Edward Smith, Indiana University Medical Center, 1100 W Michigan St., Indianapolis 7.

American Board of Pediatrics: *Written.* New York Cit January 1961. Final date for filing application is Dec. Administrative Sec., Mrs. Eleanor J. Mitchell, Rosemon Pa.

American Board of Physical Medicine and Rehabilitation: *Oral and Written.* New York, June 17-18. Sec., D Earl C. Elkins, Mayo Clinic, Rochester, Minn.

American Board of Plastic Surgery: *Oral and Writte* Milwaukee, May 1960. Final date for filing applicatio was January 1. Corresponding Secretary, Mrs. Estelle Hillerich, 4647 Pershing Ave., St. Louis 8, Mo.

American Board of Proctology: *Oral and Written, Par I and III,* Philadelphia, Sept. 24. Final date for filin application is June 30. Sec., Dr. Stuart T. Ross, 52 Franklin Ave., Garden City, N. Y.

American Board of Psychiatry and Neurology: Ne York, New York, Dec. 12-13. *Child Psychiatry.* Chicag April 25-26. Sec., Dr. David A. Boyd, Jr., 102-110 Secon Ave., S.W., Rochester, Minn.

American Board of Radiology: *Examination.* Cincinnat June 6-10; Dec. 5-9. Deadline for filing applications f the June examination was Jan. 1. Filing deadline for th December examination is July 1. A special examinatio in *Nuclear Medicine (for those diplomates in Radiolog* or Therapeutic Radiology) will be offered provided ther are sufficient applications. Sec., Dr. H. Dabney Ker Kahler Hotel Bldg., Rochester, Minn.

American Board of Surgery: *Oral Examinations (Part II)* Kansas City, Kans., May 16-17, and Los Angeles, Ma *19-20. Sec., Dr. John B. Flick,* 1617 Pennsylvania Blvd Philadelphia 3.

Board of Thoracic Surgery: *Oral.* May 1960. Final dat for filing application was Dec. 1. Sec., Dr. Wm. M. Tuttle 1151 Taylor Ave., Detroit 2.

American Board of Urology: *Written.* December. *Oral Clinical.* Chicago, February 1961. Exec. Sec., Mrs. Ruby L. Griggs, 30 Westwood Road, Minneapolis 26.

GOVERNMENT SERVICES

AIR FORCE

General Powell Awarded Legion of Merit.—Major Gen. William H. Powell Jr., assistant to the surgeon general, U. S. A. F., was awarded the Legion of Merit recently in ceremonies held in Washington, D. C., prior to his retirement on Jan. 31. The award was presented for his outstanding service to the United States while serving as chief medical officer, upreme Headquarters Allied Powers Europe, from uly 3, 1957, to Sept. 3, 1959. He was cited for his utstanding leadership, exemplary foresight, and ceptional judgment in resolving medical and gistic support problems of the various national rces within Allied Command Europe.

ir Force Clinical Surgeons Meet.—The annual eeting of the Society of Air Force Clinical Sur- ons will be held at the U. S. A. F. Hospital, avis Air Force Base, Calif., April 13-15, 1960. is meeting will include original papers in various rgical specialties. Moderators and other speakers ve been chosen from among senior Air Force rgeons, national consultants to the surgeon gen- al, and specially invited medical authorities in the n Francisco bay area.

OOD AND DRUG ADMINISTRATION

urt Actions.—In December 42 tons of nuts for e Christmas trade were found insect-infested, oldy, spoiled, shriveled, and with empty shells. cause of rodent contamination 150 tons of bulk eat was seized. Rotten eggs were found in 20 ns of frozen whole eggs intended for commercial od processing, and spoiled chicken was found in tons of cut-up chicken in consumer packages. nong foods taken off the market as hazards to alth were candy suckers with pointed wooden cks that could injure children, wheat in which rcury-treated seed wheat was mixed, and fresh d processed cranberries containing aminotriazole. alth violations were also charged against 148,000 blets of low-strength vitamin products. Seized as onomic cheats were 5 tons of canned freestone aches not labeled to show they were below stand- l in quality.

Of the 11 drugs and devices seized in December, were alleged to be misbranded by false and mis- ding claims. Canned "natural" celery juice was ered as part of a vegetable "juice therapy" pro- am for diseases including arthritis, rheumatism, uritis, chronic appendicitis, high blood pressure, oplexy, and arteriosclerosis. Two makes of so-called air purifiers—portable cabinets into which room air was drawn and caused to flow through an electrostatic field or exposed to ultraviolet light—were seized because of claims that they were effective in treating or preventing hay fever, asthma, sinus trouble, and allergies to airborne substances. Alleged to be adulterated as well as misbranded were 300,000 digitalis tablets that were substantially lower in strength than the 100 mg. claimed on the label.

"Reducing-Aid" Cigarettes.—A federal court decision affirmed the government's view that Trim Reducing Aid cigarettes are not effective for weight reducing and are a "new drug" for which safety has not been established. The tobacco in "Trim" cigarettes contains added amounts of tartaric acid, allegedly an appetite suppressant, and flavoring oils. The product was offered as a new scientific weight-reducing discovery approved by physicians and other scientists after years of clinical testing. According to other promotional claims in the literature of the manufacturer, Cornell Drug Corporation, New York, you could "puff your pounds away" or "watch your weight go up in smoke" by smoking three Trims daily. No attention to the diet was necessary, the promoter said.

Drug Firm Prosecuted for Poor Controls.—Inadequate drug manufacturing controls led to the prosecution of an Iowa firm for shipping a dangerous drug prescribed for reducing weight at two-and-a-half times the strength declared on the label, the Food and Drug Administration reports. Desoxyephedrine hydrochloride, with a strength of 10 mg., was shipped in a drum labeled 4 mg., and the label failed to bear the statement, "Caution: Federal law prohibits dispensing without prescription." On Nov. 2, 1959, Sentral Laboratories, Des Moines, Iowa, and James H. Roberts, president, pleaded guilty to the charges and a fine was imposed.

Physician Convicted and Loses License.—A physician already convicted of selling amphetamine drugs without a proper physician-patient relationship violated the terms of his probation and was sent to prison. On Oct. 29, 1959, Dr. Harry G. Williams pleaded guilty to five counts of dispensing the "pep pills" or "bennies" without prescription and in unlabeled vials. The court fined him $1,000, suspended a one-year jail term, and placed him on probation for three years. Within a month he was charged with violating his probation by selling 1,284 tablets of the same drugs to a drug addict. The physician pleaded guilty and was sentenced to serve the previously suspended jail sentence. The state of Nebraska revoked his license to practice medicine.

DEATHS

Ady, Albert Emmett Ⓜ West Liberty, Iowa; State University of Iowa College of Medicine, Iowa City, 1923; veteran of World Wars I and II; associated with the Mercy Hospital in Iowa City, where he died Dec. 19, aged 63.

Anderson, Lewis Ridley Ⓜ Gainesboro, Tenn.; (licensed by years of practice); past-president of the Jackson County Medical Society; served on the school board of Jackson County; past-president of the Gainesboro Rotary Club; died in the Jackson County Hospital Dec. 14, aged 68.

Bailey, Willard Chapin, San Jose, Calif.; Cooper Medical College, San Francisco, 1899; served as city health officer; for many years member of the board of directors of the San Jose Hospital; twice president of the Chamber of Commerce; died Dec. 18, aged 84.

Barham, Oscar T., Lewisville, Ark.; College of Physicians and Surgeons, Little Rock, 1911; died in Dallas Dec. 19, aged 85.

Barney, J. Dellinger Ⓜ Lenox, Mass.; Harvard Medical School, Boston, 1904; chairman, Section on Urology, American Medical Association, 1931-1932; specialist certified by the American Board of Urology; member of the American Association of Genito-Urinary Surgeons, of which he was past-president, and the American Urological Association; fellow of the American College of Surgeons; member of the honorary staff of the Massachusetts General Hospital in Boston; died in Milton Dec. 15, aged 81.

Bear, Lowery Hartford Ⓜ Vevay, Ind.; Medical College of Indiana, Indianapolis, 1892; served as secretary of the Switzerland County Medical Society; for many years county health officer; died Nov. 26, aged 91.

Billings, Ralph Everett Ⓜ Franklin, Minn.; University of Minnesota Medical School, Minneapolis, 1929; member of the American Academy of General Practice; past-president of the Renville-Redwood Counties Medical Association; past-president of the school board; served as village health officer; died in the Veterans Administration Hospital Dec. 19, aged 69.

Bonar, Elwood D., Columbus, Ohio; Ohio State University College of Medicine, Columbus, 1926; died in the White Cross Hospital Dec. 16, aged 71.

Boyd, Frank Harrison, Opelika, Ala.; Emory University School of Medicine, Atlanta, Ga., 1930; died Dec. 19, aged 54.

Braunlin, William Henry Ⓜ Marion, Ind.; Miami Medical College, Cincinnati, 1904; member of the American Academy of Ophthalmology and Otolaryngology; died in the Marion General Hospital Dec. 22, aged 77.

Brust, Paul Raymond Ⓜ San Diego, Calif.; Stanford University School of Medicine, San Francisco, 1926; served as police department surgeon; formerly on the staffs of the Mercy and Children's Hospitals; died Dec. 26, aged 65.

Buckner, Frank Wooldridge Ⓜ Martinsville, Va.; Duke University School of Medicine, Durham, N. C., 1936; interned at the Duke Hospital in Durham, N. C., and the New Haven Hospital in New Haven, Conn., where he served a residency; served a residency at the Memorial Hospital for the Treatment of Cancer and Allied Diseases in New York City; veteran of World War II; certified by the National Board of Medical Examiners; died Dec. 21, aged 52.

Buckner, Kathryn Ⓜ Philadelphia; Baylor University College of Medicine, Dallas, Texas, 1928; specialist certified by the American Board of Psychiatry and Neurology; member of the American Psychiatric Association; served on the faculty of Temple University School of Medicine; associated with St. Christopher's Hospital for Children; died Dec. 28, aged 57.

Burns, Joseph Albert, Little Rock, Ark.; University of Arkansas School of Medicine, Little Rock, 1927; served as a member of the staff of the State Hospital; died Dec. 17, aged 56.

Cady, Laurence Hammond Ⓜ Minneapolis; University of Minnesota Medical School, Minneapolis, 1923; member of the American Academy of General Practice; on the staff of St. Andrew's Hospital; died Dec. 18, aged 68.

Campbell, Eleanor Milbank Anderson, New York City; Boston University School of Medicine, 1916; co-founder and served as director of the Judson Health Center; died Dec. 29, aged 81.

Chaney, Thomas Morris Ⓜ Colonel, U. S. Army, retired, Dunkirk, Md.; University of Maryland School of Medicine, Baltimore, 1906; at one time city health officer of Winston-Salem, N. C.; veteran of World Wars I and II; entered the regular Army

---

Ⓜ Indicates Member of the American Medical Association.

in 1921 and retired March 31, 1947; died in the Walter Reed Army Hospital, Washington, D. C., Dec. 29, aged 76.

Clayton, Bonnar Marcus, Birmingham, Ala.; Chattanooga (Tenn.) Medical College, 1908; for many years associated with the Woodmen of the World Hospital in San Antonio, Texas; died Dec. 14, aged 80.

Colman, John Kennedy Ⓜ Butte, Mont.; born in Dunkirk, N. Y., Dec. 31, 1905; University of Michigan Medical School, Ann Arbor, 1931; interned at the University Hospital in Ann Arbor, where he served a residency; specialist certified by the American Board of Orthopaedic Surgery; member of the American Academy of Orthopaedic Surgeons; fellow of the American College of Surgeons; orthopedic surgeon, crippled children's division, state board of health; chairman of the department of physical medicine and rehabilitation at Butte Community Hospital; associated with the Shodair Crippled Children's Hospital in Helena and St. James Hospital; consultant, Veterans Administration Hospital in Fort Harrison; died Dec. 19, aged 53.

Como, Nicholas Frank Ⓜ Brooklyn; Yale University School of Medicine, New Haven, Conn., 1954; ertified by the National Board of Medical Exminers; served in the U. S. Naval Reserve; on the taffs of the Victory Memorial and Holy Family ospitals; died Dec. 25, aged 29.

Conti, James G. Ⓜ Pittsburgh; Maryland Medical College, Baltimore, 1911; died in the Presbyterian Hospital Dec. 5, aged 72.

Cross, Roland Robert Ⓜ Springfield, Ill.; American Medical College, St. Louis, 1912; past-president f the Jefferson-Hamilton Counties Medical Soiety; spent six years in Indian work; veteran of World War I; formerly superintendent of the health istrict in Southern Illinois; for many years direcor of the Illinois Department of Public Health; ied Nov. 28, aged 71.

Dalton, David, Glenolden, Pa.; Medico-Chirurgical College of Philadelphia, 1908; also a pharmacist; or many years president of the Sharon Hill (Pa.) chool Board and at one time postmaster; served n the staff of the Taylor Hospital in Ridley Park nd the Thomas M. Fitzgerald Mercy Hospital, Darby; died Dec. 28, aged 90.

Davidson, Andrew Blaine Ⓜ San Diego, Calif.; Jeferson Medical College of Philadelphia, 1909; rered from the U. S. Navy Jan. 1, 1943; died in the U. S. Naval Hospital Nov. 20, aged 75.

Denney, Elliott Stevenson Ⓜ Mooseheart, Ill.; Harard Medical School, Boston, 1920; fellow of the American College of Surgeons; medical director at he Philadelphia Memorial Hospital; associated with St. Joseph Mercy Hospital and the Copley Memorial Hospital in Aurora, where he died Dec. 23, aged 67.

Donovan, Paul Royal Ⓜ Medford, Mass.; Tufts College Medical School, Boston, 1925; veteran of World War I; on the staff of the Whidden Memorial Hospital in Everett, New England Sanitarium and Hospital in Stoneham, Mount Auburn Hospital in Cambridge, Winchester (Mass.) Hospital, and the Winthrop (Mass.) Community Hospital; chairman of the medical board of the Lawrence Memorial Hospital, where he died Dec. 22, aged 63.

Drennan, Clyde Leo Ⓜ Polo, Ill.; Northwestern University Medical School, Chicago, 1937; interned at the Evanston (Ill.) Hospital; member of the American Fracture Association; veteran of World War II; member of the Polo Community High School Board of Education; on the staff of the Dixon (Ill.) Public Hospital; died Dec. 18, aged 51.

Du Bois, Paul Walter Ⓜ Detroit; University of Michigan Medical School, Ann Arbor, 1925; fellow of the American College of Surgeons; associated with the Harper Hospital; died Dec. 27, aged 62.

Duffy, Edgar Albert Ⓜ Trenton, Mo.; Marion-Sims College of Medicine, St. Louis, 1899; also a pharmacist; secretary-treasurer of the Grand River Medical Society; member of the American Association of Railway Surgeons; division surgeon for the Rock Island Railroad; president of the staff of the Wright Memorial Hospital, where he died Nov. 28, aged 81.

Dunavant, Andrew Poindexter, Pontotoc, Miss.; Memphis (Tenn.) Medical College, 1910; died in Memphis, Tenn., Dec. 22, aged 70.

Edie, Elliott Bard Ⓜ Uniontown, Pa.; Jefferson Medical College of Philadelphia, 1904; served during World War I and received the Distinguished Service Cross; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; on the staff of the Uniontown Hospital; died in St. John's Hospital, Springfield, Mo., Nov. 26, aged 80.

Farr, Walter John Ⓜ Teaneck, N. J.; Cornell University Medical College, New York City, 1925; veteran of World War II; associated with the Holy Name Hospital in Teaneck, Valley Hospital, Ridgewood, North Hudson Hospital, Weehawken, and the Hasbrouck Heights (N. J.) Hospital; died in the Holy Name Hospital Dec. 15, aged 58.

Feinblatt, Henry M., Brooklyn; Long Island College Hospital, Brooklyn, 1913; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; veteran of World War I; served on the faculty of his alma mater; for many years associated with Kings County Hospital; author of "Clinical Laboratory Medicine" and "Transfusion of Blood"; died Dec. 24, aged 68.

Ferguson, William George, Niagara Falls, N. Y.; University of Western Ontario Faculty of Medicine, London, Ont., Canada, 1924; since 1930 director of the Child Guidance Clinic of the Martha H. Beeman Foundation; served with the Canadian Expeditionary Force in France during World War I; associated with the Mount St. Mary's Hospital and the Memorial Hospital, where he died Dec. 9, aged 60.

Fieramosca, Ettore Francesco Ⓢ Staten Island N. Y.; Loyola University School of Medicine, Chicago, 1933; on the staff of the Staten Island Hospital; died Dec. 31, aged 54.

Gager, Leslie Tracy Ⓢ Washington, D. C.; Johns Hopkins University School of Medicine, Baltimore, 1918; served on the faculty of George Washington University School of Medicine and Howard University College of Medicine; past-president of the Washington Pathological Society; veteran of World Wars I and II; retired from the U. S. Veterans Administration in June, 1953; on the staffs of the George Washington and Garfield hospitals; died Dec. 25, aged 69.

Gardiner, Sheridan Ellsworth, Mount Pleasant, Mich.; Jefferson Medical College of Philadelphia, 1893; served as health officer of Mount Pleasant; died Nov. 20, aged 94.

Gokey, Harold Lewis Ⓢ Alexandria Bay, N. Y.; McGill University Faculty of Medicine, Montreal, Que. Canada, 1917; past-president of the Jefferson County Medical Society; formerly mayor of Alexandria Bay; veteran of World War I; died in the House of the Good Samaritan, Watertown, Dec. 17, aged 66.

Grant, Richard S. Ⓢ Chicago; Meharry Medical College, Nashville, Tenn., 1904; died Dec. 31, aged 81.

Grieco, John Vincent, New York City; Universita di Napoli Facolta di Medicina e Chirurgia, Italy, 1921; died Dec. 13, aged 63.

Groenlung, Wilho Arvid, Vancouver, Wash.; Northwestern University Medical School, Chicago, 1909; died Dec. 10, aged 87.

Gudenkauf, Henry Joseph, Minster, Ohio; Ohio Medical University, Columbus, 1907; formerly member of the county board of health; died in St. Rita's Hospital, Lima, Dec. 20, aged 84.

Hamilton, Guy W. Ⓢ Monrovia, Calif.; University of Louisville (Ky.) Medical Department, 1899; for many years a medical missionary in China; formerly associated with the Madison (Ind.) State Hospital; died Nov. 24, aged 85.

Hertel, Alphons Joseph Ⓢ Whitefish Bay, Wis New York Homeopathic Medical College an Flower Hospital, New York City, 1915; vetera of World War I; on the staffs of St. Joseph's Ho pital and St. Mary's Hospital, Milwaukee, whe he died Nov. 30, aged 68.

Hiestand, Harley Judson Ⓢ Pennville, Ind.; India Medical College, School of Medicine of Purd University, Indianapolis, 1906; served as preside of the Pennville State Bank; died Dec. 23, aged 7

Hohman, Roy Max Ⓢ Chicago; Rush Medical Co lege, Chicago, 1931; member of the Americ Academy of General Practice; veteran of Wor War II; staff member of the Evangelical Hospit died Dec. 23, aged 53.

Holmes, James Ⓢ Springfield, Mass.; University Maryland School of Medicine, College of Physicia and Surgeons, Baltimore, 1917; veteran of Wor War I; associated with the Springfield Hospit where he died Dec. 21, aged 74.

Houser, John Francois Ⓢ Versailles, Ohio; Unive sity of Louisville (Ky.) School of Medicine, 194 interned at the Miami Valley Hospital in Dayto member of the American Academy of Gener Practice; captain in the medical corps of the Arm of the United States from July 5, 1946, to May 2 1948; member of the staff of Wayne Hospit Greenville, Ohio; died Dec. 22, aged 39.

Hynes, John Eldon Ⓢ Minneapolis; University Minnesota Medical School, Minneapolis, 190 member of the American Academy of Gener Practice; past-president of the Minnesota Academ of Medicine; died Dec. 16, aged 81.

Karbach, Hylmar E. Ⓢ New Braunfels, Texas; Un versity of Texas College of Medicine, Galveston 1924; member of the American Academy of Genera Practice; veteran of World Wars I and II; on th staff of the New Braunfels Hospital, where he die Dec. 6, aged 60.

Lee, James Grant Ⓢ Bonner Springs, Kan.; Kansa City (Mo.) Medical College, 1892; died in th Bethany Hospital, Kansas City, Dec. 20, aged 91

Lindsay, John William Ⓢ Conway, Mo.; St. Loui University School of Medicine, 1905; died in th Baptist Hospital, Springfield, Dec. 15, aged 84.

Linsky, Harold Ⓢ Kew Gardens, N. Y.; Columbi University College of Physicians and Surgeons New York City, 1922; fellow of the American Col lege of Surgeons; associated with the Terrace Heights Hospital in Hollis, where he died Dec. 28, aged 60.

Lippman, Richard William, Beverly Hills, Calif.; Columbia University College of Physicians and Surgeons, New York City, 1940; interned at the Beth Israel Hospital in New York City; veteran of World War II; one of the founders of the National Nephrosis Foundation; died in Los Angeles Dec. 26, aged 43.

Loeb, Leo Ⓜ St. Louis; born in Mayen, Germany, Sept. 21, 1869; Universität Zurich Medizinische Fakultät, Switzerland, 1898; emeritus professor of pathology at Washington University School of Medicine, where he joined the faculty in 1915 as professor of comparative pathology and later retired as Edward Mallinckrodt professor of pathology; served at McGill University, the University of Illinois, New York State Pathological Laboratory, Buffalo, and the University of Pennsylvania; from 1910 to 1912 secretary of the Section on Pathology and Physiology, American Medical Association; in 1935 received the John Phillips Memorial Medal of the American College of Physicians; in 1942 the St. Louis Medical Society presented him with its award of merit and gold medal; past-president of the Society of Cancer Research; member of the Association of American Physicians, the Endocrine Society, American Association of Pathologists and Bacteriologists, of which he was past-president, and the American Socitey for Experimental Pathology; in 1936 the Mu Chapter of the Phi Beta Pi Medical Fraternity established a lectureship in his honor; served as director of the department of pathology at the Barnard Free Skin and Cancer Hospital; in December, 1950, the American Medical Association honored him by devoting an issue of *Archives of Pathology* to him; author of "Basis of Individuality"; his research included, among other subjects, tissue and tumor growth, physiology of generative organs, pathology and circulation, venom of Heloderna, and analysis of experimental amebocyte tissue; died Dec. 28, aged 90.

Lowe, David Earl Ⓜ Uniontown, Pa.; Jefferson Medical College of Philadelphia, 1912; veteran of World War I; associated with the Uniontown Hospital; died Dec. 19, aged 72.

McCarthy, William Daniel Ⓜ Brooklyn; Queen's University Faculty of Medicine, Kingston, Ont. Canada, 1930; died Dec. 28, aged 53.

McNeill, Willard Payne Ⓜ Spencerville, Md.; College of Medical Evangelists, Loma Linda and Los Angeles, 1935; interned at the Maryland General Hospital in Baltimore; served a residency at the Sibley Memorial Hospital in Washington, D. C., and the Bryn Mawr (Pa.) Hospital; certified by the National Board of Medical Examiners; served on the staff of the Washington Sanitarium and Hospital in Takoma Park, where he died Dec. 28, aged 49.

Mackenzie, Wellie Smith, Adrian, Mich.; Rush Medical College, Chicago, 1905; veteran of the Spanish-American War; served as health officer; associated with the Bixby Hospital; died in Clearwater, Fla., Nov. 19, aged 80.

Main, Roscoe Conkling, Santa Barbara, Calif.; Rush Medical College, Chicago, 1911; formerly health officer of Santa Barbara County; served as health officer of the city of Marquette, Mich.; died Nov. 28, aged 77.

Malik, Nur Muhammad Ⓜ Detroit; University of Michigan Medical School, Ann Arbor, 1927; died Dec. 2, aged 63.

Merica, Forrest Wayne Ⓜ Lakewood, Ohio; Indiana University School of Medicine, Indianapolis, 1925; specialist certified by the American Board of Otolaryngology; member of the American Academy of Ophthalmology and Otolaryngology, American Laryngological, Rhinological and Otological Society, and the American Broncho-Esophagological Association; fellow of the American College of Surgeons; associated with the Lakewood (Ohio) Hospital and the Fairview Park Hospital in Cleveland; died in the Lakewood Hospital Dec. 2, aged 58.

Meyer, Maximilian, New York City; Friedrich-Alexanders Universität Medizinische Fakultät, Erlangen, Bavaria, Germany, 1917; died Nov. 13, aged 71.

Miller, Eunice Wilson, Hazel, Ky.; University of Louisville Medical Department, 1910; died Dec. 9, aged 77.

Miller, James Ⓜ Corning, Ohio; Georgetown University School of Medicine, Washington, D. C., 1899; president of the Corning Board of Education; a director of the Perry County Health Department; member of the board of directors of the Corning Bank; died in the Bethesda Hospital, Zanesville, Dec. 18, aged 85.

Moe, George Ⓜ Berkeley, Ill.; Chicago Homeopathic Medical College, 1893; died in the Memorial Hospital of Du Page County in Elmhurst Oct. 29, aged 97.

Morrall, Ralph Richard Ⓜ Youngstown, Ohio; University of Michigan Medical School, Ann Arbor, 1911; specialist certified by the American Board of Orthopaedic Surgery; member of the American Academy of Orthopaedic Surgeons; fellow of the American College of Surgeons; veteran of World War I; associated with the Youngstown Hospital, where he died in the Southside Unit Dec. 21, aged 71.

Morrison, Lindsey Ⓜ Hammond, Ind.; Hospital College of Medicine, Louisville, 1900; for a time postmaster in West Point, Ky.; veteran of World War I; past-president of the American College of Proctology; served as president of the staff, St. Margaret Hospital; died Dec. 18, aged 89.

Morroway, James Henry Ⓜ St. Joseph, Mo.; Creighton University School of Medicine, Omaha, 1900; member of the American Psychiatric Association; past-president of the Harrison County Medical Society; for many years on the staff of the State Hospital Number 2; died in the Mercy Hospital, Marshalltown, Iowa, Dec. 12, aged 80.

Mulholland, William James Ⓜ Chicago; University of Illinois College of Medicine, Chicago, 1916; veteran of World War I; on the staff of St. Bernard Hospital; died in the South Shore Hospital Dec. 22, aged 72.

Nark, Pius Anthony Ⓜ Minersville, Pa.; Hahnemann Medical College and Hospital of Philadelphia, 1936; veteran of World War II; on the staff of the Pottsville (Pa.) Hospital; died Dec. 18, aged 50.

Nerseth, Marvin Ⓜ Klamath Falls, Ore.; University of Nebraska College of Medicine, Omaha, 1931; veteran of World War II; on the staffs of the Hillside and Klamath Valley hospitals; died in the Hillside Hospital Dec. 24, aged 53.

Nosik, William Andre Ⓜ Cleveland; born in Milwaukee May 18, 1911; University of Wisconsin Medical School, Madison, 1935; specialist certified by the American Board of Neurological Surgery; member of the Harvey Cushing Society, Association for Research in Nervous and Mental Diseases, and the Central Neuropsychiatric Association; fellow of the American College of Surgeons; past-president of the Cleveland Society of Neurology and Psychiatry and Ohio State Neurological Society; veteran of World War II; associated with St. Luke's, St. Vincent's Charity, Huron Road, Glenville, Doctors, and Lakeside hospitals; in 1955-1956 editor of the *Bulletin of the Cleveland Academy of Medicine;* died Dec. 6, aged 48.

O'Donnell, Albert Thomas Ⓜ Port Orchard, Wash.; Creighton University School of Medicine, Omaha, 1952; veteran of World War II; died in Bremerton Dec. 23, aged 42.

Osborn, Dean Hill, Klamath Falls, Ore.; State University of Iowa College of Medicine, Iowa City, 1910; veteran of World War I; associated with the Klamath Valley Hospital and the Hillside Hospital, where he died Dec. 25, aged 74.

Perlman, Samuel Ⓜ Carthage, Texas; Indiana University School of Medicine, Indianapolis, 1930; member of the American Academy of General Practice; member and past-president of the staff of the Panola General Hospital; died Dec. 22, aged 57.

Pelant, Francis Joseph, Newton, Ill.; Chicago College of Medicine and Surgery, 1914; died in St. Anthony Memorial Hospital, Effingham, Dec. 5, aged 73.

Picozzi, John Avand Ⓜ Providence, R. I.; Tufts College Medical School, Boston, 1922; formerly county medical examiner; served on the staff of the Veterans Administration Hospital, where he died Dec. 3, aged 61.

Prior, James Howland Ⓜ Cranston, R. I.; Hahnemann Medical College and Hospital of Philadelphia, 1902; specialist certified by the American Board of Internal Medicine; served on the state board of health and the state board of medical examiners; formerly on the staff of the Rogers Williams General Hospital in Providence, where in 1953 the nurses' home was named Prior Hall in his honor; died Dec. 23, aged 81.

Proxmire, Theodore Stanley Ⓜ Lake Forest, Ill.; the Hahnemann Medical College and Hospital, Chicago, 1904; veteran of World War I; served as president of the Lake County Tuberculosis Association; fellow of the American College of Surgeons; a founder and for many years president of the Lake County Tuberculosis Sanatorium, Waukegan; on the staffs of St. Therese Hospital in Waukegan and the Lake Forest Hospital; for many years director of the Allendale School for Boys, Lake Villa; died Dec. 16, aged 77.

Rattunde, Henry Frederick, Duarte, Calif.; University of Wisconsin Medical School, Madison, 1949; interned at the Broadlawns Polk County Hospital in Des Moines, Iowa, where he served a residency; served a residency at the Iowa Methodist Hospital in Des Moines; associated with the City of Hope; spent two years in the Air Force; died Nov. 28, aged 35.

Regner, Mathias Frederick Ⓜ Colonel, U. S. Air Force, New York City; born in West Bend, Wis., Dec. 16, 1912; University of Wisconsin Medical School, Madison, 1937; veteran of World War II; received the Bronze Star Medal, European Theater of Operations Medal, American Defense Service Medal, German Occupation Medal, Army Accommodation Medal, National Defense Service Medal, World War II Victory Medal, and the Air Force Longevity Service Award with four bronze Oak Leaf Clusters; released from active military service February, 1946, and entered the Army Reserve Corps and private practice; returned to active military service March 11, 1949, and his duties included surgeon of the 311th Air Division at Topeka, Kan., surgeon 93d Bomb Wing, Castle AFB, Calif., surgeon 6th Air Division, MacDill AFB, Fla., chief of professional services, and wing and base flight surgeon; his last assignment in the Zone of Interior (U. S.) was hospital commander and division surgeon at the 380th TAC Hospital, Plattsburgh, N. Y., at which time he was reassigned to Germany and to the 7112th Central Medical Group, Wiesbaden Air Base, Wiesbaden, Germany, where he assumed command on July 15, 1959; promoted to the grade of colonel April 15, 1953; specialist certified by the American Board of Preventive Medicine; member of the American Academy of General Practice and the Aero Medical Association; died at Wiesbaden, Germany, Nov. 20, aged 46.

Ressa, Daniel Arcangelo, Pittsburgh; Fordham University School of Medicine, New York City, 1916; served on the staffs of St. John's and St. Joseph's hospitals; died in the Shadyside Hospital Dec. 16, aged 72.

Roach, Fulton R., Queen City, Texas; (licensed in Texas by years of practice); died Dec. 6, aged 83.

Robbins, Bernard S., New York City; University of Cincinnati College of Medicine, 1929; specialist certified by the American Board of Psychiatry and Neurology; fellow of the American Psychiatric Association; clinical professor of psychiatry at the New York University College of Medicine; on the staff of Flower and Fifth Avenue Hospitals; died Dec. 16, aged 54.

Robins, Bernard Leo, Glendive, Mont.; University and Bellevue Hospital Medical College, New York City, 1915; died Dec. 28, aged 66.

Rogers, James Dudley Ⓜ Wyandotte, Mich.; University of Western Ontario Faculty of Medicine, London, Ont., Canada, 1931; associated with the Wyandotte General Hospital, where he died Nov. 30, aged 53.

Roller, William Crawford, Mint Spring, Va.; University of Virginia School of Medicine, Charlottesville, 1899; died in Staunton Nov. 23, aged 83.

Rosenberg, Theodore Ⓜ New York City; Rush Medical College, Chicago, 1932; veteran of World War II; interned at the Michael Reese Hospital in Chicago; director of medical care of the department of welfare; died Dec. 28, aged 54.

Roy, Bert William Ⓜ Sussex, N. J.; Albany (N. Y.) Medical College 1908; past-president of the Sussex County Medical Society; died Nov. 17, aged 81.

Rundlett, Emilie Viett Ⓜ Jersey City, N. J.; Medical College of South Carolina, Charleston, 1901; served on the faculty of Seton Hall College of Medicine and Dentistry; fellow of the American College of Physicians; associated with the isolation facilities of the Medical Center of Jersey City, where she died Nov. 17, aged 83.

Russell, Ralph Swisher Ⓜ San Diego, Calif.; University of Nebraska College of Medicine, Omaha, 1925; fellow of the American College of Surgeons; associated with the Paradise Valley Sanatorium and Hospital, National City, Scripps Memorial Hospital, La Jolla, and Children's Hospital and Quintard Hospital in San Diego; consulting obstetrician and gynecologist, La Mesa Community Hospital in Coronado; veteran of World War I; died in the Scripps Memorial Hospital, La Jolla, Dec. 10, aged 59.

Schumacher, Nicholai A., St. Johns Station, Mo.; St. Louis College of Physicians and Surgeons, 1906; died Nov. 6, aged 74.

Scull, Ralph Horace Ⓜ Chicago; Rush Medical College, Chicago, 1929; specialist certified by the American Board of Dermatology; member of the American Academy of Dermatology and Syphilology; served on the faculty of his alma mater; died Dec. 16, aged 61.

Shafer, Irving Everett Ⓜ Salisbury, N. C.; North Carolina Medical College, Charlotte, 1914; past-president of the Rowan-Davie Counties Medical Society; member of the American Academy of General Practice; served as a member of the county board of health; veteran of World War I; associated with the Rowan Memorial Hospital; died Dec. 6, aged 71.

Shaw, Christopher Campbell Ⓜ Captain, U. S. Navy, Philadelphia; born in Chichester, N. Y., June 12, 1901; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1931; specialist certified by the American Board of Internal Medicine and the American Board of Preventive Medicine; certified by the National Board of Medical Examiners; member of the American College of Cardiology and the Aero Medical Association; fellow of the American College of Physicians, of which he was educational director; captain in the medical corps of the U. S. Naval Reserve from 1941 to 1945; since 1948 captain in the medical corps of the U. S. Navy; during World War II a flight surgeon aboard the aircraft carrier escort Solomons; senior medical officer in charge of industrial medicine at the Philadelphia Naval Base; on the faculty of Hahnemann Medical College; formerly director of the research division for the Bureau of Medicine and Surgery in the U. S. Navy; at one time medical director of the medical research laboratory for Sharp & Dohme Inc.; in 1954 the Association of Military Surgeons awarded him the Sir Henry Wellcome medal and prize and in 1950 the Louis Livingston Seaman prize; died in the U. S. Naval Hospital Dec. 5, aged 58.

Shevitz, David Mattus Ⓜ Hackettstown, N. J.; Medical College of Virginia, Richmond, 1929; on the staffs of the Newton (N. J.) Memorial Hospital and the Morristown (N. J.) Memorial Hospital, where he died Dec. 3, aged 53.

Showak, George Ⓜ Saxonburg, Pa.; Temple University School of Medicine, Philadelphia, 1956; interned at the Naval Hospital in Philadelphia, where he served a residency; served in the regular Navy; died Dec. 17, aged 31.

Silsby, Harry Zettlemeyer Ⓜ Sanford, Fla.; Louisiana State University School of Medicine, New Orleans, 1936; veteran of World War II and received the Bronze Star in the Pacific Theater; died Dec. 22, aged 58.

Simonton, Richard Deweese Ⓜ Boise, Idaho; University of Oregon Medical School, Portland, 1930; in 1946 member of the House of Delegates of the American Medical Association; since 1957 councilor of the Idaho State Medical Association; fellow of the American College of Surgeons, of which he was a charter member, and in 1955 president of its Boise Valley chapter; died in St. Luke's Hospital Dec. 6, aged 54.

Simpson, Henry Hardy Ⓜ Elon College, N. C.; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1925; member of the American Academy of General Practice; died in the Baptist Hospital, Winston-Salem, Dec. 19, aged 62.

Sirmons, Derrel Chatfield Ⓜ Dahlonega, Ga.; Medical College of Georgia, Augusta, 1943; interned at the Macon Hospital in Macon, where he served a residency; died Dec. 5, aged 44.

Skirball, Louis Irving Ⓜ Boston; University of Vermont College of Medicine, Burlington, 1913; fellow of the American Academy of Pediatrics; for many years a medical consultant of the rehabilitation department of the Veterans Administration; died Nov. 25, aged 69.

Smith, Augustus Kenly Ⓜ Logan, Ohio; Medical College of Ohio, Cincinnati, 1889; died in the Hocking Valley Hospital Dec. 2, aged 92.

Smith, Robert Lee Ⓜ Pomona, Calif.; University of Nashville (Tenn.) Medical Department, 1902; member of the staff of the Pomona Valley Community Hospital; two terms president of the Pomona Branch of the Los Angeles County Medical Association; died Dec. 9, aged 85.

Smith, Robert Wilhoyte Ⓜ Owensboro, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1938; interned at the Columbia Hospital in Milwaukee, where he served a residency; served a residency at the Milwaukee Children's Hospital; past-president of the Daviess County Medical Society; member of the Southeastern Surgical Congress; veteran of World War II; died Dec. 16, aged 45.

Summers, J. Dent Ⓜ Hickory, N. C.; University of Pennsylvania School of Medicine, Philadelphia, 1939; interned at the George F. Geisinger Memorial Hospital in Danville, where he served a residency; served a fellowship in surgery at the Cleveland Clinic Foundation Hospital in Cleveland; fellow of the American College of Surgeons; veteran of World War II; on the staff, Richard Baker Hospital; died Nov. 23, aged 46.

Swango, William Ray Ⓜ Ironton, Ohio; Tulane University School of Medicine, New Orleans, 1937; veteran of World War II; died in the Lawrence County General Hospital Dec. 5, aged 52.

Thomas, George Norfleet Ⓜ Vineland, N. J.; Jefferson Medical College of Philadelphia, 1923; fellow of the International College of Surgeons; past-president of the Cumberland County Medical Society; veteran of World War I; associated with the Newcomb Hospital; died Dec. 2, aged 63.

Thomison, Harry Elijah Ⓜ Upper Montclair, N. J.; Jefferson Medical College of Philadelphia, 1918; served on the staff of the St. Barnabas Medical Center in Newark; died Dec. 15, aged 64.

Wallace, Lew Edwin, Seymour, Ind.; Medical College of Indiana, Indianapolis, 1902; died in the Jackson County Hospital Nov. 25, aged 82.

Westphaelinger, Henry Frederick Ⓜ St. Louis; St. Louis University School of Medicine, 1919; for many years associated with the Veterans Administration Hospital; died in the Deaconess Hospital Dec. 8, aged 64.

Wetmore, William Olendorf Ⓜ Major, U. S. Army, retired, St. Petersburg, Fla.; George Washington University School of Medicine, Washington, D. C., 1895; retired from the U. S. Army in December, 1933; veteran of World War I; served on the faculty of his alma mater; died Nov. 28, aged 85.

Willett, Robert Herman Ⓜ Jonesboro, Ark.; University of Louisville (Ky.) Medical Department, 1910; on the staff of St. Bernard's Hospital, where he died Dec. 2, aged 78.

Williams, John H., Louisville, Ky.; Meharry Medical College, Nashville, Tenn., 1902; veteran of the Spanish-American War and World War I; died Nov. 29, aged 80.

Wofford, Helen Dyson Ⓜ Johnson City, Tenn.; University of Pennsylvania School of Medicine, Philadelphia, 1928; on the staff of the Jones Eye, Ear, Nose and Throat Hospital; died in the Holston Valley Community Hospital, Kingsport, Dec. 2, aged 52.

Womeldorf, John M., Glendale, Calif.; Rush Medical College, Chicago, 1897; died Nov. 30, aged 90.

DENMARK

Radioactive Gold for Cancer.—Hanson and Haug (*Ugesk. laeger*, Oct. 22, 1959) used radiogold in the treatment of 56 patients who had carcinomatous effusions into the pleural and peritoneal cavities. The injection into these cavities was made at the time of the aspiration of the effusion, some of which was left in place to facilitate the spread of the injected solution. The site of the original tumor was in most cases the breast or ovary. Because of the advanced stage of the disease when this treatment was started, 48 of the 56 were dead at the conclusion of this study, yet it was concluded that in about 28 of these patients a good palliative effect was achieved and that in another 11 or 12 there was moderate relief. Better results might have been obtained by repeating this treatment several times. It might also be used as a prophylactic measure directly after surgical treatment. Primary tumors of the pleura with effusion might also respond well to this treatment, which in this series provoked no serious side-effects.

Potency After Prostatectomy.—Dr. V. Hvidt (*Nord. Med.*, Nov. 19, 1959) investigated the influence of prostatectomy on potency. The literature on the subject betrays great variations in the findings of different observers. In his series of 211 there were 126 with postoperative retention of potency, but 11% of those under the age of 60 years had become impotent. While 182 had had retropubic prostatectomy, 29 had had the transvesical operation. A comparison of their postoperative sexual functions suggested that the retropubic operation was the more likely to cause impotence. For comparatively young candidates for prostatectomy it might therefore be well to let the choice of operation depend to some extent on the likelihood of its interference with sexual functions.

Simulation of Malignant Disease by Miliary Tuberculosis.—Dr. B. Zachau-Christiansen (*Ugesk. laeger*, Nov. 5, 1959) stated that it was difficult to diagnose miliary tuberculosis in spite of the many tests for it available in a modern hospital. His three women patients were aged, respectively, 40, 73, and 65 years. Pulmonary tuberculosis was suspected in the first, but x-ray and clinical findings pointed to carcinosis, and it was not until after her death that tubercle bacilli were found in the stomach contents. The diagnosis of tuberculosis was confirmed post mortem. In the second patient no tubercle bacilli could be found in the sputum, and the x-rays were suggestive of pulmonary metastases. The macroscopic findings post mortem were suggestive of but not unequivocally indicative of tuberculosis, and it remained for the microscopic examination to give the correct diagnosis. Even then no tubercle bacilli were found. The third patient had no previous record of tuberculosis, but she had been operated on for cancer of the thyroid four years earlier. A pleural effusion yielded neither cancer cells nor tubercle bacilli. She died after an attack of pneumonia. The macroscopic postmortem findings indicated carcinosis of the lungs, pleura, peritoneum, liver, and regional lymphatic nodes, but the microscopic findings reversed the diagnosis in favor of tuberculosis. In view of these cases it may be wise to give antituberculous treatment even when there is only a suspicion of this disease.

GERMANY

Lymphocyte Systems.—E. Grundmann of Freiburg (*Klin. Wchnschr.* 37:66, 1959) said that two types of lymphocyte which are different in genesis and structure may be distinguished in man, as in the rat. A macronucleolar form develops exclusively in the follicles, and a multinucleolar form develops, usually in the sinuses of spleen and lymph nodes. Both types of cells are easily shown by phase contrast in crush preparations, but they are also easily identified in smears from peripheral blood after modified methylene blue staining. In the blood smears from 15 healthy adults it was found that about 72% of the lymphocytes were of the follicular type and 28% of the sinus type. In children before puberty this proportion was 79:21.

Prevention of Kernicterus.—Linneweh and Bickel of Marburg (*Klin. Wchnschr.* 37:963, 1959) stated that the bilirubin encephalopathy of premature infants, which causes permanent cerebral damage or death from kernicterus, may be prevented by timely exchange transfusion. Physicians do not agree about when this therapy should be instituted. A critical bilirubin level of about 20 mg. per 100 ml. is not a suitable indication because kernicterus sometimes occurs even at bilirubin blood concentrations below 15 mg. per 100 ml. and sometimes fails to occur at concentrations above 30 mg. per 100 ml. The bilirubin blood level is only one of several factors that influence the development of kernicterus. The need for exchange transfusion was considered imperative

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

mainly when prodromal symptoms appeared. Reexamination showed that 15 children 1½ to 3¼ years of age who were subjected to exchange transfusion after purely clinical indications developed normally and 16 premature infants with hyperbilinuremia of 21 to 32 mg. per 100 ml. remained without clinical symptoms although no exchange transfusion was performed. They too had developed normally up to the age of 1½ to 3¼ years.

The authors concluded that one may await the appearance of prodromal symptoms of bilirubin encephalopathy in premature infants with hyperbilirubinemia before resorting to exchange transfusion because these symptoms are entirely reversible and do not endanger the later development of the children. The prodromal symptoms include feeding difficulties, severe loss of weight, variations in temperature, restlessness, excessive yawning, and dulness. In absence of such clinical indications, exchange transfusion is unnecessary and should be avoided because of the risk involved.

Wound Treatment.—H. Krieger of Düsseldorf (*Medizinische,* pp. 1172-1174, 1959) stated that a new wound cover, a cross-woven dense foil, permeable to humidity and air, which consists of 77% cellulose, 7.8% water, 15% glycerin and glycol, and 0.2% copper, has proved valuable. It is applied dry to aseptic wounds. For septic wounds it may be covered with moist muslin or applied dry; for superficial wounds it is applied over a thin layer of ointment or zinc muslin; and for dermatological wounds, eczema, etc., it is moistened.

Prednisolone for Multiple Sclerosis.—Schrader and Schild of Marburg (*Klin Wchnschr.* 37:946, 1959) said that prednisolone should be tried in all patients with acute or subacute multiple sclerosis. The improvement of hitherto refractory symptoms, in some patients noticeable after the first day of this treatment, proves that the treatment is effective. In patients with chronic or slowly progressing multiple sclerosis, however, even prednisolone will usually not induce any improvement. The use of prednisolone is definitely indicated for patients in whom the disease appears for the first time and for patients with fresh progressions, especially when there is fresh involvement of the optic nerve. Therapy should be intensive. Large doses should be given intermittently. More than one course of the drug should be administered, but in chronically progressive cases this is advisable only if the first course caused a noticeable improvement.

Effects of Low Cardiopulmonary Minute Volumes.—G. Schönbach and co-workers of Giessen (*Thoraxchirurgie,* p. 516, 1959) studied the behavior of various organs during and after artificial perfusion with different minute volumes of blood in 42 experiments on animals. Nine dogs were given perfusions for 25 to 60 minutes with 20 to 35 cc. of blood per minute per kilogram of body weight. When the low-flow principle was used, the arterial blood pressure fell to about 25 mm. Hg. After 45 minutes of perfusion the blood pressure could be raised for only a brief period by increasing the minute volume. The body temperature fell regularly, in some animals by 4 C (7.2 F), although the blood was warmed during extracorporeal circulation. Acidosis occurred shortly after the artificial perfusion was started, and after 45 minutes this acidosis could not be corrected by increasing the minute volume. Albumen was repeatedly found in urine samples taken after perfusion, especially when perfusion lasted for more than 30 minutes.

In four animals pulmonary edema was found on histological examination. A granular destruction of the myocardial fibers was noted in the heart, especially on the left side, and also in the cellular protoplasm of the liver. Protein bodies and erythrocytes were found in Bowman's capsules and the renal tubules as well as in the interstitial tissues. The adrenal bodies showed severe lipoid degeneration in contrast to the findings in animals given perfusion with a normal minute volume. The epithelial cells of the thyroid gland became very active, which is an alarm reaction. Microscopic examination revealed contraction of arterioles and reduced speed of flow when the minute volume was reduced to about 65 cc. per kilogram, and when it was reduced to 40 cc. per kilogram the flow became sluggish and some of the capillary areas appeared cut off. On further reduction of the minute volume there was only minimal perfusion in the small arteries and arterioles and the capillary blood stream was disrupted almost completely. These studies showed that, with use of the small minute perfusion volumes of the low-flow principle, hypoxemia of the tissues leads to changes in organic structure which may be reversible or irreversible, depending on their severity.

Osteoarthritis of the Knee.—H. Leonhard (*München med. Wchnschr.* **101**:974-975, 1959) stated that the chief problem connected with osteoarthritis of the knee is the recurrence of symptoms when treatment is discontinued. A series of about 50 patients remained free of symptoms or were at least essentially improved for several years after being treated the following way: the knee joint was punctured at the upper out margin, effusions were evacuated, 1 cc. (25 mg.) of desoxycorticosterone acetate suspension was instilled, and the joint was actively and passively exercised and then covered with an ichthyol dressing. This dressing was left in place for one to three weeks. It may be necessary to repeat this treatment once or twice, and it may also be repeated in a relapse. When the condition is one of true osteoarthritis, no contraindications are apparent.

Radiation Sickness.—Schubert and Maass of Hamburg University (*Deutsche med. Wchnschr.* 84:1130-1133, 1959) stated that the era of A-bomb tests has caused men to search for chemical protection against exposure to ionizing radiations. No known substance provides protection if it is given after irradiation. Some substances, however, reduce the body's sensitivity to irradiation if they are applied prior to exposure. Such protective substances include sodium cyanide, which is too toxic for practical use, and cysteine. The effect of cysteine is due to its sulfhydryl (SH) group which reactivates enzymes, the SH groups of which were oxidized by the irradiation insult. Cystin, the disulfide form of cysteine, is ineffective as it has no free SH group. Other effective substances are cysteamine, cystamine, and serotonin. The various protective substances do not counteract irradiation reactions to the same degree. It may be that early reactions, such as a steep drop in the leukocyte count, loss of weight, and inhibition of desoxyribonucleic acid are not modified but that recovery is accelerated when the protectors have been given before. Late reactions, however, such as changes of cell structure and of the composition of the blood proteins are reduced by administration of cysteine. The substance also protects reproductive ability and embryonal development but does not effect the rate of mutation induced by radiation.

Chlorpromazine in the Treatment of Cancer.—At the first International Symposium on Chemotherapy, in Geneva, in September, Prof. W. Lührs of Berlin reported surprising results with chlorpromazine in the treatment of malignant tumors. The tumor cells, which proliferate at a high rate, are in a state of relative energy deficiency, since the rapid growth demands multiple high synthetic performances which involve a high energy consumption and these cells have reduced efficiency because of their characteristic metabolism, which is different from that of other cells. Energy released on the oxidation of substrate hydrogen is used mainly for the synthesis of high-energy phosphate compounds, such as adenosine triphosphate. Cell respiration and construction of high-energy phosphates are therefore connected in the fundamental process of oxidative phosphorylation. Only the energy released when high-energy phosphates are split up is available for the anabolism of the cell.

It was thought possible to deprive the malignant tumor which works with increased energy requirements but decreased energy supplies by disconnecting the construction of high-energy phosphate from the process of cell respiration in oxidative phosphorylation of biologically utilizable energy enough to impair the vitality of the tumor. According to this hypothesis, the tumor cell would then more easily succumb to the body's defenses and to cytostatic substances and ionizing rays. While previous antimitotic treatments were mainly based on the difference in proliferation rates between normal and malignant cells, the decoupler principle makes use of the different energy requirements of normal and malignant cells, and when this principle is applied the uneconomical metabolism of tumor cells probably is a further factor which promotes therapy.

In vitro tests showed that high concentrations of chlorpromazine acted as a potent decoupler of oxidative phosphorylation. The effect on tumor mitochondriae was more marked than that on mitochondriae of normal cells. The drug does not stimulate the respiration of isolated mitochondriase. Low concentrations of chlorpromazine, on the other hand, may promote oxidative phosphorylation. Only high concentrations have the decoupler effect. Chlorpromazine in suitable concentration retarded the growth of tumors in the animal experiments. The first clinical trials of chlorpromazine showed its effectiveness as a sensitizer of the tumor cell to cytostatic substances and high-energy rays also in the treatment of malignant tumors. Chlorpromazine, 400 mg. given daily by mouth for several months, with cytostatic or x-ray treatment or hormones, effected impressive remissions. The large doses of chlorpromazine were surprisingly well tolerated.

Nucleic Acid Content in Tumor Tissue.—Bürger and Wüst of Leipzig University (*München med. Wchnschr.* [no. 44] 101:1941, 1959) studied the nucleic acid content of cancer tissue and matrix and compared it with that of normal tissue. Normal tissues were found to have various nucleic acid levels, specific for each type of tissue. On the other hand, malignant tumors and their metastases had an almost uniform nucleic acid content in spite of the multiplicity of biological and morphologic differences. The average content of desoxyribonucleic acid and ribonucleic acid was almost the same in bronchial carcinoma, gastric carcinoma, colonic carcinoma, carcinoma of the uterus, and their metastases. Tumors originating from interstitial tissue did not differ from epithelial neoplasms in their biochemistry.

In patients with chronic leukemia the liver had a significantly higher desoxyribonucleic acid content than the homologous normal organ. There were marked differences in ribonucleic acid content and desoxyribonucleic acid content between liver, lung, and lymph node metastases and their matrixes. An interrelationship between histological fine structure and nucleic acid content was also found in the case of bronchial carcinoma. The small-celled bronchial carcinomas, which are considered particularly malignant, had a much higher nucleic acid content than the differentiated tumors of the bronchi. Benign tumors had much lower nucleic acid levels than malignant growths. Increased protein hynthesis is the cause of the high ribonucleic acid content in cancerous growth. The cause of high desoxyribonucleic acid content may be seen in the great number of cells, the high rate of division, and the increase of desoxyribonucleic acid in the cell nucleus.

INDIA

Anemia and Cirrhosis of Liver.—Sengupta and Aikat (*J. Indian M. A.*, vol. 33, Nov. 16, 1959) stated that hepatic cirrhosis is fairly common in India. They studied a series of 53 patients who were not receiving any hematinic treatment. Of these, 38 were found to have orthochromia and 15 hypochromia which was probably due to an iron deficiency. Those with macrocytosis had a less severe degree of anemia than those with other morphologic types. The range of the reticulocyte count varied from 1 to 16%. This count was not related to the type or degree of anemia. Some patients with severe anemia showed anisocytosis and poikilocytosis. Target cells were found in 30 patients. All those with hypochromia had a fair number of target cells in the peripheral blood. Their presence was related to hyperbilirubinemia. Leukopenia was frequently associated with enlargement of the spleen. The only patient with leukocytosis had no such enlargement. Many patients had neutropenia and almost all had lymphopenia. Thrombocytopenia was observed in 32.

Fractional gastric analysis showed that hypochlorhydria was common, but achlorhydria was found in only two. The values for total direct and indirect bilirubin showed no correlation with the degree of anemia or with the different morphologic types of anemia. Increased reticulocyte count was found in 75% of those with normal range of total indirect bilirubin. A high direct-indirect quotient was found to be frequently associated with macrocytic anemia, but it had no relation to the degree of anemia. The fecal urobilinogen content also showed no relation to the degree or type of anemia. Examination of the marrow showed normoblastic hyperplasia with macronormoblasts in 50% of those with macrocytic anemia independent of bleeding. Eleven patients had an increased percentage of basophilic normoblasts, and 16 showed increased late normoblasts. Three patients with macrocytic anemia showed giant metamyelocytes. Increased plasma cells related to hyperglobulinemia were found in many patients. The marrow changes were characterized predominantly by normoblastic hyperplasia. The association of a high direct-indirect quotient with macrocytosis suggested that macrocytosis occurred when the balance in the two types of bilirubin altered.

Of the 53 patients 13 had macrocytic, 2 microcytic, and 38 normocytic anemia. About 12 of those with normocytic anemia showed a tendency to macrocytosis. Only one patient with macrocytosis had a high reticulocyte count, which would account for the macrocytosis only in this single case. Leukopenia and thrombocytopenia were almost uniformly present. All these factors suggest that nutritional factors play an important role in the causation of anemia in patients with cirrhosis. A history of hemorrhage, recent or old, was obtained from only four patients. Anemia with normoblastic marrow, leukopenia, and an enlarged spleen were present in 23 of the patients and could be explained on the basis of hypersplenism. An epinephrine test of 12 patients, however, showed negative results for all. Some improvement occurred in some anemic patients with enlarged spleen after splenectomy. Hypervolemia, which could also lead to anemia, was found in six patients who showed hyperplastic changes in the marrow. The factors that could have been responsible for causing anemia in these patients with cirrhosis were dyshemopoiesis, hemorrhage, hypersplenism, hypervolemia, and hemolysis, each of which might have operated alone or in combination.

Visual Method of Reading the Systolic Blood Pressure.—P. L. Deshmukh (*Current M. Pract.*, vol. 3, Oct., 1959) stated that the visual method is more accurate than the auscultatory method for reading the systolic blood pressure. He often noticed that fluctuations appeared in the mercurial column long before sounds could be heard by auscultation over the brachial artery after gradual deflation of the armcuff. The earliest point where such fluctuations appeared was taken as the systolic reading. A difference of 5 to 30 mm. Hg was often observed between the reading so recorded and that obtained by the usual auscultatory method. This difference was most marked in the group over 40 years of age where evidence of arteriosclerosis was present. As a result of these sclerotic changes, the artery does not readily respond to the systolic input by distension as a healthy vessel would. The difference between the visual and auscultatory readings would give an idea of the extent of the sclerosis.

Post-lumbar-puncture Headache.—G. B. Hanji (*Current M. Pract.*, vol. 3, Oct., 1959) said that one of the major sequelae of spinal anesthesia is post-lumbar-puncture headache, which is often refractory to the usual analgesics. The beneficial effect of dihydroergotamine in these headaches as described by some has no definite pharmacological basis. The author tried this drug in a series of 50 patients with post-lumbar-puncture headache. The anesthetic used in all these patients was dibucaine with 5% dextrose in doses of 1 or 2 cc. The amount of spinal fluid lost during lumbar puncture did not exceed 1 or 2 cc. Identical 22-gauge needles were used in every case. Patients in whom the first puncture was not successful were excluded from the series, as the headache is sometimes attributed to the trauma of the periarachnoid area after repeated tappings.

The prepuncture tension, which was judged by the rate of flow of the cerebrospinal fluid, was almost identical in all. These patients were given 1 cc. (0.2 mg.) of dihydroergotamine intramuscularly. Usually one injection was enough. Only nine received a second injection two hours after the first when symptoms recurred. The headache was moderate or severe. No other drugs were used. Dihydroergotamine was given only a few hours after the headache started, usually in the earlier part of the night in patients operated on in the morning. Some patients also complained of backache. Of the 50 patients 33 showed rapid improvement. The headache disappeared completely or was greatly relieved in about an hour. Of the rest, 11 had slight relief and 6 showed no response. Of the five who complained of backache, none was relieved of this symptom after the injection, although the headache was relieved in two. In nine patients a relapse occurred which invariably responded to a second injection of dihydroergotamine. No untoward side-effects were noted.

Antihypertensive Drugs.—Datey and Joshi (*J. Postgraduate Med.*, vol. 5, Oct., 1959) evaluated the effects of various antihypertensive drugs, alone and in combination, in 53 patients with hypertension. Blood pressure was recorded from both arms. The maximum blood pressure in the series was 230/160 mm. Hg, and the minimum systolic pressure (140 mm. Hg.) was found in a patient with a diastolic pressure of 100 mm. Hg. The lowest diastolic pressure (90 mm. Hg) was recorded in a patient with a systolic pressure of 170 mm. Hg. The antihypertensive drugs used were tablets containing 0.25 mg. of reserpine; Adelphane tablets, a combination of 10 mg. of 1-4 dihydrazino-phthalazine and 0.1 mg. of reserpine; hypotensen tablets each containing 0.3 Gm. of Rauwolfia, 30 mg. of theobromine, and 15 mg. of phenobarbital; 100-mg. tablets of Rauwolfia; 50-mg. tablets of hydralazine; 25-mg. tablets of chlorisondamine; 40-mg. tablets of pentolinium tartrate; injections containing 138 mg. of hexamethonium tartrate; and 10-mg. tablets of mecamylamine hydrochloride.

The same patient was given different drugs at different times. If a drug failed to act, the dosage was increased until side-reactions occurred, at which time another drug was substituted or a combination of drugs was used. The basal blood pressure was determined in most patients before starting the trial by giving 30 mg. of phenobarbital three times a day for 8 to 21 days. Patients with malignant hypertension; those with grade 3 hypertensive retinopathy and severe headache, giddiness, or signs of congestive cardiac failure; and those with cerebrovascular episodes were immediately put on antihypertensive treatment. Thirty-seven patients complained of headache and 35 were giddy when walking or after exertion. Other symptoms included cough with expectoration, palpitation, epistaxis, hemoptysis, precordial pain, dyspnea on exertion, nocturnal dyspnea, and edema of the ankles. Fundoscopy revealed grade 1 retinopathy in 13 patients, grade 2 in 8, grade 3 in 7, grade 4 in 4, arteriosclerotic changes in 7, lenticular opacities in 3, diabetes in 1, and anemia in 1. Only two had normal fundi. Twenty-one had a urea nitrogen level above normal, and the nonprotein nitrogen level was high in 17.

After treatment the headache was improved in 20 of 37 patients as the blood pressure decreased. Only three patients became less giddy. The nonprotein nitrogen level showed a significant decrease after treatment in nine.Ophthalmodynamometry done in 27 patients showed cephalic hypertension in 22 which became lower after treatment in 6. Reserpine lowered the pressure in 16 of 20 patients. Of the four who failed to respond, two had malignant hypertension; three of the four responded to the ganglion-blocking agents. Reserpine helped in maintaining the decreasing pressure after it was brought down by mecamylamine. Hypotensen lowered the pressure in four of five patients and six received this drug after they received reserpine. Five of these responded. Hypotensen caused a greater reduction in the pressure than did reserpine. This could have been due to the different content of reserpine in these preparations, and there might have been some synergism between reserpine and the other constituents of Hypotensen. The contained phenobarbital made some patients extremely drowsy. One patient who did not respond to Hypotensen and had a grade 3 retinopathy also failed to respond to ganglion-blocking agents. Rauwolfia given to seven patients caused some lowering of pressure in all, but normal levels were attained in only five. Three patients developed tolerance to this drug. Postural hypotension to some extent occurred in all patients after the use of Rauwolfia or its derivatives.

This group of drugs did not significantly alter the pressure in patients who had failed to respond to the ganglion-blocking agents. In one patient in whom the pressure was decreased by a ganglion-blocking agent it could be maintained at the lowered level by reserpine. Side-reactions with reserpine and the crude preparation of Rauwolfia were about the same. Adelphane tried in four patients produced a moderately good response, but three developed a tolerance, while side-reactions such as shivering, nausea, and headache occurred if the dosage was increased. Of the three patients who were given both reserpine and Adelphane, the latter produced better results in two. Hydralazine was tried in a few patients. It also produced tolerance in three while the pressure was lowered moderately in one and not at all in two. Hexamethonium lowered the pressure in five. The patients did not respond to other drugs given later. In two pentolinium was substituted for hexamethonium along with reserpine when a temporary fall in pressure was produced. Increasing the dosage of pentolinium produced side-reactions.

As an emergency measure two patients were given reserpine and hexamethonium intramuscularly but only one responded. Mecamylamine was effective in all 10 patients to whom it was given. Postural hypotension occurred in all but one. Although the combined action of more than one antihypertensive drug in any one patient was more effective, in actual practice it was easier to regulate the doses of each of the antihypertensive drugs when they were used separately and not incorporated in one tablet. On the whole the Rauwolfia drugs proved useful in patients with mild and moderate hypertension. Their side-reactions did not necessitate withdrawal of the drug, as the margin of safety is wide. Although they did not help patients who were not improved by ganglion-blocking agents, they could be safely and effectively used to prolong the hypotensive response induced by these drugs when their continuous administration would likely have led to side-effects.

Although tolerance to Rauwolfia does occur, it could be overcome by increasing the dose. When used in combination with other antihypertensive agents, reserpine helps in lowering the dose of the other agent thus reducing the possibility of side-reactions. Chlorisondamine and mecamylamine proved effective in patients who had become refractory to other agents. Results with both were similar, although chlorisondamine was less potent. Partial tolerance developed more quickly and more often with this drug than with mecamylamine. Tolerance was common with Adelphane and side-reactions were same as with Rauwolfia. Hydralazine proved of little use in refractory patients, while side-reactions and partial tolerance were common.

Sulfadiazine Lipid Emulsion.—K. J. Vyas (*J. Indian M. A.*, vol. 33, [Nov. 16] 1959) reported good results with the use of sulfadiazine lipid emulsion, a long-acting form of the drug, in 29 children with acute infections, of whom 10 had acute upper respiratory infections, 7 had an acute upper respiratory infection with diarrhea, 6 had acute gastroenteritis, 3 had acute rysentery, 1 had bronchopneumonia, 1 had cystitis, and 1 had whooping cough. Sulfadiazine lipid emulsion was the only antimicrobial agent used, and it was given in a concentration of 10%. Children up to 2 years of age received 0.5 Gm. each morning in a single dose, and those above that age were given a single daily dose of 1 Gm. and an alkaline mixture. The duration of treatment varied from one to nine days. No patient with dehydration was included in this study.

Of the 29 patients 19 were cured, 7 obtained marked relief, and 2 obtained moderate relief. One patient had to stop taking the drug. Most of the patients responded well to treatment within two to four days. The drug was well tolerated and readily accepted. Side-reactions occurred in four patients. One child developed anuria, two developed oliguria, and one vomited the drug on the first day. The treatment was discontinued in the last patient. The anuria and oliguria disappeared when plenty of fluids and alkalies were given. The author recommended giving plenty of fluids orally and maintaining a chart of urinary output to guard against this complication.

Spleen in Thalassemia.—A. M. Mukherjee and coworkers (*J. Indian M. A.*, vol. 33, Dec. 1, 1959) examined 30 specimens of spleen from patients with thalassemia. Of these patients 21 were 10 years of age or less and 9 were between 11 and 25. The spleen was enlarged in all patients to about five times the normal size, and it was firm. The capsule was thickened in all, but evidence of perisplenitis was found in only four. The cut surface was red with prominent trabeculae. The splenic sinuses showed variable degrees of congestion on histological examination. The red pulp showed hyperplasia of cells of the reticuloendothelial system. Ten showed a moderate to large number of foam cells in large clumps; in 17 they were present in a smaller number; and 3 had no such cells. Extramedullary hemopoietic activity was also evident in the red pulp. This was marked in 6, moderate in 12, and slight in the rest.

The degree of hemopoietic activity was not related to either the degree of anemia, splenomegaly, or the proportion of fetal hemoglobin. The malpighian corpuscles were hyperactive in 4, normal in 9, and attenuated in 17. Splenomegaly in patients with thalassemia was thus essentially due to congestion of a greatly increased and dilated vascular bed, hyperplasia of reticuloendothelial cells, and extramedullary hemopoiesis. The presence of hemosiderin could be attributed to blood transfusions in most of the patients. The principal pathological changes consisted of congestion of the sinuses, reticuloendothelial hyperplasia, foci of hemopoiesis, atrophy of malpighian corpuscles, presence of hemosiderotic nodules, and increase of connective tissue.

Dihydroergotamine for Mumps.—Desphande and Vahalia used dihydroergotamine in the treatment of 25 patients with mumps and compared the results with those in another 25 patients who served as controls (*J. Indian M. A.*, vol. 33, Dec. 1, 1959). The duration of illness before admission varied from one to seven days. A single intramuscular injection of 1 cc. was given on the first day to adults and smaller doses were given to children. This was repeated after 48 to 72 hours in 10 patients in whom the swelling did not respond to the first injection. Most patients received treatment on the second day of illness. The drug did not seem to have a marked effect on the subsidence of fever, but the average period for the temperature to return to normal was 3.1 days in the control group and 2.5 days in the treated group. The average period for complete disappearance of the swelling in the two groups was 5.4 days and 4.0 days respectively.

Almost every patient showed a reduction in the size of the swelling within 24 hours of the administration of dihydroergotamine. In 33% of the patients receiving the drug, the swelling disappeared completely within 48 hours of treatment, whereas the swelling did not disappear in most of the patients in the control group until the third or fourth day after they fell ill. The associated orchitis in some patients was not affected by the drug, for in both groups it took about four days for this to subside. The pain in the parotid swelling subsided within 2.0 days in the control group and 2.3 days in the treated group, although other observers have noted prompt relief of pain after administration of this drug.

NORWAY

Comparisons of Angiographic Mediums.—Presthus and Bruland (*Acta psychiat. et neurol. scandinav.* 34:479-488, 1959) gave 35% iodopyracet compound to about half of a series of 133 patients for cerebral angiographies and 25% acetrizoate to the other half. The former compound contained 50% and the latter 68% iodine. The side-effects observed during the injection of contrast medium and within 24 hours after the examination were not remarkable in either group. No definite difference was noted in the image quality.

Ataractic Drugs.—J. B. Lien and co-workers (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:40-50, 1959) reported that, during the first three years in which ataractic drugs were used in the Norwegian Mental Hospital of Gaustad in Oslo, the turnover rose from 270 to 350 patients per year without increase in the ratio of first admissions to readmissions or increase in the number of beds. Of 1,600 patients treated in this period nearly 600 received ataractic drugs (438 were given chlorpromazine, and 120 were given reserpine). The authors believed that these drugs were the chief factor responsible for the improvement, as other factors remained fairly constant. In addition to chlorpromazine and reserpine, mepazine and 2-ethyl-crotonyl-urea were tried but on a smaller scale. In the analysis of the chlorpromazine-treated patients special consideration was given to the differing degree of response of the various diseases and symptoms. The significance of such differences was difficult to judge, but depressed, idle, and incontinent patients definitely responded less than did those in other categories.

Comparisons were made between chlorpromazine treatment and convulsive and insulin therapy, respectively, in the same patients. In many patients chlorpromazine seemed to be more effective than other drugs, but in some patients the opposite was the case. This investigation did not justify the complete replacement of the well-established methods of treatment by a method with chlorpromazine. A similar comparison made in 30 patients receiving reserpine showed the effect of the two drugs to be equal. A comparison of 405 of the chlorpromazine-treated patients and 120 reserpine-treated patients which were judged to be prognostically equal showed, however, that reserpine was less effective. Comparison of repeated chlorpromazine treatment showed inconstant results probably because of difference in intensity of treatment. The authors concluded that treatment with electric shock, insulin, and ataractic drugs all had their advantages and disadvantages, but none of them could be claimed generally to be superior to the others.

Prochlorperazine and Chlorpromazine.—Sundby and Lien (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:82-88, 1959) treated 118 chronically psychotic patients with prochlorperazine and compared the results with those of previous chlorpromazine treatment in 113 of them. About 67% had chronic mental disorders of more than five years' duration, and 75% were schizophrenic. Of the 89 women in the series, 11 had earlier insulin treatment and 74 had several series of electric convulsive therapy with an average of 46 treatments each. With prochlorperazine treatment 23 patients, or 19.5%, showed no improvement; 46 patients, or 38.9%, showed a slight improvement; 43 patients, or 36.4%, had marked improvement; and 6 patients, or 5.1%, recovered.

A better effect was observed with prochlorperazine than with chlorpromazine in 52 patients, or 46.0%. The same effect with both treatments was noted in 47 patients, or 41.7%. A better effect was obtained with chlorpromazine than with prochlorperazine in only 14 patients, or 12.4% of the 113 patients considered. The side-effects were more troublesome than those produced by chlorpromazine. The patients were more active and alert when given the maintenance dosage. There was no photosensitization, which in the present group had been one of the major complaints about previous chlorpromazine medication. Prochlorperazine appeared to be a useful tranquilizer with certain advantages over the older ones. The authors also found a combination of prochlorperazine and chlorpromazine to be of value in patients who were resistant to chlorpromazine and suffered from restlessness when taking prochlorperazine alone.

Iproniazid for Psychoses.—Lien and Fossum (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:91-97, 1959) treated 26 chronically depressed and 48 schizophrenic patients with iproniazid. Of the 74 patients, 24 were treated with chlorpromazine and 4 with reserpine before the investigation started. The maximum dose of 150 mg. of iproniazid a day was given for four months or more to 20 patients without causing unpleasant side-effects. Doses were reduced in most patients to 75 mg. a day, and in 21 the treatment was discontinued because the patient became worse or suffered from side-effects or because the desired result was obtained. In the chronically depressed patients about 70% improvement was noted, but in the schizophrenic patients the results were disappointing as there was improvement in only 10% and agitation in 30%. Such side-effects as lassitude, giddiness, and unsteadiness were noticed in 21 patients. The addition of reserpine increased the effectiveness of iproniazid in nearly half the patients receiving this combination.

SWEDEN

Ulcerative Colitis with Malignant Degeneration.—N. P. G. Edling and co-workers (*Acta radiol.* 52:123-128, 1959) reviewed the roentgenographic aspects of 26 patients who had ulcerative colitis with malignant degeneration. In 14 the entire colon showed signs of severe chronic inflammation when the diagnosis of carcinoma was made. In four, similar signs of ulcerative colitis in the entire colon were found at roentgenographic examinations three to six years before a carcinoma was discovered at operation or autopsy. Among the remaining eight patients five had involvement of the entire colon and one of the distal part of the colon at the first roentgenographic examination. On subsequent examinations the length of the colon was increased and the loops were again present, the appearances at times being normal. The roentgenographic findings indicated that a true improvement or healing of the inflammation had occurred, even as the malignant degeneration appeared. The histories of the two other patients suggested ulcerative colitis for several years, but the roentgenographic findings were normal except for the cancerous strictures. In 23 patients the inflammatory changes involved or had at some time involved the entire colon. The distal part of the colon was affected in one only. No final assessment was possible in the remaining two patients.

In this series 19 patients were between 17 and 31 and 7 patients between 40 and 58 years of age. The average duration of the disease until the discovery of malignant degeneration for all patients was 15.4 years. No constant roentgenographic findings were associated with ulcerative colitis and the subsequent development of carcinoma. Many patients had short, contracted colons, but in others the colitic changes had improved, or the colon had returned to normal length and haustration. The series also showed that severe changes in the wall of the colon due to colitis might heal without fibrosis of the muscular layer and the serosa. This healing, if it occurred, was, however, no guarantee against malignant degeneration, even though the patient's symptoms might have also decreased or even disappeared.

Gas Myelography.—Syringomyelia is a well-defined entity characterized by a dissociated reduction in sensibility with loss of appreciation of painful stimuli and temperature at an early stage, often in combination with atrophy of the hand muscles and segmental pain. Klefenberg and Saltzman (*Acta radiol.* 52:129-138, 1959) endeavored to ascertain by gas myelography whether enlargement of the spinal cord could be demonstrated in 28 patients with clinically typical syringomyelia. The results obtained were compared with those from gas myelograms of 20 normal subjects and 9 patients with intramedullary expansive processes without signs of syringomyelia. In most of the patients with syringomyelia on whom a technically satisfactory gas myelographic examination could be made, the revealed anatomy of the spinal cord differed from that of the normal controls. In patients with syringomyelia enlarged segments were noted in the cervical and upper part of the thoracic spine and atrophic areas were wholly or predominantly localized in the thoracic region. When both of these changes were present in the same patient the enlarged part of the cord was always situated cranially to the atrophic area. Syringomyelia with spinal cord enlargement but without atrophy could not be distinguished from an intramedullary expansive process of some other type.

The study of nine patients with intramedullary spinal cord processes without signs or symptoms of syringomyelia suggested that a combination of enlargement and atrophy might be a characteristic feature of syringomyelia as no change of this nature could be demonstrated in the spinal cords of the other patients. Tomography was a valuable aid when the caliber of large areas of the spinal cord was to be estimated by gas myelography. Theoretically a technique based on the use of high voltages should also offer great advantages. It was especially important in patients with syringomyelia in whom the cord lesions were distributed over large areas of the spine that the conditions for examination should permit a reliable estimation of all parts of the cord. The authors did not perform myelographic examinations with iodized oil in patients with clinically characteristic syringomyelia because they believed that gas myelography offered better opportunities for studying the spinal cord in patients with syringomyelia.

Toxoplasmic Encephalopathy.—According to Torsten Hafström (*Acta psychiat. et neurol. scandinav.* 34:311-321, 1959), toxoplasmosis may be either congenital or acquired. In the newborn infant it may be characterized by enlargement of the liver and spleen with or without jaundice, pneumonia, or myocarditis and in particular by encephalitis with intracerebral calcification, chorioretinitis, and hydrocephalus, the spinal fluid being xanthochromic and having an increased protein content. Retarded mental development and epileptic seizures often appeared as sequelae. In infants and young children epileptic seizures as well as impairment of vision and chorioretinitis may be symptomatic of congenital toxoplasmosis. The acute stage of acquired toxoplasmosis is occasionally associated with a severe course with high temperature and symptoms in various organs due to hematogenous spread.

Soon after the eruption interstitial pneumonia may develop with roentgenographically demonstrable, patchy changes in the lungs and interstitial myocarditis with infiltration and necrosis of individual muscle fibers. The lymphadenitis, which is usually localized in the cervical, axillary, and inguinal lymph nodes, may persist for several months. The most serious manifestation of toxoplasmosis is the meningoencephalomyelitis. In adults meningoencephalitis and a mild myocarditis may occur. Toxoplasma are found in the muscles, heart, brain, and spinal cord. Fibrillar twitching is occasionally observed. In the acute stage the protein content of the spinal fluid may be greatly increased. Usually there is no increase in cell count of the spinal fluid, which consists almost exclusively of mononuclear elements. The sugar content of the fluid varies, but it is generally below normal.

The author studied a series of 15 patients with toxoplasmosis, including 6 with acute encephalopathy. In each patient the onset was sudden and was characterized by marked malaise, lymphadenitis, and fever. The disease may have a prolonged course with remissions and exacerbations. The neurological symptoms may appear six to nine months after the onset of the disease.

Urinary Excretions in Mental Diseases.—Arne Bergsman (*Acta psychiat. et neurol. scandinav.* [supp. 133] 34:5-107, 1959) studied the 24-hour urinary output of epinephrine and levarterenol in 84 patients with mental disorders and a control series of 27 healthy subjects. The high epinephrine output during all manic periods and the low output in the endogenous depressions suggested that those two conditions were opposite not only with regard to the clinical manifestations but also biologically insofar as the excretion of catechol amines was concerned. It was assumed that an endogenous factor was present which caused both types of aberration, though it was possible that the emotions might be reflected in an altered catechol amine output and that the high excretion possibly gave rise to emotional disturbances. Since the chronic schizophrenics showed on the whole a normal output of epinephrine and levarterenol, there was no evidence of a relationship between chronic schizophrenia and the production and excretion of catechol hormones. The small urinary output of epinephrine and the high output of levarterenol in patients with senile dementia were assumed to be due to the disease as such and not to the patients' age. The high levarterenol level was thought to reflect the emotional state of these patients during the tests.

Chlorethiazol.—E. Osterman and co-workers (*Acta psychiat. et neurol. scandinav.* [supp. 136] 34:56-61, 1959) found that chlorethiazol (SCTZ), a drug chemically related to thiamine, the ethandisulphonate of 4-methyl-5-β-chlorethyl-thiazole, had anticonvulsant, sedative, and sleep-inducing properties. The functions of the autonomic nervous system and other biological constants were not affected by therapeutic doses. Clinically, it was most suitable in delirium produced by alcohol, manias, and diseases accompanied by pronounced psychomotor agitation and anxiety. The drug could also interrupt epileptic attacks. The authors used it to treat 16 patients until complete sedation was induced or for at least 10 days. No patients with mental aberration due to senility or arteriosclerosis were included. Four of the patients had varying degrees of mania. A physiological sleep rhythm was restored in practically all the 16 patients. These limited observations indicated that this substance could rapidly interrupt delirium tremens and prevent death. For this purpose SCTZ appeared to be superior to other forms of therapy. In addition it had a strong sedative effect on manic patients, although neuroleptic drugs or electroshock was also required.

UNITED KINGDOM

New Hypotensive Drug.—The recent introduction of the hypotensive drug, bretylium tosylate, has been followed by that of another, guanethidine, a report on which was made by Leishman and coworkers (*Lancet* 2:1044, 1959). A series of 25 patients of both sexes with hypertension of varying severity was treated with guanethidine for 3 to 11 weeks. Over half had previously received treatment with ganglion blocking drugs. All patients were initially hospitalized for about three weeks while the dose of guanethidine was stabilized. Owing to individual sensitivity and the prostrating hypotensive effect of an overdose, a test dose of 30 mg. was given initially and the dose increased by 10 or 20 mg. daily, according to the response. Dosage was reviewed weekly and if necessary increased or decreased by 10 mg. until the blood pressure was satisfactorily controlled. Six of the patients had hydrochlorothiazide in addition to guanethidine. The blood pressure of 13 of the 19 patients receiving guanethidine alone was satisfactorily controlled, and all but one of the 25 patients treated showed some reduction in blood pressure.

The results confirmed Dr. Irvine Page's observation that guanethidine given by mouth is a potent hypotensive agent, the effect being mainly postural, although some reduction in blood pressure occurs in the recumbent position. A fall in blood pressure was generally noted within four hours of taking the drug. Symptoms due to postural hypotension were common, but were immediately relieved by recumbency. The only noticeable side-effects were mild diarrhea, which developed within four hours of taking the drug and coincided with the first fall of blood pressure; myalgia and muscle weakness after giving large doses; and bradycardia. Guanethidine differs from bretylium tosylate in the greater duration of its hypotensive effect. The blood pressure of 18 of the 25 patients was satisfactorily controlled when they were last seen. The hypotensive effect of guanethidine is due to selective blockage of the sympathetic nervous system, probably by inhibiting the release or distribution of transmitter substances from sympathetic nerve terminals.

Health Service Reciprocity.—Full health service reciprocity is now given to nationals of the United Kingdom and its colonies by Norway, Sweden, and Yugoslavia. Since the inception of the National Health Service in 1948, the nationals of any country, whether resident in Britain or only on a visit, have been entitled to free medical care there. In Norway, full treatment, including medicines, is available in public hospitals to British subjects. A refund can be obtained of 75% of the amount of the physician's fees for treatment outside hospital, but there is a drug charge. The local health service office refunds the doctor's fee on production of a signed certificate and a British passport. In Yugoslavia, general medical, dental, and hospital services, as well as drugs prescribed, are free on production of evidence that the patient is British. Forms for intending visitors are issued by the Yugoslav consulate in London. In the Channel Islands, as in Britain, hospital medical treatment is free to visitors, and doctors' services are free, except in Jersey. An agreement for full health service reciprocity for British nationals in Denmark has been considered but not finally ratified. Limited health service facilities are available in France, Belgium, Holland, and Luxemburg for British subjects working in these countries if they are insured there.

Food and Indigestion.—P. H. Friedlander (*Brit. M. J.* Dec. 26, 1959) studied the diet of 70 patients with nonulcerous dyspepsia who attributed their dyspeptic symptoms to certain specific foods. Of these, 36 were given an "indigestible" food mixed with barium sulfate, and roentgenograms were made at intervals for three hours. Simultaneous studies of gastric acidity were also made in 21 patients. The studies were subsequently repeated, the patients being given a "digestible" food. An attempt was made to correlate the patients' symptoms during the tests with the findings from these investigations. Only four patients developed symptoms with the ingestion of the indigestible food. Gastroesophageal reflux was present in two, but no mechanism was apparent in the other two. One other patient had symptoms with both the indigestible and the control food, and three had symptoms with the control food alone. It was concluded that in these patients the composition of the food did not play an important part in the causation of their dyspeptic symptoms.

Phenol for Paraplegic Spasticity.—If a patient has the misfortune to be paralyzed in the legs, it is usually better for the limbs to be flaccid rather than spastic. Spastic paralysis is associated with painful spasms and often with incontinence. It can be converted into flaccid paralysis by division of the anterior spinal roots or by chemical anterior rhizotomy. After trial of various substances Nathan (*Lancet* 2:1099, 1959) decided that permanent destruction of all fibers of the anterior roots was best achieved by a 10 to 20% solution of phenol in glycerol or a 25% solution in iophendylate. The amount of solution injected was determined by the number of nerve roots it was designed to affect, 1 ml. usually affecting seven to eight roots, and 0.5 ml. two to three roots.

It might be thought that such strong solutions of phenol might be harmful, but no untoward reactions, such as meningitis or phenol poisoning, were encountered by Nathan, who treated patients with paraplegic spasticity due to multiple sclerosis, amyotrophic lateral sclerosis, compression of the cord by growths, collapse of the vertebrae, and congenital diplegia. He commented that the immense difference that removal of pain, spasticity, and spasms made to the lives of these severely incapacitated patients was striking. Their lives became bearable and enjoyable. With the lower limbs made flaccid they were able to go about in wheel chairs and enjoy social life.

The injection was made under radiologic control to determine with certainty into which space the phenol should be introduced. The patient was placed in the lateral position for lumbar puncture with the side to be treated lowermost, and, by means of a tilting table and use of hard cushions, the spine was positioned so that the roots to be treated were at the lowest point. The needle was inserted at the space corresponding to the exit foramen of the most important root, and the bevel was turned so that the injected fluid flowed on the nerve roots in their intervertebral foramina. The patient was left in the same position for half an hour to keep the solution in contact with the nerve roots. The postinjection treatment was the same as that used after a myelogram is made. An essential precaution was to keep the patient from lying flat to avoid any possibility of the solution reaching the head. Regeneration of nerve fibers after injection could occur, as spasticity returned in one patient after a year, necessitating a further injection.

Kelly and Gautier-Smith treated a series of spastic paraplegic patients by the same method with good results (*Lancet* 2:1102, 1959). They recommended, however, that the method be used only in bedridden patients.

Percutaneous Introduction of Cardiac Pacemaker.—Treatment of complete heart-block after open-heart surgery is to some extent eased by the use of an artificial pacemaker. Electrodes are placed at operation and removed only when a suitable ventricular rate has become established or when the conduction mechanism has recovered. Sometimes, however, the onset of heart-block is delayed until the postoperative period, and immediate restoration of an adequate ventricular rate by means of a pacemaker is essential. Reopening the wound and introducing an electrode into the myocardium may be dangerous.

Ross and Harkins (*Lancet* 2:1109, 1959) reported the case of a 14-year-old boy who had transposition of the great vessels and a common ventricle and who underwent exploratory ventriculotomy. By the second postoperative day a complete atrioventricular block had occurred that did not respond to drug treatment. Introduction of the cardiac electrode of an artificial pacemaker seemed unsafe, so an electrode was placed by percutaneous ventricular puncture. At the bedside, under sterile conditions, the indifferent electrode was implanted subcutaneously in the epigastrium and the myocardial wire electrode directed into the ventricular chamber through a hollow-bore needle inserted in the fifth intercostal space, 8.25 cm. from the midline. The needle was removed and, with the pacemaker turned on, the electrode was withdrawn until the heart rate matched the pacemaker impulse, indicating that the bare wire of the electrode was in contact with the myocardium. The current amplitude was then adjusted to be just above threshold level and the wire fixed to the skin by a suture. The electric pacemaker controlled the ventricular rate for 27 hours, at which time a satisfactory idioventricular rate had returned. The electrodes were removed after 57 hours. There was no clinical or radiologic evidence of bleeding from the puncture wound in the heart. The patient made a complete recovery with disappearance of complete heart-block on the 16th postoperative day.

Synthetic Penicillin.—The isolation and characterization of 6-amino-penicillanic acid has provided an approach for the synthesis of new penicillins. A new synthetic penicillin derived from this, the potassium salt of 6(α-phenoxy-propionamido) penicillanic acid, Broxil, was studied by Knudsen and Rolinson (*Lancet* 2:1105, 1959). They compared its absorption and excretion after oral administration with that of the potassium salt of penicillin V also given orally, and with the sodium salt of penicillin G given by intramuscular injection. The absorption of Broxil was superior to that of potassium penicillin V, judged by the serum levels and urinary excretion over a six-hour period. Serum concentrations of the former were at least twice those obtained with the latter after administration of equivalent doses. Doubling the dose of Broxil in the 125-mg. to 500-mg. range doubled the serum concentration. Blood levels obtained after its oral administration were at least equal to those obtained after the intramuscular injection of approximately equivalent weights of the sodium salt of crystalline penicillin G.

Migraine and Hypertension.—A survey of migraine in general practice was made by Dr. C. H. Walker of Liverpool (*Brit. M. J.* 2:1430, 1959). Among his 5,785 patients, 281, or nearly 5%, gave a history of attacks of migraine. Of these, 79% were women. Just over 50% had a family history of migraine. The criteria on which the diagnosis was made were unilateral recurrent headache, associated visual symptoms, nausea or vomiting, and a family history of migraine. Observing that 52% of a group of hypertensives also suffered from migraine, Walker investigated the incidence of hypertension in 150 subjects with migraine, comparing the blood pressure with that of 150 controls of the same age and sex distribution suffering from other conditions.

The difference between the mean systolic pressures and between the mean diastolic pressures, of the patients, age for age, with migraine and the controls was 10 mm. Hg. This difference is statistically significant. The incidence of migraine and hypertension in those over 40 years of age was then determined. It was found that the incidence of migraine rose as the blood pressure increased. A family history was also found to be common in both conditions, and the personality structure of the two disorders had several points in common. Patients with both conditions presented evidence of suppressed emotional conflict. Essentially the same mechanism is operative in producing the headache associated with hypertension and migraine—namely, dilatation and distension of the cranial arteries.

CORRESPONDENCE

PHOTODYNAMIC RESPONSE OF A NEW TETRACYCLINE

To the Editor:—On Sept. 28, 1959, a new tetracycline antibiotic, demethylchlortetracycline (Declomycin) was introduced to the medical profession. Much clinical and laboratory evaluation of this drug prior to its release established that, through its greater persistence in body fluids, reduced milligram administration achieves an equivalent or greater antibacterial activity, compared with other tetracyclines. Extensive pharmacological and laboratory toxicity studies failed to demonstrate any significant therapeutic difference from the other tetracyclines.

In the course of clinical evaluation the drug was distributed to 1,354 physicians. In the analysis of the 2,682 reports received to date, a photodynamic reaction to sunlight has been observed in 40 patients, most of whom were on prolonged therapy. In the analysis of these data every patient whose response might be even remotely related to this phenomenon was considered to represent a positive case. This reaction occurs to intense hot sunlight and is apparently similar to that seen with other tetracyclines, at least one of the phenothiazines, the sulfonamides, barbiturates, and gold salts. The sunburn reaction fades within a day or two on reduction of dosage or discontinuation of therapy. It occurs only on exposed parts of the body.

The average dosage of demethylchlortetracycline, in adults, is 600 mg. daily in divided doses, and it is thought to be unnecessary to exceed single doses of 300 mg. Because of the possibility of a photodynamic response to sunlight, patients should be cautioned, while on demethylchlortetracycline therapy, to avoid unnecessary exposure to intense sunlight. Should this reaction occur, demethylchlortetracycline administration should be discontinued until the sunburn clears, at which time therapy may be reinstituted, provided the patient exercises caution in exposure to the sun. Ambulant patients on maintenance therapy, the most likely to be exposed to sunlight, should probably receive a daily dose smaller than the recommended therapeutic dose. Because such a response is rare, it is necessary to expend great effort to verify these findings. Appropriate control studies are in progress under the supervision of competent investigators and the results of these investigations will be published as they become available.

TISSUE NECROSIS AND METARAMINOL BITARTRATE

To the Editor:—We have been disturbed by th implications and deductions in the article by Dipp and Dorney "Tissue Necrosis and Slough Produce by Metaraminol Bitartrate" in The Journal, Aug. 1959, page 1647. A patient was described as havin hemiplegia and thrombosis of the terminal aort with obstruction of the circulation below the lev of the renal arteries, which would be sufficient t have resulted in gangrene without invoking th treatment with metaraminol as a causative facto This patient received several intramuscular an subcutaneous injections without developing tissu necrosis. Nine hours after extravasation of a dilut metaraminol solution (30 mg. per liter), gangren developed in a previously pulseless extremity. Th agent implicated was the extravasated dilut metaraminol, like the straw that broke the camel back. Certainly, the straw cannot be blamed without implicating the other heavy loads carried b the camel.

We have been interested in tissue necrosis cause by levarterenol, from both an experimental and practical viewpoint (*J. A. M. A.* 165:444 [Oct. 1957; *Am. J. M. Sc.* 236:755 [Dec.] 1958). Zucke (*J. A. M. A.* 163:1477 [April 20] 1957) noted that intracutaneous injection of 1 ml. of levarterenol (1 mg per ml.) on the shaved abdomen of a rabbit regularly resulted in an area of ischemic necrosis. W (*Am. J. M. Sc.* 236:755 [Dec.] 1958) have also foun this to be invariably true; however, we could no produce ischemic necrosis with 1 ml. of metaramin (10 mg. per ml.) by this technique.

We have treated a large number of patients i coronary and surgical shock with intravenous injections of metaraminol (as much as 300 mg. i 1,000 cc. of fluid) in 10 times the concentratio used by Dippy and Dorney, or with intramuscula or subcutaneous injections of 1 to 2 cc. of metaraminol every hour, as needed, without one incident o ischemic necrosis. In certain instances we have use the intramuscular treatment as further depot support to the intravenous method. Although we hav not completely tabulated our cases, we can stat that while metaraminol is an effective sympathomimetic substance, its effectiveness does not approach that of levarterenol in patients with sever coronary shock. It is effective in postoperative shoc and in the hypotension that sometimes follow operation. We do not as yet have enough patient who had coronary shock treated with metaraminol by the intravenous route, supplemented by intrauscular injections when necessary, to make a state- ent of its efficacy. We have found no instances of chemic necrosis in a fairly large experience.

In the case described by Dippy and Dorney we lieve that the metaraminol extravasation had tle, if anything, to do with the subsequent de- lopment of gangrene. The stage was set for this fortunate development long before metaraminol as infused into the vein at the ankle. We believe at the use of an extremely useful therapeutic ent should not suffer because of questionable cumstantial evidence.

HYL ALCOHOL LEVELS IN THE BLOOD

the Editor:—In The Journal, June 27, 1959, ge 1108, Dr. Joseph Beeman disagreed with edemann and Bubowski (*J. A. M. A.* 170:47 ay 2] 1959), who stated that alcohol applied to skin has a negligible effect on the alcohol con- t of the blood drawn when alcohol is used as an iseptic. Dr. Beeman has found as much as 200 . of ethanol per 100 ml. of blood, or 0.20%.

paper of my own (*Am. J. Path.* 32:169 [Aug.] 9) on this subject indicates that alcohol on the has a very slight effect on the percentage of ohol found in the blood. It is more likely that Beeman's experience paralleled mine, namely, t the syringe had been rinsed with alcohol be- it was used to withdraw the blood. On two asions I found more than 1.0% alcohol in speci- ns, a percentage which would be incompatible h life, in persons who were very much alive.

ince writing this paper I have repeated my ex- iments, using needles of various sizes, and found t the most alcohol was found when the largest dles were used, namely, 21 gauge. Such needles uld not be used ordinarily; and even with this ge caliber I found only 0.008% alcohol in spite the fact that I did not simply daub the site with ohol but actually poured alcohol over the skin I immediately thrust the needle through a layer alcohol. I agree with Dr. Beeman that alcohol or er reducing agents should not be used when od alcohol tests are made, since this procedure uld cause needless arguments in court, but in zens of experiments I have not found that alco- applied to the skin had a significant influence the blood alcohol test result.

DRUG NAMES

To the Editor:—The question of drug names is rapidly becoming a matter of international importance. As it stands now, there is international uniformity with respect to the systematic chemical name for new chemical compounds that may be introduced as drugs. These chemical names are thoroughly systematized and carry real structural meaning to chemists. On the other hand, to members of the health professions these chemical names are practically meaningless. Accordingly, relatively simple names for general public use have to be devised, and these are referred to as either "official," "generic," or "public." In addition, there are trade names, which are the legal property of the company exploiting the drug. Unfortunately, the public names for drugs vary in different countries. Sometimes this is due to trade name factors. Thus, the name adrenaline is a "public name" in Britain, but "Adrenalin" is a trade name in the United States. Accordingly, the public name for the drug in the United States is epinephrine.

It is time that an international effort be made to bring about some degree of unity in connection with public names for the same chemical compound which may be used as a drug in different parts of the world. The British Pharmacopeia Commission devises "Approved Names" for drugs, and "The intention is that if any of the drugs to which these Approved Names are applied should eventually be described in the British Pharmacopeia, the Approved Name should be its official title." Lists of these approved names are distributed monthly by the General Medical Council of Great Britain to all physicians, dentists, veterinarians, and pharmacists. These monthly lists of approved names are also distributed by the Royal Society of Medicine to its members. In this way, physicians in Great Britain have ready reference to the approved names of drugs and can have some idea of what it is, chemically, that they are giving their patients. These lists also contain proprietary names for cross reference.

The British Pharmacopeia Commission has set forth 10 guiding principles to be used in devising or selecting new approved names. It might be appropriate for American drug manufacturers, as well as for American organizations in the health professions, to consider these guiding principles regarding new approved names for drugs, so that some reasonable standards may be used for drug names in this country and some approach may be made to international uniformity in connection with drug names.

MEDICAL FILM REVIEWS

Carcinoma of the Stomach: Gastrectomy: 16 mm., color, sound, showing time 29 minutes. Prepared in 1958 by Waltman Walters, M.D., and William H. ReMine, M.D., Rochester, Minn. *Procurable on loan from Section of Photography,* Mayo Clinic, Rochester, Minn., or American College of Surgeons, 40 E. Erie St., Chicago 11.

The first few minutes of this film are devoted to a comparison of figures on resectability—three-year and five-year survival rates during a recent period (1940-1949) compared to survival rates in a series reviewed three decades previously. The techniques of radical subtotal gastrectomy and radical total gastrectomy are shown. The authors illustrate how the common duct is isolated and actually opened to prevent its injury during the radical resection of the stomach with a sizable cuff of duodenum. In both types of operations all of the nodes of the gastrohepatic omentum are removed along with the fatty tissue overlying the pancreas. Splenectomy is included in the radical subtotal gastrectomy and radical total gastrectomy. In the total gastrectomy, a loop of jejunum is brought posterior to the colon and anastomosed to the esophagus; jejunojejunostomy is then performed. The authors stress the danger of medical treatment of the chronic gastric ulcer, which they have found to be malignant in 20% of the patients. Early diagnosis for optimum results is properly emphasized. The film is well organized and the narration and photography are excellent. It is recommended for medical students, general practitioners, and surgeons.

Rescue Breathing: 16 mm., color or black and white, sound, showing time 21 minutes. *Produced in 1958 at the* Roswell Park Memorial Institute and the Buffalo General Hospital by and procurable on purchase from American Film Producers, 1600 Broadway, New York 19.

This film is designed to teach the techniques of rescue breathing (mouth to mouth and mouth to nose). An animated sequence shows how the tongue usually blocks the throat of an unconscious victim and how a rescuer can rectify this condition with rescue breathing. A series of dramatizations are shown which demonstrate how rescue breathing is used to save the lives of unconscious victims of drowning, choking, drugs, electric shock, gas asphyxiation, and chest injury. The film deserves much commendation for the way it overcomes the psychological obstacles that make it hard for many people to accept the idea of mouth-to-mouth breathing. The photography is good and the narration is intelligible. This film can be shown profitably to audiences at every level from fourth or fifth grade up. It will be of great interest to physicians who may not have had an occasion either to see the method demonstrated or to see the operation of an oximeter so well shown.

How To Do Rescue Breathing: 16 mm., black and white, sound, showing time 5 minutes. Consultants: Prof. Charles E. Silvia, Springfield College, and Dr. Harold T. Friermood, *National Council* Y. M. C. A.'s. *Demonstrated by* Ray T Smith, M.D. Produced in 1959 by and procurable on purchase ($49.50) from Seminar Films Inc., 480 Lexington Ave., New York 17.

The purpose of this film is to demonstrate and teach the performance of rescue breathing, including changing operators and moving the victim without use of special equipment. It begins by stressing the need for immediate action in cases o asphyxiation and then demonstrates the performance of the method explaining each step. It stresse the fact that rescue breathing can be done in an position which enables the operator to get at th victim's head and that it can and should be don even while the victim is being moved. This film good, short, and to the point. It demonstrates th procedure in a simple direct way. No indicatio advantages, or disadvantages are shown. The ph tography and narration are good. It will be prima ily of value to lay groups, provided some profe sional instruction accompanies the showing of t film.

NEW FILM ADDED TO A. M. A. MOTION PICTURE LIBRARY

Rehabilitation Adds Life to Years: 16 mm., color, sou showing time 30 minutes. Presented by the American Me cal Association, Committee on Rehabilitation. Produced 1959 by Reid H. Ray Film Industries, Minneapolis. P curable on loan (no service charge) from Motion Pict Library, American Medical Association, 535 N. Dearb St., Chicago 10.

This film is designed to show the medical prac tioner the important role of rehabilitation in t total patient care, organization of rehabilitati services in the community, and the application services to individual patients and to demonstra the type of disability requiring referral to a mo elaborate rehabilitation center. The key position the family physician in rehabilitation is stresse It shows the rehabilitation in the community h pital of a hemiplegic housewife and of a pati with a myocardial infarction, and then the progr of a paraplegic patient in a rehabilitation center depicted. The philosophy, organization, and te niques of rehabilitation in the local community a well presented. The multifaceted approach of t rehabilitation center is well shown. The film is excellent presentation of the need for rehabilitati and the various resources for accomplishing t goals. The color photography is very good. The fi is recommended to be shown to physicians.

ILLUSTRATED FILM REVIEWS

REHABILITATION ADDS LIFE TO YEARS

This film was sponsored by the American Medical Association and was produced under the auspices of he Committee on Rehabilitation. Its purpose is (1) to acquaint the practitioner with the magnitude of the ehabilitation problem from the standpoint of patients' needs and the opportunities that physicians have to ncrease their services by helping in the rehabilitation of their patients; (2) to show the medical profession he techniques necessary to organize medical and other phases of rehabilitation at the community level; 3) to show a practical example of how the practitioner can see to it that his patients receive these rehabiliation services which have been organized in the community; and (4) to indicate the type of rehabilitation roblems which warrant referral of the patient to a comprehensive center.

The film shows how the rehabilitation center can serve the patient while still respecting the referring phyician's interest in his patient. It is designed primarily for a medical or other related professional audience.

Fig. 1.—This doctor's career seemed to have been ended poliomyelitis when he was 30 years of age, but with etermination and rehabilitation he is now able to practice a pathologist.

Fig. 2.—This victim of coronary thrombosis was treated in his own small community by the family doctor and was put back to work by his employer in a job he could do.

Fig. 3.—Hydrotherapy is used as part of the treatment of is rheumatoid arthritis patient. Hip arthroplasty, theraeutic exercises, and occupational therapy rehabilitated her useful homemaking for her family.

Fig. 4.—The medium-sized community hospital provides occupational therapy which helped this patient, who had a stroke, master her disability.

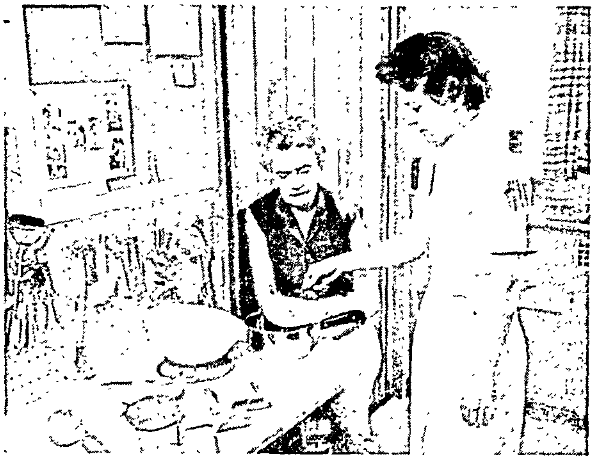

Fig. 5.—In the case of the hemiplegic, kitchen chores with one untrained hand are skills that must be learned. *Assistive devices are used.*

Fig. 6.—This victim of an automobile accident was sen from his smaller community to a comprehensive rehabilitation center.

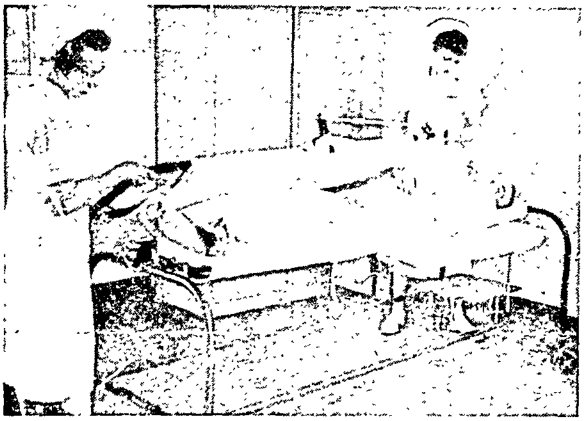

Fig. 7.—At the rehabilitation center, the patient soon left *his frame to begin therapeutic exercises to strengthen the* upper extremities and to begin gait training.

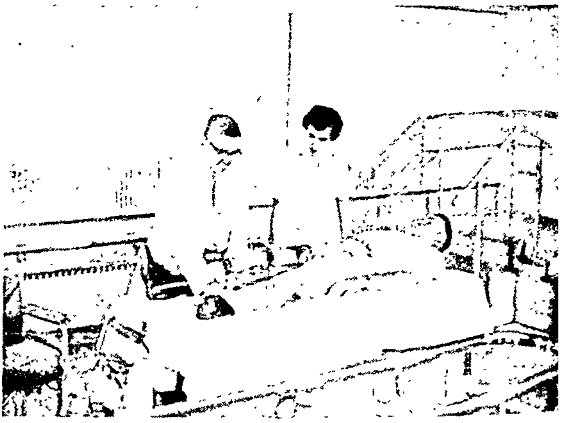

Fig. 8.—After fitting with braces, ambulation was accomplished. The patient then received *prevocational* training and subsequent full-time employment.

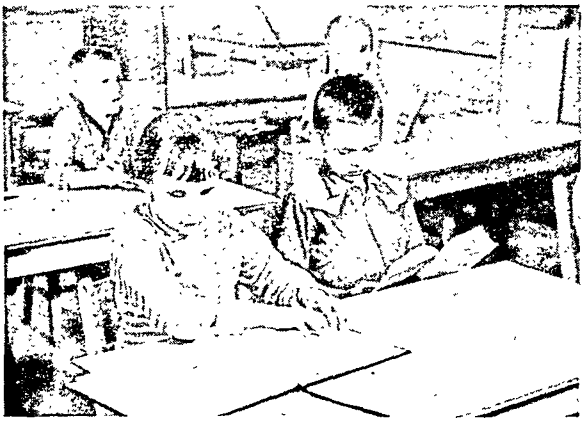

Fig. 9.—*Community services should be utilized. Here, the* department of special education in the local school is used in the training of the blind and those with partial sight.

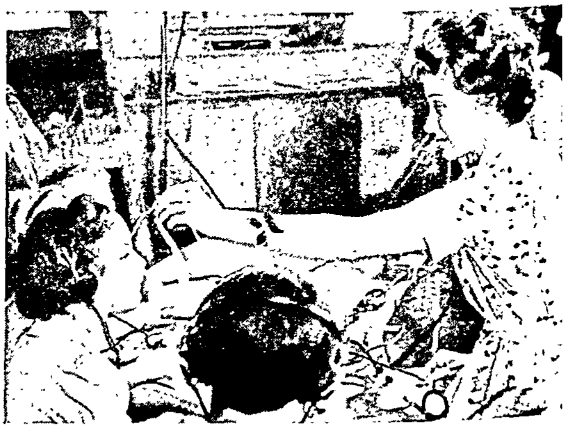

Fig. 10.—*Speech training in a class for* hard-of-hearing and deaf children is part of the community school system's special education program. Rehabilitation calls for the combined efforts of many disciplines so that real meaningful *life may be added to every patient's years.*

MEDICAL LITERATURE ABSTRACTS

SURGERY

A Study of Pancreatography. M. Birnstingl. Brit. J. Surg. 47:128-139 (Sept.) 1959 [Bristol].

The studies were undertaken to correlate the roentgenologic appearances of the duct system of the pancreas with the histological findings in patients without overt pancreatic disease. The intention was to provide a basis for the interpretation of operative pancreatograms, obtained in the living subject, and to investigate the incidence of epithelial metaplasia and hyperplasia in routine autopsy material. The material was obtained at autopsies at St. Bartholomew's Hospital, London, from adult subjects dying of a variety of diseases. Apart from the exclusion of cases of known primary pancreatic disease, an attempt was made to examine organs from consecutive patients. The series consisted of 94 male and 56 female subjects. The pancreas, together with the duodenal loop, was removed from the body, and a probe was passed down into the duodenum, through the common bile duct, to locate the papilla. The latter was then lifted away with toothed dissecting forceps, and the duodenal mucosa was dissected back as a cuff until about 1 cm. of the wall of the ampulla was exposed. By making a nick in the inferior aspect of the ampulla, the main pancreatic duct could be entered. A 2-mm. cannula was tied into the duct, and radio-opaque medium was injected. An average volume of 2 ml. was required to fill the ducts. In a few specimens injection by the above route was unsuccessful, but was achieved either by cannulation of a prominent lesser duodenal papilla or by retrograde injection along the main duct after transection of the tip of the tail of the pancreas.

After roentgenography the organs were placed for 24 hours in a formaldehyde solution for fixation. The material was sliced at about 0.5-cm. intervals and examined for gross abnormality, after which an average of 4 histological sections were made from each pancreas. The anatomic variations which influence the interpretation of pancreatograms were reviewed on the basis of combined roentgenologic and histological studies. The main pancreatic duct showed variations in caliber, ranging between maximum diameters of 1.8 and 9.2 mm.; the upper limit of the normal diameter of this duct is about that of an ordinary lead pencil (8 mm.). Appearances of isthmic stenosis, terminal dilatation, and an undulating outline in this duct were occasionally seen and represent anatomic variants. The accessory pancreatic duct communicated with the main ductal system in 68% of specimens, but only appeared patent in 55%. Dilatation and irregularity of the secondary pancreatic ducts were commonly seen on the pancreatograms and produced an appearance of pancreatectasis in a few specimens. These variations closely reflected the development of hyperplastic and metaplastic changes in the ductal epithelium.

Columnar epithelial hyperplasia was seen in 29% of organs; the change was most frequent in the secondary ducts and in the ampullary region of the accessory pancreatic duct. It was most common in the form of intraductal proliferation, but hyperplasia of mucus-secreting glandular structures related to the ducts was also seen. *These variants* resemble cholecystitis glandularis proliferans, with which they are comparable. Subclinical focal pancreatic necrosis was encountered in 5 specimens, in which it was apparently related to the presence of hyperplastic epithelial lesions in the ducts. Squamous epithelial metaplasia was present in 10% of organs, although never to the extent shown by columnar hyperplasia, with which the change was generally associated. In view of the wide range of roentgenologic and histological appearances in an apparently normal autopsy material, the author feels that pancreatograms obtained during abdominal surgery require cautious interpretation.

Adenocarcinoma of the Large Bowel: 1,340 Cases with 100 Per Cent Follow-Up. V. A. Gilbertsen. Surgery 46:1027-1042 (Dec.) 1959 [St. Louis].

The author reports on 1,340 patients with adenocarcinoma of the large intestine, who were seen at the University of Minnesota Hospitals in Minneapolis between 1940 and 1955. Of the 1,340 patients, 693 had primary lesions in the rectum, 605 had primary lesions in the colon, and 42 had lesions in several different anatomic sites of the large intestine. The operative rate was 98%. The over-all resection rate was 84%, with 87% for adenocarcinoma of the colon and 82.3% for adenocarcinoma

The place of publication of the periodical appears in brackets preceding each abstract.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by persons in continental United States or Canada who subscribe to its scientific periodicals. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover 1956 to date for English language and 1958 to date for foreign language journals. No photoduplication services are available. No charge is made to members, but the fee for others is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

of the rectum. The general composition of the group indicated that patients were somewhat older than in the usually reported series. Operative, resection, and survival rates, however, compared favorably. Two-thirds of the patients with carcinoma of the colon died of their disease without 5-year survival; 32% of the patients survived cancer-free 5 years. When patients underwent excisions for cure, however, about two-thirds of those with cancers of the colon and one-half of those with cancers of the rectum survived 5 years. When patients with Dukes A lesions are considered, 83% of those with colon lesions survived 5 years, including 100% with lesions of the splenic flexure, hepatic flexure, and transverse colon.

The most favorable prognosis after excision for cure was associated with lesions of the transverse colon (90% 5-year postoperative survival); the least favorable prognosis was associated with lesions of the rectum (49%). The popular reluctance against employment of larger operations for large cancers receives little support; enlarged excisions allowed substantial survival of patients whose disease might otherwise have been inoperable for cure. Curative excisions in patients, aged 44 years or less, were followed by acceptable survival rates. This was not noted in patients, aged 80 years or older, except those few with lesions of the transverse colon. Palliative excisions were associated with measurable palliation, as were colostomies performed without resection; cecostomy, catheter enterostomy, and ileostomy, however, were not.

The Development of Carcinoma of the Large Intestine in Ulcerative Colitis. I. M. P. Dawson and J. Pryse-Davies. Brit. J. Surg. 47:113-128 (Sept.) 1959 [Bristol].

This survey is based on a study of 663 patients with ulcerative colitis, who attended the Gordon Hospital, London, in the 11¾ years up to December, 1958. The records of 735 patients with suspected colitis were examined, and in 663 cases the diagnosis was considered proved. The final diagnosis of ulcerative colitis was based on proctoscopy, sigmoidoscopy, and the roentgenologic appearances after barium enema. In 284 cases there was confirmation of ulcerative colitis by rectal or colonic biopsy, and in 183 a part or all of the colon was examined after resection.

Carcinoma of the large intestine was found in 19 of the 663 patients (2.9%) with ulcerative colitis. There were 409 (61.7%) women and 254 (38.3%) men; and in the carcinoma group there were 12 women and 7 men. The average age of the patients at the time of onset of the symptoms of colitis was 35 years, but more than 12% were less than 21 years old. In the carcinoma patients the colitic symptoms appeared at an average age of 26.1 years; 7 patients were less than 21 years old. The average duration of colitic symptoms was 9.6 years, but in the carcinoma group the average duration was 17.8 years, and in 13 of the 19 carcinoma patients symptoms of colitis had existed for more than 15 years prior to the discovery of carcinoma. The development of carcinoma appears to be related to the duration of colitis rather than to the age at onset. The average age at diagnosis of cancer was younger than the usual age for cancer of the large intestine.

While there was no specific picture indicating the presence of carcinoma in ulcerative colitis, the existence of a stricture did seem to be an important feature. In 7 cases strictures were diagnosed prior to operation; in 3 of these the strictures had developed more than a year before the carcinoma was diagnosed, and in 2 others the strictures probably preceded the growth. Although some investigators are of the opinion that strictures generally result from the carcinoma, the present authors believe that carcinomas sometimes arise at a preformed stricture and that the presence of a stricture requires a careful survey for carcinoma.

In 10 patients the carcinoma was in the rectum, and in 7 in the colon; in 2 cases the primary site was not determined. The growth was well differentiated in 4 cases, moderately differentiated in 6, and poorly differentiated (or anaplastic) in 7. Early spread beyond the intestine and early metastasis were common features. Carcinoma in the colon developed on a basis of chronic active ulcerative colitis, while carcinoma of the rectum developed in active or quiescent colitis. Microscopic features of the carcinoma are discussed, and the possible origin from "buried" epithelium considered. Polyps were frequently associated with the carcinoma. They were of adenomatous, pseudopolypoid, and transitional forms. The possibility of transition from pseudopolyp to true adenoma and carcinoma is discussed. The prognosis of carcinoma in ulcerative colitis is poor. Cases of ulcerative colitis, both chronic active and quiescent, of long duration, require careful, regular follow-up, with biopsy, if possible, especially in the presence of stricture.

Intestinal Lipomatosis. C. S. Ling. C. Leagus and L. H. Stahlgren. Surgery 46:1054-1059 (Dec.) 1959 [St. Louis].

The authors report on a 60-year-old woman with diffuse symptomatic submucous lipomas of the intestine. She was admitted to the Philadelphia General Hospital because of copious bright red rectal bleeding. A barium enema revealed a polypoid lesion of the terminal ileum with ileocecal intussusception, but the patient refused laparotomy and was discharged. Six years later she returned to the hospital and complained of intermittent lower abdominal pains of about 8 months' duration. The pains were cramping in nature and were relieved by the passage of flatus or feces, but generally subsided spontaneously. She also had nausea and vomiting in recent weeks and had noted increasing constipation. A firm, movable, slightly tender fusiform mass was palpable in the right lower quadrant in the area of the cecum. Peristalsis was normal. Numerous polypoid lesions were identified throughout the colon and the small intestine by barium enema examination. Surgical exploration revealed numerous intraluminal, polypoid, soft, movable tumors of the small intestine and colon. Two areas of ileoileal intussusception were noted, and both were easily reduced. In each, a large polypoid intraluminal mass was palpated at the intussuscepting point. A resection of the ileocecal intussusception and the distal ileum which contained the most concentrated area of polyps was performed. Enterotomies were then performed at the side of the 2 ileal intussusceptions. Lipomas measuring about 2 by 3 cm. were shelled out from the submucosa. Postoperatively the patient did well and was discharged on the 10th postoperative day. Pathological examination of the operative specimen, consisting of 195 cm. of the terminal ileum and ascending colon, revealed 107 submucosal sessile and polypoid lipomas of sizes varying from 5 mm. to 5 cm. in diameter. They were scattered throughout the intestine, some singly and others in clumps. Microscopic examination showed lobulated collections of mature fatty tissue, mostly submucosal in location.

Symptomatic lipomas usually arise in the submucosa and project into the lumen. Symptoms are usually due to intussusception caused by lipoma. Bleeding due to ulceration or trauma to the mucosa overlying a lipoma is less common. Lipomas of the colon which produce symptoms occur twice as frequently as lipomas of the small intestine. Operative treatment should be conservative and should consist of enterotomy and shelling out of the lipomas or limited resection of the intestine in which the greatest concentration of lipomas exists. The prognosis is good, but symptoms of intestinal obstruction or bleeding may recur. A familial incidence has not been established.

Diverticulosis of the Duodenum. J. D. Bloom and W. J. Gillesby. Am. Surgeon 25:931-936 (Dec.) 1959 [Baltimore].

The authors report on 120 patients in whom a diagnosis of diverticulosis of the duodenum was made at Hines (Ill.) Veterans Administration Hospital between 1950 and 1954. These patients were subdivided into 5 groups. The first group, consisting of 56 patients, had symptoms probably due to other abnormal gastrointestinal conditions. The second group consisted of 9 patients with symptoms which could have been due to other abnormal gastrointestinal conditions, but less definitely so, since these included such ailments as hiatus hernia, gastritis, prolapsed gastric mucosa, or cirrhosis; they often produced a vague symptom complex and rendered the actual source of the symptoms less certain, particularly since none of these 9 patients underwent surgical treatment. The third group consisted of 20 patients in whom the diagnosis was established by x-ray, but who, at the time of discharge, carried no other diagnosis to explain the symptoms presumably present to warrant a barium meal. The fourth group consisted of 30 patients who were admitted with varying abdominal complaints which led to such diagnoses as gallbladder disease, peptic ulcer, or hiatus hernia; these diagnoses were not established during the course of the examination, but barium studies revealed duodenal diverticula. In general, the patients of group 4 responded well to a mild ulcer regimen and were discharged; a few who responded poorly were labeled psychoneurotic; in most patients of this group, duodenal diverticula were not considered a cause of their symptoms. The fifth group consisted of 5 patients who underwent surgical treatment for symptoms believed to have arisen from diverticula; of these, 2 had simple excision, and 3 had gastric resection. Bleeding was difficult to control during dissection, and one patient, who had excision of a diverticulum, died of a sudden hemorrhage on the 9th postoperative day.

Particular attention to the last 3 groups led to the assumption that the symptoms of the 20 patients in group 3 were caused by diverticula. There was almost constant complaint of epigastric pain which occasionally radiated to the right upper quadrant and to the back. This pain frequently occurred before meals, but in several patients it occurred about half an hour after eating. Vomiting occurred in about 33% of the patients. More than half of them lost 10 to 20 lb. (4.5 to 9.1 kg.) in weight. In general, the symptoms were so mild and vague that in none of the patients was the diagnosis made before x-ray examination. In 60% of the patients the diverticula were located in the second portion of the duodenum; in 35%, in the third portion; and in 5%, in the fourth portion. They were solitary in 75% of the patients, and multiple in 25%. Two of them were subsequently shown to arise from the stomach near the pylorus. The retention of barium, as shown on the 5-hour roentgenogram, in 54% of the patients in the last 3 groups is considered evidence that the diverticulum is the producer of the symptoms. The pathogenesis is probably stasis of food particles in the lumen with supervening bacterial overgrowth and resultant inflammation. The incidence of duodenal diverticula is probably greater than is indicated by these figures. When there is a well-adjusted patient, giving a history of pain, vomiting, and loss of weight intermittently over a period of a year, and when roentgenograms show a diverticulum with a fair amount of retention after 5 hours, it is reasonable to think that a causal relationship exists. If bland diet and administration of antacids cannot keep symptoms to a minimum, surgical excision should be considered.

Nature and Treatment of Stenosing Tenosynovitis. M. Zwicker. Deutsche med. Wchnschr. 84:2161-2164 (Nov. 27) 1959 (In German) [Stuttgart, Germany].

Before describing his own observations on 54 patients with stenosing tenosynovitis, the author mentions de Quervain's description of the condition in 1895, and reviews the topographic anatomy of the wrist joint. All but 6 of his 54 patients were women: 21 were housewives; 5, nurses; 5, office workers; and the rest, dressmakers, domestics, and the like. Stenosing tenosynovitis is the result of fibrous or cartilaginous narrowing of the common tendon sheath of the abductor pollicis longus and the extensor pollicis brevis muscles. The process interferes with the free play of the tendons and produces annoying pain in the thumb, the hand, and the forearm. The patients are mostly women of middle age or older, whose work involves certain repetitious manipulations. Since conservative treatment is rarely successful, the author recommends early surgical treatment. The operation can be carried out under local infiltration anesthesia. The indurated portions of the tendon sheath are incised or excised. The results of this treatment proved excellent in the patients presented.

Leiomyosarcoma of the Duodenum: Case Report and Summary of Literature. R. R. Bradham. Am. Surgeon 25:950-957 (Dec.) 1959 [Baltimore].

The author reports on a 47-year-old man with leiomyosarcoma of the duodenum, who was admitted to the Medical College Hospital in Charleston, S. C., with the chief complaint of rectal bleeding. Associated with the bleeding were symptoms of dyspnea, marked fatigability, weakness, malaise, and several attacks of syncope. There was no history of weight loss. Upper gastrointestinal roentgenograms showed in the third portion of the duodenum, a segment, measuring roughly 7 cm. in length, which was narrowed as though by an intramural tumor. There was no delay in the passage of barium, and the pattern of the small intestine was otherwise normal in appearance. Laparotomy was performed, and a tumor, measuring 6.5 by 4.5 cm. and arising from the inferior wall of the third portion of the duodenum, was easily mobilized and resected with adequate margin. No metastases were found. Primary end-to-end anastomosis was done. Microscopic examination of the operative specimen revealed, within the submucosa and fibromuscular wall, a poorly defined neoplastic mass, composed of closely packed bundles of spindle and fusiform cells of smooth muscle origin, in which there were nuclear atypicalities and increased mitotic activity consistent with the diagnosis of leiomyosarcoma o the duodenum. The patient made an uneventfu recovery, and there has been no recurrence up t the time of publication of this report.

Fifty-three additional cases of leiomyosarcom of the duodenum were collected from the literature. The age of the youngest patient was 25 year and that of the oldest was 80 years. There was a equal distribution in the 2 sexes. Duration of symptoms varied from a few days to 13 years. Weaknes and ease of fatigability were the most commo symptoms. Fifty per cent of the patients ha marked gastrointestinal hemorrhage, as manifeste by melena and hematemesis.

Roentgenograms are extremely helpful in makin the diagnosis of leiomyosarcoma of the duodenum If the tumor is predominantly intraluminal, a fil ing defect with rounded borders and distortion overlying mucosa may be found. Extralumin tumors show pressure defects and interruption peristalsis. Ulceration can occur with either typ and, as the tumor enlarges, fistula and sinus tra formation are common. Choice of treatment is e cision of the tumor with adequate margins of th duodenum and any invaded organs.

A Clinical Study of 25 Patients with Carcinoi Tumors of the Rectum. G. W. Peskin and M. Orloff. Surg. Gynec. & Obst. 109:673-682 (Dec 1959 [Chicago].

The clinical and pathological characteristics carcinoid tumor of the rectum in 25 patient treated at the Hospital of the University of Pennsy vania in Philadelphia between 1933 and 1958, a reported. There were 15 men and 10 women, wi ages ranging from 20 to 79 years. The greatest fr quency (13) was in the 40-to-59 age group. Ev dence of malignancy was found in 10 patients i whom the tumor extended into or beyond th muscle coat of the intestine, as demonstrated b the biopsy specimen obtained at sigmoidoscop Six patients showed metastases at laparotomy, an in one other metastases developed after the oper tion. In 15 patients the diameter of the tumor wa less than 2 cm.; in the other 10 it was 2 cm. or mor Nine of the 10 tumors measuring 2 cm. or mor were metastasized and/or extended locally. Of th 15 tumors measuring less than 2-cm. diameter, onl one showed signs of malignancy and extende through the intestinal wall, without spreading t lymph nodes or other organs. The most frequen symptoms among the 25 patients reported wer pain, bleeding, and constipation, each occurring i about one-fourth of the patients. One-third of th patients had no symptoms; their rectal tumors ha been discovered incidentally during a routine examination for some unrelated abnormality.

Three forms of treatment were used, namely local excision, radical resection, and palliativ measures, such as colostomy. Fourteen patient whose tumors had less than a 2-cm. diameter were treated by local excision. All of them were in good health, with no signs of recurrence at the time this article was written (the postoperative period varied between 1 month and 14 years). The 15th patient with a tumor of less than 2-cm. diameter underwent abdominoperineal resection, mainly because of an associated rectal polyp showing carcinomatous changes; the patient was well 5 years after the operation. Four patients with extension of the tumor into the muscle layer of the intestine also underwent abdominoperineal resection. Three of them were alive and well at the time of this survey (3½ years, 2½ years, and 2 months, respectively, after the operation). One patient died of widespread metastases 7 months after the operation. Six patients with large lesions received only palliative treatment. All of them died of cancer, 5 within 2 years from the initial treatment. The 6th patient lived 9 years before he succumbed to widespread metastases. The authors conclude that 2 factors should influence the surgeon in the direction of radical therapy. These are evidence of extension of he carcinoid into or beyond the muscle coat of the ntestine and a tumor measuring 2 cm. or more in diameter.

Compression Arthrodesis of the Ankle. A. H. Ratiff. J. Bone & Joint Surg.41-B:524-534 (Aug.) 1959 London].

The author presents an analysis of the results of compression arthrodesis of the ankle, which requires a transverse incision with division of the extensor tendons. Fifty-nine operations, of which 4 were bilateral, were performed on 55 patients reated at the Royal Infirmary in Manchester, Engand. The majority of the patients were between 18 and 60 years of age. The patients were followed up for from 1 to 9 years after the operation. Arthrodesis was performed on 21 patients with osteoarthritis, 12 with tuberculosis, 7 with poliomyelitis, 7 with spastic hemiplegia, 3 with cluboot, and 3 with chronic arthritis; 6 miscellaneous conditions were the cause for the operation. Twenty-nine of the 59 ankles were immobilized for only weeks, and the remaining 30 ankles required immobilization for from 9 weeks to 9 months. As a result of this study, it is now recommended that he compression pins be removed 4 weeks after the operation and that a below-knee walking plaster cast be applied. All fixations should be discarded 8 weeks after the operation, regardless of the radiographic appearances.

Bony fusion occurred in 54 of the 59 ankles. In particular, it occurred in all the patients with osteoarthritis. In 4 patients the operation resulted n fibrous ankylosis, but the patients were satisfied with the result, and it was impossible to distinguish these ankles from those in which bony fusion had occurred. In one patient the fusion failed; arthrodesis had been performed for a Charcot's joint; the joint surface came apart after removal of the pins 4 weeks after the operation, but bony union was secured after a further operation. Thirty-four patients had no pain after the operation, 16 noticed a slight ache after intensive exercise, and 2 complained of pain. The gait was studied in 30 patients and was classified as perfect in 24; 4 patients showed a mild limp, and 2 (both over 60 years of age) showed a marked limp. In this series there was no serious complication, and no death occurred from the operation.

Investigation for any consequent ill-effects of the transverse incision showed that loss of sensation was usually present, but in no patient was it a serious complaint. No evidence of impaired circulation was found in any patient. The action of the extensor tendon of the toes and tibialis anterior, which was studied in 26 feet, was good in 23. In the remaining 3 feet the tendons were weak, and the results were regarded as poor. A lateral radiogram of the foot and ankle was taken of every patient, standing barefoot with the knees extended. The plane of the sole was outlined by a metal wire. The angle between the plane of the sole of the foot and the line of the tibia was measured, and this was defined as the position of arthrodesis. The ankles of all patients (except one) with a perfect gait were arthrodesed, either exactly at the right angle or in slight calcaneus or equinus position.

NEUROLOGY & PSYCHIATRY

Psychological Implications of Hysterectomy. S. H. Sturgis and H. S. Robey. Connecticut Med. 23:786-792 (Dec.) 1959 [New Haven].

When a condition is found in the gynecologic clinic that demands hysterectomy, the resident surgeon explains the diagnosis and the operative procedure. A few patients accept the news with apparent relief. More often, however, the connotations of "operation" and "hysterectomy" induce an emotional black-out in which all further explanations and reassurances are rejected. There is little time in a busy clinic to allow for adequate recovery from this state, and misunderstandings often remain uncorrected. During an investigation of the influence of emotional factors on recovery from hysterectomy, one of the authors interviewed a selected group of 20 patients who had been advised to undergo hysterectomy. In the belief that an operation on the reproductive organs strikes deeply at a woman's psychological integrity, these women were seen before admission with the purpose of giving them a chance to talk freely about their proposed hospital experience. A quiet noncommittal "opening of the door" to whatever each woman wished to express first became the most favorable approach. Feeling genuine sympathy for what the patients were going through, and using psychiatric social-work techniques, the social worker established a warm and friendly relationship.

Each of the 20 patients, unprepared for what she would find in a social-work interview or in herself, was given the chance to voice her concerns and fears. The drive to express these and the accompanying anxiety varied according to each woman's emotional involvement and the strength of her personality defenses. These 20 clinic patients varied widely in education, social background, race, and religion. They showed also a considerable variation in duration and severity of symptoms and extent of pathology. The interviewer purposely did not review the medical history and physical findings. She was assured by the referring physician only that the tentative diagnosis was that of benign uterine disease. Just as every woman differed, so the process of each interview differed. The range of response ran from a denial, or blocking even, of knowledge of the planned operation to a "sensible" acceptance of the news; from confused thinking to obvious mastery of the situation; from blind fears and superstitions to controlled reality questioning and evaluation.

The interview itself apparently gave all the women a sense of support and relief, and the authors felt that the readiness of some to accept psychiatric aid stemmed from satisfactions arising out of the interview. Although these were clinic patients, the authors believe that similar reactions, with different coloring, are probably aroused to a certain extent in private patients faced with the same news. Since these women seemed to profit from the opportunity to verbalize their feelings about the anticipated operation, the authors suggest that a general hospital might consider making available some similar preoperative interview opportunity for patients anticipating major surgery.

The Epileptic in Relation to Pregnancy. H. Dimsdale. Brit. M. J. 2:1147-1150 (Nov. 28) 1959 [London].

The author reports on 5 women in whom epileptic attacks occurred in relation to pregnancy. As a result of better therapeutic and social management, the epileptic woman has increased opportunities of marriage, and epilepsy is likely to become a more frequent complication of pregnancy. The effect of pregnancy on the epileptic patient is unpredictable. The attacks may increase in number or remain unchanged. Reduction in incidence of convulsions is often related to better therapy. Epilepsy associated with menstruation usually persists in pregnancy. When attacks first appear in pregnancy (gestational epilepsy), these are likely to be partial or focal in character. The metabolic changes in pregnancy, such as hydration, hyperventilation, and dilution of calcium, sodium, and magnesium in the serum, favor an increase of convulsions. The variations in excretion of aldosterone are probably compensatory to fluctuation in sodium intake. Excessive gain in weight and sodium retention may precede the onset of increased convulsions. A genetic or constitutional factor is important in the appearance of seizures in toxemia of pregnancy. A persistent epileptic tendency may result. Status epilepticus is a rare but grave complication, especially when occurring in later pregnancy, and has a higher mortality than eclampsia. The onset of status epilepticus in pregnancy may be the first manifestation of a cerebral dysrhythmia.

The epileptic woman should not be discouraged from pregnancy, unless her attacks are difficult to control in the nonpregnant state, but there is no excuse for regarding this complication of pregnancy lightly. Antenatal care should be as thorough as in suspected toxemia of pregnancy. Management of pregnancy consists of suitable anticonvulsants, with dosage corrected for gain in weight. Phenobarbital in a slowly absorbed capsule form (Spansule), given at night, may carry the patient over the morning hours when retention of tablets is difficult, owing to vomiting. Anemia should be treated, and macrocytic forms, whether due to pregnancy or administration of anticonvulsants, will require administration of folic acid. Excessive gain in weight should be controlled by diet, restricted salt intake, and rest. If the response is unsatisfactory, the use of acetazolamide or ion-exchange resins should be considered. Status epilepticus may require the use of continuous intravenous administration of anticonvulsants, with controlled respiration. Investigation of gestational epilepsy to exclude a neoplasm may be indicated.

Isolated Trigeminal Neuropathy: A Report of 16 Cases. J. D. Spillane and C. E. C. Wells. Brain 82:391-416 (Part 3) 1959 [London].

Although isolated lesions of the trigeminal nerve are held to be uncommon, the authors have observed 16 patients with such lesions in the past 7 years. They point out that W. Harris, in his vast experience with trigeminal tic from 1935 to 1950, described 5 cases of neuralgia which was preceded by numbness of the face and trigeminal anesthesia. All the Harris patients had sudden, painless loss of feeling in one side of the face, which after weeks, months, or years was followed by paroxysmal trigeminal pain, similar to trigeminal neuralgia but lacking the characteristic triggers. Harris suggested that the initial lesion was an area of "neuritis" in the trigeminal sensory root, analogous to the lesion of retrobulbar neuritis. The paroxysms of pain did not begin before the facial numbness was regressing: this suggested to him that the pain was caused, in part at least, by stimuli arising distally in the aws and teeth and passing through nerves made bnormally "irritable" by the neuritic process.

The authors think that the site of the lesion of solated trigeminal neuropathy may be at any part f the first sensory neuron of the 5th nerve in its xtrapontine course. The data on the 16 patients re tabulated. In 15 of the 16 patients the predomi- ant lesion was impairment of sensation in the ter- itory of one or more divisions of the trigeminal erve. The course of the disorder tended to be enign. Taste was involved in some cases, and metimes autonomic fibers. In one case there was ophic destruction of the nose, bilateral xeroph- almia, and xerostomia. The histories of this pa- ent and of one other, which was a typical example sensory neuropathy, are presented in detail.

The one patient with involvement of both motor d sensory functions of the left trigeminus was fferent from the others in the series. His initial mptoms which were sensory extended rapidly roughout the territory of the second and third visions on the left, and within a week he was are of impairment of taste and of muscular akness on the same side. Actual muscle wasting s soon evident, and on opening his jaw it devi- ed to the left. When he was admitted to hospital weeks after the onset, the process had already ached its peak, and improvement had begun en he left 3 weeks later. Recovery thereafter s tedious, but was complete within a year. The olution of this illness suggested a virus infection: e patient had no signs of herpes zoster; the ex- sive sensory loss precluded a diagnosis of polio- elitis; and the solitariness of the lesion, together th the normal content of protein in the cerebro- inal fluid, made the Guillain-Barré syndrome im- obable. Similar cases have been reported in the erature under the title of "monoplegia mastica- ia."

Isolated trigeminal neuropathy must be differ- tiated from disorders which may encroach on the sory pathways from the face. Inquiries suggested at cases of similar neuropathy are seen from time time in neurological clinics. Many of them are vestigated as cases of suspected tumor, the nega- e findings on lumbar puncture and radiologic vestigation leading to a "negative" diagnosis. mor of the gasserian ganglion or of the sensory ot or the very rare neurinoma of a peripheral vision and other tumors beginning in or near eckel's cave constitute one of the most important fferential diagnoses of trigeminal pain and sen- ry disturbance.

GYNECOLOGY & OBSTETRICS

Trichomonas Vaginalis Cervicitis and Its Relationship to Cervical Cancer: A Histocytological Study. L. G. Koss and W. H. Wolinska. Cancer 12:1171-1193 (Nov.-Dec.) 1959 [Philadelphia].

During the latter part of 1951 and the first 6 months of 1952, the authors subjected 1,929 female patients of the Strang Cancer Prevention Clinic in New York, who had either a vaginal discharge or a clinically "inflamed" cervix or who showed cytological evidence of inflammation, to a hanging drop examination for the detection of Trichomonas vaginalis. Two hundred twenty-seven (11.7%) of these patients were found to harbor the parasite, whereas 1,702 patients were free of it. Of the 227 patients harboring T. vaginalis, 204 had routine "1-point" biopsies of the cervix. These were taken either from the posterior lip or from areas variously described as showing "erosion" or "redness" or being "iodine negative." Twenty-four of the 204 patients were eliminated from the final study because of insufficient smears or biopsies, and 8 additional patients had significant abnormalities of the cervical epithelium; the remaining 172 patients were available for the basic study of cervicitis due to T. vaginalis. Of the 172 patients, 42 had no follow-up, and 130 were followed up for periods ranging from 1 to 5 years or more, in order to establish the degree of persistence of cytological abnormalities commonly attributed to Trichomonas organisms and especially to see whether any of these inflammatory atypias may conceivably constitute a stage in the development of cervical cancer, as has been advocated by some workers. No routine biopsies were obtained in the 1,702 patients who were free of T. vaginalis; of these, 627 had no follow-up, and the remaining 1,075 patients were followed for periods ranging from 1 to 5 or more years. The purpose of evaluating this group of patients was to determine whether statistically significant differences in the behavior of the cervical epithelium could be established between the patients harboring T. vaginalis and those free of the parasite. All patients in both groups with suspicious results in the cytological examinations had multiple biopsies of the cervix, mainly of the "4-point" type. As additional control, biopsies and smears were examined in a group of 104 patients who were not part of the initial study but who were thought, on clinical grounds, to have some form of cervicitis not associated with T. vaginalis and who were used for comparison of cytological and histological changes with the Trichomonas group. All histological observations were based on the hematoxylin-eosin stain, and all cytological observations on the Papanicolaou stain.

The findings in these 3 groups of patients justified the following conclusions. Cervicitis associated with Trichomonas organisms is characterized by a greater intensity of the inflammatory phenomena than is seen in the absence of these organisms. The inflammatory changes affecting the squamous epithelium of the cervix are especially severe. Extensive vascular participation and considerable epithelial atypia may be observed. With experience, these phenomena may be readily differentiated from disorders with malignant traits, such as dyskaryosis and in situ carcinoma. Bacteriological data indicate that T. vaginalis alone can be implicated as the offending agent. Great caution should be exercised in attempting to estimate estrogenic activity in the presence of cervicitis due to T. vaginalis. Uncomplicated Trichomonas infection, even with severe inflammatory changes, does not warrant any particularly careful cytological follow-up. The incidence of Trichomonas infection *in patients with in situ carcinoma is higher than* the incidence in the population at large. The same is true of other gynecologic disorders and is probably the result of epithelial injury that favors the growth of Trichomonas organisms. The behavior of in situ carcinoma is not predictable, and a biopsy cure occurs in about 10 to 15% of all cases if the patients are kept under uniform conditions of follow-up. The presence or absence of T. vaginalis has no bearing whatever on this behavior. Dyskaryosis, an obscure phenomenon of cell abnormalities bordering on cancer, is observed with approximately the same frequency in the presence as in the absence of T. vaginalis.

The Effect of Pregnancy on Hepatolenticular Degeneration (Wilson's Disease): Report of a Case. J. H. Bihl. Am. J. Obst. & Gynec. 78:1182-1188 (Dec.) 1959 [St. Louis].

The author reports on a 26-year-old woman with advanced hepatolenticular degeneration (Wilson's disease), in whom pregnancy was successfully carried out and terminated with the delivery of a living, normally developed, healthy, full-term male infant. The patient's family history revealed hereditary evidence of Wilson's disease. At the age of 17 the patient noted a tremor of the right hand and speech difficulties; 3 years later she was hospitalized because of abdominal discomfort and dysarthria. At that time the diagnosis of Wilson's disease was established. The patient had previously been treated with chelating agents. During the eventful course of her illness, she had 2 early abortions. Her physical condition at the age of 22 showed some improvement, but her mental condition necessitated commitment to a mental institution. At the time of admission she was pregnant in the first trimester. During the first weeks of pregnancy there was an extensive hyperemesis associated with nephrotoxic signs. On one occasion she became febrile and confused and was treated for impending hepatic coma. Treatment with luteal hormones improved her condition during the latter part of this trimester. The control of her mental condition required the administration of promazine and rauwolfia. She continued to improve and was given leave of absence from the institution.

At the beginning of the third trimester, the patient returned to the hospital with abdominal cramps and low-grade fever. Pus and bacteria were found abundantly in the urine. Typical segmental arteriolar spasms were seen in the fundi of the eyes. In an attempt to consolidate the improvement of the disease, she was continued on a low-sodium diet, and rauwolfia was given to the end of pregnancy. About 4 weeks before delivery the patient developed intense prodromal labor pains with uterine contractions. The pains were more and more accompanied by vomiting and mental confusion, the closer the day of confinement approached. On the 297th day of pregnancy labor began. Uterine inertia was present, but the woman delivered an infant with all signs of maturity, without any developmental or pathological abnormalities, within 10 hours and 45 minutes. There was, however, less vernix caseosa covering the slightly macerated skin, and the subcutaneous turgor was diminished as seen in a stage of dehydration.

The remission of Wilson's disease in this patient continued. The liver impairment receded to subclinical manifestations, and the secondary blood dyscrasia returned to an almost normal pattern. The neurological symptoms, such as tremor dysarthria, and motor incoordination, diminished greatly. The kidney impairment was reversed only to a minor degree. Daily urine copper excretion decreased to normal. Mental symptoms and the Kayser-Fleischer ring remained unchanged. Thus this case shows that nature will take care of itsel in many instances and that pregnancy is a decided blessing in more than one respect.

Pregnancy as a Factor Influencing Relapse in Disseminated Sclerosis. J. H. D. Millar, R. S. Allison E. A. Cheeseman and J. D. Merrett. Brain 82:417 426 (Part 3) 1959 [London].

Inasmuch as the possible association between pregnancy and relapse in women with disseminated (multiple) sclerosis has been discussed repeatedly the authors analyzed the information obtained by 2 of them in a survey in Northern Ireland. The case records compiled by these investigators (Allison and Millar) in 1954 included information about sex, marital condition, age and date of onset, and dates of relapses and pregnancies. A diagnosis of multiple sclerosis was made in 390 women, and in this report the authors are concerned with 26 of these women. Findings suggested that the relapse rate experienced immediately after childbirth was higher than that experienced at other times by single or married women. They raise the possibility of a causal association between childbirth and relapse. The authors discuss 7 factors which suggest 2 possible explanations of the apparent causal connection: 1. Women who have pregnancies tend to date subsequent relapses closer to the childbirth than is true. 2. Women who have pregnancies experience the risks of relapse similar to other women, but, in addition, a relapse may occur earlier.

The authors conclude that there is no evidence of an ultimately worse prognosis in terms of frequency of relapse for childbearing women than for others. Some relapses which would have occurred in women who experience pregnancy are sometimes "anticipated" by the pregnancy. It is suggested that this "anticipation" might be brought about by the stresses of labor and increased work and responsibility of the puerperium, since other stresses, such as trauma, infection, and emotional disturbances, have elsewhere been implicated. With regard to treatment, the authors' studies imply that women with multiple sclerosis should be relieved of as much strain and work during pregnancy, childbirth, and the puerperium as is possible. Severity of relapse or length of subsequent remission was not taken into account in this study, but the authors feel that both of these factors will require investigation.

PEDIATRICS

Myocardial Infarction in the Perinatal Period: Report of Two Cases in Newborn Infants. R. Richart and K. Benirschke. *J. Pediat.* 55:706-712 (Dec.) 1959 [St. Louis].

Two cases of myocardial infarction occurring in the neonatal period are reported. In both instances the delivery was the outcome of an uncomplicated pregnancy; and both infants, born with the cord around the neck, were revived and appeared to be normal at the ensuing physical examination. The first infant, a girl weighing 6 lb. 9 oz. (2,976 Gm.), became cyanotic, although she was placed in 40% oxygen in the nursery. A low-pitched, rumbling, grade 3 systolic murmur was heard over the entire precordium with a maximum at the left sternal border. The second heart sound was inaudible in the aortic area, and the femoral pulses were weak. The electrocardiogram taken at this time was "consistent with congenital heart disease." Despite the intramuscular administration of 0.1 mg. of digitoxin, the infant became progressively cyanotic and died 15 hours and 9 minutes after birth. At autopsy the heart was found to be enlarged, without any other apparent abnormality. An infarction of the tip of a papillary muscle of the mitral valve was found incidentally on microscopic examination. The coincidental occurrence of cyanosis, systolic murmur, and rapid deterioration of the infant appears most consistent with the infarction of a papillary muscle in utero and its rupture shortly after birth. The rupture may have been precipitated by the sudden cardiac stress of extrauterine life.

The second infant, a girl weighing 6 lb. 6 oz. (2,891 Gm.), delivered by low forceps under gas-oxygen-ether anesthesia, progressed satisfactorily during 4 days, then began to have breath-holding spells and became lethargic. A chest roentgenogram showed an enlarged heart, and the electrocardiogram revealed atrial hypertrophy and an interventricular conduction defect. Cyanosis, absence of peripheral pulses, a gallop rhythm, a grade 2 systolic murmur, and an enlarged liver developed in succession, and the infant died at the age of 7 days. At autopsy the only gross abnormality was the heart hypertrophy. In the left ventricle the endocardium had the sclerotic, pale appearance characteristic of subendocardial fibroelastosis. On microscopic examination one small area of myocardial necrosis was found in the right ventricle. Areas of myocardial infarction were scattered over the interventricular septum and on the anterior left ventricle.

The authors believe that myocardial infarctions and coronary artery disease in the neonatal period are more common than is generally known. They emphasize the need for more extensive ante-mortem and postmortem studies regarding the etiology of such pathological changes.

Maternal Influenza and Congenital Deformities: A Prospective Study. V. P. Coffey and W. J. E. Jessop. Lancet 2:935-938 (Nov. 28) 1959 [London].

In an investigation into the incidence of congenital deformities in Dublin carried out in 1955, it was noted that 18.4% of the mothers of abnormal infants gave a history of having had what they termed "influenza" during their pregnancies. When it was predicted that the pandemic of Asian influenza would probably reach Ireland in October-November, 1957, it was decided to use this opportunity to investigate further the possible relation of maternal influenza to fetal deformities. During the 1957-1958 epidemic of Asian influenza in Dublin, 663 pregnant women attending antenatal clinics in the 3 maternity hospitals stated that they had had influenza during their pregnancies. The incidence of congenital deformities in the children born to these women was 2.4 times that in the children of the control group. This is a significant increase. The abnormalities were almost entirely of the central nervous system, and the commonest was anencephaly. The proportion of anencephaly to other abnormalities was about the same in the children of the maternal-influenza group as in the children of the controls. The risk of a malformation was greatest if the infection took place in the first 3 months, and it declined progressively in the 2 subsequent trimesters. There was no significant difference in the incidence of stillbirths and prematurity between the maternal-influenza group and the controls, and the sex ratio of the children was the same in the 2 groups.

Prophylaxis of Rickets in Premature Infants. H. Willi. Helvet. pædiat. acta 14:351-371 (Oct.) 1959 (In German) [Basel, Switzerland].

The author studied clinically, roentgenologically, and chemically 4 different methods of continuous prophylaxis of rickets in 100 premature infants, with a birth weight of 1,500 Gm. (3¼ lb.) or less, in the nursery for suckling infants of the gynecologic clinic of the University of Zurich, Switzerland. Fifty-five infants were given large doses of vitamin D, 15 were given moderate doses of this vitamin, 16 were given small doses of vitamin D and, in addition, calcium biphosphate, and 14 received small doses of vitamin D and, in addition, calcium gluconate or calcium lactate. The food given to these infants consisted mainly of human milk, to which later some buttermilk and nutrient sugar were added. Less failure (27%) of preventing the occurrence of rickets in premature infants was observed with daily doses of vitamin D ranging from 4,000 to 6,000 I. U. than with doses of 1,000 to 2,000 I. U. (53%). The best results, however, were obtained with small doses of vitamin D ranging from 500 to 1,000 I. U. combined with calcium biphosphate (400 to 800 mg. per day). The combination of vitamin D with calcium gluconate or calcium lactate showed the greatest incidence of failure (71%). The results of therapeutic experiments in twins showed particularly well that premature infants fed human milk need, in addition, small doses of vitamin D, calcium, and phosphor to be protected against rickets.

Clinical observations have shown that craniotabes is a less reliable sign of rickets than the thickening of the malleoli. Roentgenograms of the skeleton were of great help in differentiation of rachitic lesions. The author does not share the opinion of other workers that metaphysial osteoporosis of the extremities is to be considered an early sign of rickets. It may often disappear without the occurrence of rickets, and vitamin D does not exert any effect on this osteoporosis, which is related to an insufficient mineralization in the premature infant. It leads shortly after birth to hypocalcemia, which can only be corrected by mobilization of the calcium deposits in the metaphyses.

Surgical Treatment of Atrial Septal Defect in Children. D. C. McGoon, J. W. DuShane and J. W. Kirklin. Pediatrics 24:992-995 (Dec.) 1959 [Springfield, Ill.].

The atrial septal defect is one of those congenital malformations of the heart which, though detectable in childhood, often do not cause significant symptoms until later life. The authors report on 58 children, 15 months to 14 years of age, who were operated on for atrial septal defect, which was not associated with other cardiovascular anomalies, at the Mayo Clinic before December, 1958. Only 3 patients were less than 4 years of age, and 2 of them had more complicated anomalies than had been suspected preoperatively. In 32 of the 58 patients, symptoms or signs noted by the patient or parent could be related to the presence of the defect. Twenty-six patients presented easy fatigability or shortness of breath on exertion, and 10 presented failure to grow and to gain weight properly. Abnormal physical findings consisted of pulmonic systolic murmur in all the patients, prominent overactivity of the heart in 6, wide splitting of the second heart sound in the pulmonary area in all with accentuation of the second pulmonic sound i only 8. Cyanosis was not encountered. On operation the atrial well technique of repair was employed in most instances. In seven cases the technique with use of extracorporeal circulation wa considered necessary; this technique was chose in each instance because other or associated anomalies were suspected. In no case in which the atria well technique was chosen was a condition discovered that was inoperable by this approach. N mortality occurred, and the results were considere excellent in all cases. The authors believe that th repair of an atrial septal defect of significant siz is advisable even in the absence of appreciabl disability. Since there is no urgency for the operation and since conditions are optimal for the operation after the patient is 4 years old, that age shoul be awaited before advising elective operation.

Hiatus Hernia in Infants and Small Children: Report of Observations on 43 Cases. F. Rehbein an W. Hüther. Monatsschr. Kinderh. 107:467-473 (Nov. 1959 (In German) [Berlin].

Reports during the last 3 decades indicate tha hiatus hernia is frequently overlooked in infant and young children. In this report the authors ar chiefly concerned with 3 problems: (1) how to arrive at an early diagnosis; (2) the best method o treatment; and (3) the therapeutic results. The discuss the physiology of the cardia during the ac of swallowing, pointing out that the multiplicity o regulatory mechanisms of the cardia explains tha its function may become readily impaired. The differentiate between sliding hiatus hernias an paraesophageal hernias. Vomiting is usually th first and the most frequent symptom of hiatu hernia. It may appear shortly after birth, and i differs from that observed in the presence of pylorospasm chiefly by the admixture of blood to the vomit. This bleeding is usually caused by a reflu esophagitis, which nearly always develops after the hernia has existed for some time. The bleeding ma lead to hypochromic anemia, and the existence o this form of anemia together with blood-tinged vomit should suggest the possibility of a hiatus hernia. The roentgenologic aspects differ somewhat, depending on whether the hiatus hernia is of the sliding or of the paraesophageal type.

Of the 43 infants and children with hiatus hernia observed by the authors between 1953 and 1958, all but one were operated on. Conservative treatment, consisting chiefly of orthostatic measures to prevent reflux, is suitable only for children with mild forms of hiatus hernia, for while conservative measures may counteract some of the symptoms, particularly vomiting, the hernia and frequently the reflux with its damaging secondary effects may persist. Only 2 of the children operated on had a paraesophageal hernia. Despite the presence of a large hernial sac in both of these cases, no adhesions existed, and so the surgical treatment presented no difficulties. In 13 of the 40 children with typical sliding hernias, roentgenologic changes were already evident on the lower portion of the esophagus, considerable stenosis being present in 8 of these 13. Operation disclosed secondary changes, consisting of indurations of the wall of the esophagus or adhesions, in 11 other children. Only one-third of the children with sliding hernias were free from secondary changes.

With regard to the therapeutic results, the authors say that 34 of the 42 children operated on can be regarded as cured. Six children showed great clinical improvement, but roentgenologic examination still indicated persisting esophageal reflux. Two children died. The authors conclude that early surgical treatment, that is, even during the early months of life, is the best treatment for children with hiatus hernia, because in this way secondary esophageal changes will be prevented.

Prednisone in Childhood Leukemia: Comparison of Interrupted with Continuous Therapy. C. B. Hyman, E. Borda C., C. Brubaker and others. Pediatrics 24:1005-1008 (Dec.) 1959 [Springfield, Ill.].

Thirty children with acute lymphatic leukemia were treated with prednisone, 2.2 mg. per kilogram of body weight per day, for 28 days. After this initial course, they were alternately given interrupted or continuous therapy. In the group receiving the interrupted therapy, the drug was gradually withdrawn over the succeeding 5 to 7 days. In the continuous therapy group, the administration of prednisone was continued, but at a reduced dose of 0.55 mg. per kilogram of body weight per day. Both groups were followed by serial evaluation of the bone marrow, blood, physical findings, and symptoms. The therapy period was considered terminated when relapse occurred, as judged by the bone marrow. The groups did not differ significantly in the number of remissions induced, their duration, or the duration of clinical control. One patient in each group failed to obtain a remission of any degree. These studies do not indicate any advantage for continuous therapy over interrupted therapy with prednisone. On the other hand, with continuous therapy, there are the disadvantages of increased side-effects, higher cost, and the probability of permanent refractoriness to the drug.

THERAPEUTICS

First Clinical Experience with a New Synthetic Antidiabetic Drug, SB 1, or N$_1$-(3-aminobenezene-sulfonyl)-N$_2$-n-butylurea. G. Bickel and O. Koralnik. Schweiz. med. Wchnschr. 89:1186-1191 (Nov. 7) 1959 (In French) [Basel, Switzerland].

Two groups of patients were treated with Sucrida Berna [N$_1$-(3-aminobenezene-sulfonyl)-N$_2$-n-butylurea]. The first group was composed of 13 diabetic patients, between the ages of 60 and 85 years, who also had either another distinct or a complicating disease, such as arteriosclerosis, arterial hypertension, myocardial infarction, and osteitis deformans (Paget's disease). These patients had been hospitalized because of the additional disease. After a preliminary Pfeiffer test they were given Sucrida Berna tablets (50 cg. each) in doses which varied from 2 to 4 tablets daily. Six patients became free from glycosuria and returned to normal glycemia levels with a minimal dose (50 cg. to 1 Gm. daily). Six others required a dosage of 4 tablets daily (2 Gm.) to reach a satisfactory balance. Only one patient with pulmonary tuberculosis failed to benefit from the Sucrida therapy, and responded only to insulin.

The second group was composed of 17 diabetic outpatients without any nutritional deficiency or acidosis, and free from associated diseases. Fourteen of them were between the ages of 40 and 92 years; the other 3 were under 40, the youngest being 26 years old. The duration of the disease varied from 15 months to 22 years. All the patients had been on a diet comparatively low in carbohydrates and fat for several months before starting the therapy; they were kept on this diet except for slight variations. The initial dose of Sucrida was 1 Gm. daily, generally taken in the morning. After 8 days the dosage was reduced or increased as required. Urine and blood examinations were made every 3 days at first, then every week. At the end of a 6-week treatment the results were considered excellent in 10 patients (no glycosuria, or a maximum of 2 Gm. in 24 hours); satisfactory in 4 patients (no glycosuria most of the time, with an occasional increase up to 6 Gm. in 24 hours); moderate in 2 patients (persistent glycosuria, with an occasional increase up to 12 Gm. a day). In one patient the therapy failed to bring any improvement.

The authors believe that Sucrida Berna is an excellent coadjuvant to the dietetic treatment of patients who develop diabetes after the age of 40 and are free from nutritional deficiency and acidosis. In doubtful cases the results can be anticipated by the performance of the Pfeiffer test. Side-reactions are similar to those of carbutamide and tolbutamide, consisting of gastrointestinal irritation or allergic reactions, mostly cutaneous. Unlike carbutamide, Sucrida does not modify the intestinal flora. Sucrida Berna is slightly more active than carbutamide and slightly less active than tolbutamide.

Use of Trimethidinium Methosulfate (A New Ganglionic Blocking Agent) in the Treatment of Hypertension. N. O. Borhani. Ann. Int. Med. 51:983-992 (Nov.) 1959 [Lancaster, Pa.].

Trimethidinium methosulfate (Ostensin) is an asymmetrical bisquaternary amine, possessing ganglionic-blocking properties but demonstrating, in addition, a central component of antihypertensive activity. This paper presents the therapeutic results observed after the oral administration of trimethidinium methosulfate to a group of hypertensive patients; these were selected from a group of patients with severe hypertensive cardiovascular disease, who previously had received one of the ganglionic-blocking drugs presently in use, in combination with other antihypertensive medications, including chlorothiazide. The previous regimen of therapy was withheld, and the oral administration of trimethidinium methosulfate at a dose level ranging from 80 to 240 mg. per day was begun. Patients were given no other medication except digitalis preparations when indicated. The patients were seen in the clinic at 2-week or 3-week intervals.

Of 45 patients treated with trimethidinium methosulfate, 30 have been treated long enough to be evaluated. The drug proved to be a potent ganglionic-blocking agent in most hypertensive patients. It should be used with great caution, because it is unpredictable. When administered by mouth, the dosage should be adjusted according to the patient's response, varying from 80 to 200 mg. a day. The drug should be administered on an empty stomach, and not oftener than twice a day. The side-effects are usually of mild to moderate degree, and may include dryness of the mouth, constipation, blurred vision, and some degree of postural hypotension. The central nervous system manifestations and the severe gastrointestinal complications sometimes seen with the use of other ganglionic-blocking agents did not occur in this clinical trial. Should longer experience with trimethidinium methosulfate confirm this observation, the drug will have merit over other ganglionic-blocking agents presently in use.

Clinical Evaluation of Trimethidinium Methosulfate: A New Ganglioplegic Agent. J. G. Janney Jr., C. Caciolo, G. W. Duane and others. Am. J. Cardiol. 4:745-751 (Dec.) 1959 [New York].

The quest for better hypotensive drugs led to the development of a new ganglionic-blocking compound, trimethidinium methosulfate (Ostensin). This vasodilator drug, which acts through its ganglionic-blocking effect as well as centrally, was tested in 37 patients with hypertension, but the authors evaluated only the 20 patients who were seen at almost weekly intervals. The hypertension was classified as severe in 2, moderate in 15, and mild in 3 of the 20 patients. Most of these patients initially received pentapyrrolidinium, which was gradually replaced by trimethidinium, while other medications were not changed or withdrawn. Trimethidinium methosulfate was given initially in 2 doses of 20 mg. each at 12-hour intervals before the morning and evening meals. Each dose was increased by 5 to 15 mg. weekly, until the level of the blood pressure was reduced to 140/95 mm. Hg, or untoward side-effects limited further increase of the dose. When the total daily dose of trimethidinium methosulfate exceeded 200 mg., the drug was given in 3 divided doses.

Eleven patients experienced an excellent response; 4, a moderate response; 2, a fair response; and 3, a poor response. The duration of trimethidinium methosulfate administration varied from 24 to 48 weeks, with an average of 35 weeks. The average daily dose of trimethidinium was 334 mg., with a range of effective dose of 80 to 780 mg. Those same patients received an average pentapyrrolidinium dose of 533 mg., with a range of 30 to 933 mg. Thus, trimethidinium methosulfate appears approximately one and a half times more potent than pentapyrrolidinium. Of the 15 patients who received pentapyrrolidinium previously, 3 patients had shown an excellent response and continued to do so during trimethidinium methosulfate therapy. Of the 7 patients who had a moderate response to pentapyrrolidinium, 5 had an excellent response to trimethidinium, while 2 were unchanged. Two patients had a fair response to pentapyrrolidinium; on trimethidinium one of these attained a moderate response, and the other remained unchanged. A poor response to pentapyrrolidinium occurred in 3 patients, 1 of whom had an excellent response with trimethidinium, while 2 remained unchanged. Tolerance to trimethidinium methosulfate developed in 2 patients. Two patients with a poor response to trimethidinium achieved an excellent response when other hypotensive drugs were added to their regimens.

Constipation, blurring of vision, weakness, and dizziness were the most common side-effects seen with trimethidinium methosulfate therapy. Comparison of the results obtained with trimethidinium with those reported in the literature for pentapyrrolidinium and mecamylamine showed the control of blood pressure to be at least as good or better and the side-effects to be less severe and more manageable.

RADIOLOGY

Barium Fecaliths Following Gastrointestinal Radiography. A. G. B. Borden and M. B. Hermel. Am. J. Gastroenterol. 32:573-576 (Nov.) 1959 [New York].

The detection of barium fecaliths in the rectosigmoid of 2 patients, in both instances more than one year after barium studies, served as a stimulus for this investigation. One of these patients, a woman of 62 years, had her upper gastrointestinal tract and colon studied because of severe constipation. The other, a woman of 67, had a barium enema examination after colostomy. No laxatives or cleansing enemas were given after those examinations, and no further barium studies were made in the interval. The presence of large semisolid barium sulfate fecaliths was established by radiographic examination of the abdomen, and all were removed by the use of rectal instruments.

One hundred patients undergoing upper gastrointestinal or enema studies with barium were examined at weekly intervals with the purpose of determining the rate of evacuation. Fifty-seven patients examined were free of barium at the end of the first week. The remaining 43 expelled the barium mixture within one month. There was no barium fecalith formation in any of the 100 patients. There was no difference in the rate of expulsion between the orally and the rectally administered barium sulfate mixture. The formation of fecaliths in the 2 aforementioned women patients, more than one year after gastrointestinal studies, most likely represents a rare occurrence. It is, therefore, concluded that in the average patient the formation of fecaliths is most unusual and can be entirely avoided by a careful cleansing of the gastrointestinal tract after barium studies.

Bronchography in Pulmonary Tuberculosis: Clinical Value in 104 Cases. P. Federico, E. G. Espil and others. Prensa méd. argent. 46:1371-1375 (May 29) 1959 (In Spanish) [Buenos Aires].

One hundred four tuberculous patients were subjected to bronchographic examination for diagnostic purposes. The indication for bronchography was confirmation of suspected bronchiectasis in 88 patients, definition of cavities in 58, investigation of suspected cavities in 15, investigation of residual fistulas in 8, and control of the treatment in 11. Fifty-four patients had direct positive sputum for tubercle bacilli. In 111 of the 114 bronchograms taken on these patients, the contrast medium used was propyliodone (Dionosil) in a water suspension, with the addition of carboxymethylcellulose. An anesthetic 0.50% tetracaine solution was used in doses of 4 to 7 cc. Postbronchographic reactions were negligible in 97.5% of the patients; an increase in coughing and expectoration in the few hours subsequent to the examination was considered normal and useful for elimination of part of the contrast medium and its vehicle. Three patients had unfavorable reactions, one of them fatal; the latter was attributed to an excessive amount of contrast medium. The second reaction was attributed to an erroneous evaluation of the patient's condition, and the third had no apparent cause.

Radiologic images of bronchodilatation were found in 89 patients; bronchiectasis had been suspected in 88 of them. Localization of the tuberculous lesions in the upper lobe, parietal retraction (especially surgical), and pleural symphysis were indicated by the lack of opacity in the corresponding pulmonary areas. Bronchographic data did not clarify the investigation and confirmation of cavities and of postoperative residual fistulas. The authors believe that bronchography performed on tuberculous patients with a hydrosoluble contrast medium is a safe diagnostic aid, applicable when the course and the extension of the disease are accurately ascertained. It is the most effective diagnostic device in bronchiectasis associated or not with pulmonary tuberculosis, although it does not indicate the degree of the tuberculous condition in these lesions. It is also useful in indications for collapse therapy and in investigation of mechanical disturbances in the tuberculous and adjacent areas.

Radiation Induced Gastrointestinal Death in the Monkey. S. G. Wilson Jr. Am. J. Path. 35:1233-1247 (Nov.-Dec.) 1959 [Ann Arbor].

Monkeys, free of disease and weighing 5 to 7 lb., were divided into groups and were irradiated. In the radiation facility utilized, 32 radiocobalt (Co^{60}) sources, rated at 237 curies each, were distributed uniformly over a spherical wire frame, 36 in. in diameter. The dose rate in the exposure chamber centered in the sphere was 803 r per minute. Radiation doses ranged from 400 to 40,000 r. An earlier report presented the pathological features in 20 monkeys dying a "central nervous system death." With 2 exceptions, these were animals irradiated with 10,000 r or more. This report is concerned chiefly with 44 monkeys which received between 1,500 and 7,500 r. They exhibited a relatively uniform physical reaction. After the initial episodes of vomiting, diarrhea, nystagmus, and tremors, occurring during and immediately after irradiation, the animals rapidly recovered. By the 5th day after irradiation, however, anorexia and diarrhea reappeared and persisted. Emaciation and dehydration were prominent in all the animals and became more severe the longer the animal survived. In some cases there was as much as a 30 to 35% weight loss by the time of death. The first death occurred on the 4th day, and the last on the 9th day.

The most prominent findings at autopsy were gastric and colonic ulceration. Colonic ulceration occurred in 33 of the animals, and gastric ulceration occurred 13 times. While it is reasonable to assume that an acute dose of 10,000 r of gamma radiation would be at least as efficient as 7,500 r in producing gastric ulceration, it has been observed that animals irradiated with 10,000 r or more die within 3 days and fail to develop ulcers. Therefore, it is concluded that at least 4 days are required for the development of such lesions. After 4 days the incidence of ulceration is a function of dose rather than time. As the total dose is increased, the incidence of gastric ulceration increases. Since gastric ulceration was limited to that portion of the mucosa richest in parietal cells, it appeared probable that selective cell damage was an important factor in regulating the repetitious pattern of the lesions. The predilection of this particular cell for radiation damage was emphasized by the pattern of mucosal atrophy, as found in this experiment as well as in the experiments of others.

Evidence presented suggests that bacteria play a dominant role in the production of gastric and colonic ulceration after supralethal doses of radiation. The severe mucosal atrophy, which occurred in both the small intestine and the colon, could be divided into 4 basic types, which reflected the severity of cytological distortion of the epithelial cells and the degree of epithelial regeneration. In the small intestine the distribution of the lesion types was a function of radiation dose; in the colon the distribution was a function of survival time.

Clinical Experiences with the Effect of Prednisolone on the General Reaction to Irradiation (So-Called Irradiation Hangover), on Hematological Changes Depending on Irradiation, and on Tumor Cachexia. B. Freyer. Strahlentherapie **110:**401-412 (no. 3) 1959 (In German) [Munich, Germany].

The authors report on 50 patients, between the ages of 22 and 86 years, 49 of whom had malignant tumors and 1 had polyarthritis, and who were treated at the Roentgen Irradiation Institute of the City Rudolf Virchow Hospital in Berlin. Forty-three of the 50 patients underwent irradiation therapy, and 7 had tumor cachexia but were not subjected to irradiation treatment. The patients were given prednisolone (Deltacortril), either orally in doses of 5 mg. twice daily or intramuscularly in doses of 10 mg. once daily, for periods ranging from 5 to 80 days. Reactions to irradiation therapy improved quickly after administration of prednisolone. Patients who were given prophylactic treatment with prednisolone before they were subjected to irradiation therapy did not show any significant symptoms of general irradiation reaction. The effect of prednisolone could be substantiated by characteristic hematological changes in 17 of the 43 patients, i. e., by a reduction in the number of eosinophil leukocytes in the peripheral blood, which had shown a marked increase due to the administration of high roentgen-ray doses before the institution of prednisolone therapy. The outstanding effects of prednisolone in patients with tumor cachexia consisted of euphoria, of a favorable influence on the neurological changes caused by tumors or metastases of the central nervous system, and of the possibility (when the administration of prednisolone was combined with that of thyroxin) to produce remissions or to maintain the disease stationary for significant periods in patients with advanced carcinoma of the breast and bone metastases.

The indications for the use of prednisolone therapy in patients with cancer are, therefore, as follows: (1) symptomatic treatment of manifestations of irradiation intolerance and of symptoms of general reactions to irradiation (irradiation hangover); (2) palliative treatment of patients with far-advanced metastasizing tumors and tumor cachexia; and (3) administration of the drug as an adjuvant to patients with neurological secondary manifestations of tumors or metastases of the central nervous system.

The Therapy of Carcinoma of the Eyelid: A Report of 109 Cases. H. Saitmacher and R. Kropp. Strahlentherapie **110:**354-366 (no. 3) 1959 (In German) [Munich, Germany].

Fifty-seven women and 60 men with carcinoma in the areas of the eyelids and of the angle of the eyelids were treated at the irradiation clinic of the University in Marburg on the Lahn, Germany, between 1942 and 1957. The authors report on 109 of these patients, 81 of whom were given primary x-ray short-distance irradiation. The 5-year cure rate was 87.5%. Recurrences of cancer were observed in 16.1% of the patients. Chaoul's short-distance roentgen-ray therapy is the method of choice if the carcinoma is still limited to the eyelid or the canthus. If the tumor has infiltrated bones or orbits, radical surgical intervention and preoperative and postoperative radiotherapy are indicated.

Vertebra Plana (Calvé). W. J. Weston and G. M. Goodson. J. Bone & Joint Surg. **41-B:**477-485 (Aug.) 1959 [London].

The authors describe a case of vertebra plana and present serial radiograms which show the remarkable speed with which the vertebra may collapse and the changes in the pedicles and in one transverse process. A 3-year-old quarter-caste Maori girl was admitted to the Hutt Hospital at Lower Hutt, New Zealand, in May, 1953. She had had several attacks of pain during the 7 days prior to admittance, but apart from these episodes she ran about and played normally. On the day of admission she passed 2 stools consisting of bloody mucus, and acute intussusception was suspected. There was no history of recent injury or infection or of tuberculosis in the family. On examination it was noted that the patient resented being moved. She would lie on her stomach or left side when resting. Radiograms showed loss of the lumbar curve but no other abnormality. During the next days the back pain became worse. There was intense spasm of the posterior spinal muscles, and on attempted movement the child screamed with pain. Further radiograms taken 8 days after the first examination showed collapse of the body of the 5th lumbar vertebra, with increase in the depth of the adjacent spaces. Reexamination a week later showed the body of the 5th lumbar vertebra now as a thin disk. The superior and inferior end-plates appeared intact, and there was a further increase in the depth of the disk spaces above and below the vertebra. There was some loss of bone substance in the pedicles.

Treatment consisted of complete rest on a plaster bed, which relieved the patient immediately from pain. This immobilization was continued for 9 months, after which she was allowed up in a spinal brace. Serial radiograms during this time showed evidence of gradual healing of the lesion, with renewed growth of the vertebral body. The child has been reexamined regularly and has remained free from pain. When she was last seen in October, 1958, the lumbar spine was rather flat, but there was no suggestion of a gibbus. The spine was freely mobile in all directions. The last radiograms showed the body of the affected vertebra to be about half the normal depth. The disk above was of the same height as that between the 4th and 5th lumbar vertebrae, and that below was a little narrower. The anteroposterior diameter of the vertebral body was 40 mm., compared with 28 mm. for the body of the adjacent vertebral body. The progress of the disease in the vertebral pedicles and transverse process in this case is so like that seen in osteochondrosis (Calvé-Perthes disease) of the hip that it is felt that one cause of vertebra plana is aseptic necrosis. Biopsy was not carried out in this patient, and thus the nature of the underlying change could not be determined.

ANESTHESIA

Significance of Electroencephalographic Changes Occurring During Cardiopulmonary Bypass. R. E. Coons, A. S. Keats and D. A. Cooley. Anesthesiology 20:804-810 (Nov.-Dec.) 1959 [Philadelphia].

The authors collected technically adequate electroencephalographic records of 76 successive patients who underwent open cardiotomy with the aid of extracorporeal circulation for surgical correction of congenital or acquired cardiac defects. A bubble-type oxygenator was used, and the perfusion of blood was carried out at low rates ranging from 35 to 50 cc. per kilogram per minute. At the same calculated rates of perfusion, the electroencephalographic pattern remained unchanged in 16 patients, showed initial deterioration followed by recovery during perfusion in 27 patients, and showed changes which progressed to an absence of discernible electroencephalographic activity for periods up to 18 minutes in 33 patients. There were no differences among these 3 patient groups in the rate at which the electroencephalogram returned to its perfusion pattern, or in the degree of awareness shown by these patients in the immediate postoperative period. It is postulated that a level of cerebral perfusion exists, during which encephalographic activity cannot be identified, but during which there is sufficient tissue oxygenation to prevent cellular damage.

It would seem from these observations that the use of a normal electroencephalographic pattern as the criterion for adequate cerebral perfusion and as a guide in the regulation of extracorporeal perfusion rates is neither necessary nor desirable. The authors, however, continue to use the electroencephalogram during clinical anesthesia for open-heart surgery as a sensitive and valuable monitor in determining when hypotension from blood loss, bradycardia, or obstructed circulation has reached dangerous levels.

A Comparison of Ether Anesthesia with Thiopental-Nitrous Oxide-Succinylcholine for Upper Abdominal Surgery. J. P. Bunker, H. H. Bendixen, M. K. Sykes and others. Anesthesiology 20:745-752 (Nov.-Dec.) 1959 [Philadelphia].

The authors report on 693 patients scheduled for elective gastrectomy, cholecystectomy, or common duct exploration at the Massachusetts General Hospital in Boston between February, 1955, and August, 1958. Nineteen (3%) of the 693 patients were excluded, because of severe asthma, pregnancy, or errors in assignment of the anesthetic, and in the remaining 674 a controlled comparison of complications and deaths occurring during and after anesthesia and surgical intervention was carried out. Of these patients, 319 were anesthetized with nitrous oxide, oxygen, and ether, and 355 were anesthetized with thiopental, nitrous oxide, oxygen, and succinylcholine. There was no difference in over-all hospital deaths between the 2 groups. The improvement in operating conditions associated with the use of succinylcholine for relaxation (relaxant technique) was not great enough to cause a detectable diminution in surgical complications, total mortality, length of surgical intervention, or duration of hospitalization.

On the basis of complications directly related to the anesthetic agent, it was not justified to state that one agent or technique was "better" or "worse" than the other. Rather, certain dangers associated with the use of each of the techniques have been identified. Specifically, it appeared that ether anesthesia for upper abdominal operations offered an increased hazard of circulatory depression in the patients of advanced age and in women. On the other hand, the use of light general anesthesia, with succinylcholine for relaxation, appeared to involve, in addition to the obvious dangers of acute hypoventilation in the operative and immediate postoperative period, an increased incidence of the serious postoperative complication of atelectasis, which was greatest in men undergoing gastrectomy.

Hypothermia and Coronary Perfusion for Surgery of Atrial and Valvular Defects. F. J. Colgan, J. A. De Weese, J. A. Manning and E. B. Mahoney. Anesthesiology **20:**811-816 (Nov.-Dec.) 1959 [Philadelphia].

The authors report on 19 consecutive patients with atrial septal defects and 11 with pulmonary valvular stenosis, who underwent open-heart surgery with the aid of hypothermia and coronary perfusion. With a few exceptions, all the patients were premedicated with from 4 to 5 mg. per kilogram of body weight of pentobarbital sodium and 0.01 mg. per kilogram of scopolamine administered intramuscularly 1½ hours before the operation. Cyclopropane was used for inducing anesthesia most frequently in children, and thiopental most commonly in adults. Shortly after induction, electrocardiographic and electroencephalographic leads were attached to the patient. Tracheal intubation was accomplished in a light plane of anesthesia with the aid of succinylcholine. Gas, oxygen, and ether were then employed to maintain anesthesia during the cooling process. The patient was lifted from the operating table and placed in a tub half filled with cold water; he was suspended in the water on a canvas hammock, the cooling being accomplished by adding about 100 lb. of ice cubes. The esophageal temperature, on removal from the ice bath, varied from 31.5 to 33 C (88.6 to 91.4 F). The patient again was placed on the operating table, previously covered with a rubber mattress containing coils through which a liquid could be circulated. This was covered with a bed sheet and a blanket of cotton, on which the patient was placed. The blanket was used to dry the patient thoroughly and was then removed. After removal from the tub, the temperature continued to fall over the next 30 minutes to 1 hour. The average drop was 3.4 C, and the average esophageal temperature at the time of circulatory occlusion was 30 C (86 F).

Before circulatory occlusion, a small dose of a relaxant was given, and the patient was ventilated with 100% oxygen. Blood used for coronary perfusion was collected by the surgeon from the patient's aorta into a heparinized vacuum blood bottle, a few minutes before the vena cava was occluded, the aorta and pulmonary arteries clamped, and the coronary perfusion needle introduced into the base of the aorta. The cardiotomy was then performed, and coronary perfusion was manually controlled by the anesthetist with a commercially available blood administration set incorporating a pressure unit. Perfusion rate was usually from 2 to 3 cc. per kilogram per minute. Blood replacement was no problem. The average amount of citrated blood transfused during the operation was 600 cc. per patient.

Of the 11 patients with pulmonary valvular stenosis, who were subjected to postoperative cardiac catheterization, all showed a reduction of the systolic gradient across the pulmonary valve to an absolute level of 20 mm. Hg or less. All the patients were asymptomatic after the operation and showed major regression of evidences of right ventricular hypertrophy. Of the 19 patients with atrial septal defects, 17 survived, and all had cardiac catheterization as well as clinical evidence of complete closure of their septal defects, with the exception of one patient who showed clinical evidence of a continued left-to-right shunt, which was verified by cardiac catheterization. In the latter the shunt ha been reduced by about 50%, and the patient has had a significant clinical improvement since operation

Hypothermia has proved to be an easily managed and predictable technique. Coronary perfusion with the patient's own arterial blood during th time of occlusion and cardiotomy maintains or restores good myocardial tone and beat. The feasibility of this method of open-heart surgery on th community hospital level has been emphasized.

A Barbiturate Antidote: Use of Methylethylglutarimide in Barbiturate Intoxication and in Terminating Barbiturate Anesthesia. M. J. Marmer. California Med. 91:266-269 (Nov.) 1959 [San Francisco].

Four hundred eighty-eight consecutive patients who were operated on at the Cedars of Lebanon Hospital in Los Angeles were studied in relation to the sleep-reversal stage. The operations varied from a 15-minute-long uterine curettage to an 8-hour-long mastectomy. Only patients anesthetized with thiamylal sodium or succinylcholine or nitrous oxide-oxygen were included in the study. The patients' ages ranged from 7 to 89 years, with most of them in the 20 to 65 age group. Premedication consisted of 25 to 75 mg. of meperidine, or 0.2 to 0.4 mg. of either atropine or scopolamine. The anesthesia was given by the same anesthesiologist to all the patients. Thiamylal was given in doses of 200 to 400 mg. for short procedures, and in twice that amount, or more, for prolonged operations. Succinylcholine was given in a 0.2% continuous drip infusion with constant back titration, and was discontinued soon enough to permit spontaneous return of respiration and of adequate pulmonary ventilation. Nitrous oxide-oxygen was given for analgesia, usually in equal parts and in no instance less than 30% oxygen. Nitrous oxide was withdrawn toward the end of the operation, and the patient was permitted to breathe oxygen only for 3 to 5 minutes. Methylethylglutarimide (Mikedimide) was injected into the rubber tubing, which is part of the infusion apparatus, at the end of the operation in a sterile 0.5% saline solution.

The criteria of arousal were return of corneal reflexes, changes in rate and depth of respiration, movement of the extremities, response to command, and return to consciousness. At the beginning of the study, only 25 mg. of methylethylglutarimide was given to each patient, which proved to be ineffective. A dosage of 50 to 100 mg. was effective in most patients (420); they showed signs of arousal within 1 to 3 minutes after the injection. Sixty-eight patients who had received a dose of 500 to 800 mg. of barbiturate required 150 to 200 mg. of methylethylglutarimide and took 2 to 5 minutes to react. Unfavorable effects were observed in only one patient who developed phlebitis of the forearm. The author concludes that, although methylethylglutarimide is not a specific barbiturate antagonist, it may be considered as a possible antidote. The effect of this drug in stimulating respiration is striking. It reverses the neurological depression resulting from barbiturate anesthesia and the deep levels of narcosis resulting from barbiturate intoxication.

PUBLIC HEALTH

Herpetic Whitlow, a Form of Cross-Infection in Hospitals. H. Stern, S. D. Elek, D. M. Millar and H. F. Anderson. Lancet 2:871-874 (Nov. 21) 1959 [London].

Soon after the establishment of the "septic hand clinic" at St. George's Hospital, London, a relatively high incidence of septic lesions of the fingers was noted among the nursing staff. Altogether 54 cases have been observed, with an average of 3 weeks' loss of work per case. The condition may be a hitherto unrecognized form of hospital cross-infection. All lesions occurred in nurses and affected the digits, the thumb or index finger being most often involved. The whitlow starts as an area of irritation, which soon becomes very painful. It first appears as a deep vesicle, usually near the nail. Soon other vesicles appear, which coalesce, giving rise to a honeycomb appearance. They may remain localized or may spread by crops of fresh vesicles. The process commonly extends under the nail, which becomes separated from its matrix. At a later stage the appearance suggests a whitlow.

In the earlier phases the lesion contains only a little clear fluid, which later becomes turbid; and still later thick yellow necrotic debris, adherent to the underlying true dermis, is found. The small deep vesicles beyond the edge of the lesion establish the diagnosis. The best management is noninterference, treatment being limited to the application of a dry dressing for protection and the prescription of analgesics for the pain. In 7 cases there was a milder recurrence at the original site, from 1 month to 3 years later. It was assumed at first that the lesion was a staphylococcic infection, but, when this could not be proved, and some sterile cultures were obtained in the absence of antibiotic treatment, a viral cause was thought of.

Material for virus isolation was obtained by puncturing an intact vesicle and drawing some of the fluid into a pipette. The material was inoculated immediately into 3 tubes of primary human-amnion-cell monolayers. A cytopathogenic effect characteristic of herpes simplex virus was usually complete within 24 hours. Identification was then carried out by neutralization with high-titer herpes antiserums prepared in rabbits. After virus studies were begun, herpes simplex virus was isolated in 13 of 14 patients with whitlow. Blood was taken from all nurses starting work in the neurosurgical wards; and from those in whom lesions developed, a second specimen of blood was obtained about 2 weeks after the onset of infection. It was thus possible to compare the levels of neutralizing antibodies before and after a lesion. In all but 2 cases no antibody could be detected before the appearance of a lesion; these were primary infections. There was a history of a preceding infection in the 2 cases in which antibodies were present at the onset.

Inquiry about herpetic lesions in the wards revealed 2 possible sources of herpes virus: patients with obvious herpetic lesions, and symptomless salivary carriers. Herpetic whitlow can be readily mistaken for a staphylococcic infection, since it becomes secondarily infected with Staphylococcus pyogenes; but it is not associated with trauma, regional adenitis, or constitutional upset. Herpetic whitlow may be common in hospitals.

Epidemic Rubella in Taiwan, 1957-1958: III. Gamma Globulin in the Prevention of Rubella. J. T. Grayston and R. H. Watten. New England J. Med. 261:1145-1150 (Dec. 3) 1959 [Boston].

Studies of the effectiveness of gamma globulin in the prevention of rubella were carried out in 3 primary-grade schools during a large island-wide epidemic on Taiwan (Formosa). About 1,700 boys from the 3rd to 6th grades, whose average weight was 25 kg. (55½ lb.), were used as subjects. Tests revealed that 5 ml. of gamma globulin, made by 2 different manufacturers, reduced the incidence of rubella by 70%, after those cases occurring during the first week after inoculation had been excluded. Rubella convalescent-phase gamma globulin in doses of 2 ml., however, did not reduce the incidence of the disease; the attack rate among the boys receiving this material was similar to that among the controls who either had received placebos or had had no inoculations at all. The period of protection provided by the commercial-source gamma globulin began 1 week after inoculation and extended for 12 weeks. There was no evidence of modification of the rubella illness occurring in boys who had received this gamma globulin or the convalescent-phase gamma globulin.

Deaths from Asian Influenza Associated with Pregnancy. D. W. Freeman and A. Barno. Am. J. Obst. & Gynec. 78:1172-1175 (Dec.) 1959 [St. Louis].

The authors describe the clinical course and autopsy findings in 11 women, their ages ranging from 19 to 35 years, who died of Asian influenza in association with pregnancy during the epidemic in Minnesota in 1957. Three of the 11 patients were primigravidas, and 8 were multiparas. Three patients died during the second trimester of pregnancy, and 7 during the third; one patient died 5 weeks after childbirth. All 11 patients died of respiratory insufficiency, associated with an overwhelming pulmonary edema and pneumonia. This was demonstrated by clinical and autopsy findings in 9 patients and by clinical evidence in the remaining 2. The patients experienced typical "flu-like" symptoms for from 1 to 10 days before the onset of severe respiratory difficulty. The course was then a fulminant one, characterized by fever, marked respiratory difficulty, cough productive of large volumes of bloody sputum, prostration, and often cyanosis and shock. After the onset of these symptoms, 6 patients died in 24 hours or less, and 2 in 30 hours. There was no evidence that any treatment which was given significantly affected the clinical course. No inoculation with influenza vaccine had been given to 10 of these patients. Autopsy findings revealed pulmonary edema and pneumonia in 9 patients, and gross pulmonary hemorrhage in 7. Hyaline membrane formation was present in 3 patients, and abscess formation in 1. Isolation of the Asian strain, type A, influenza virus from the lung was successful in 3 of the 4 patients in whom it was attempted. Coagulase-positive staphylococci were cultured from the lungs in 2 patients; nonpathogenic bacteria were isolated from pulmonary secretions in 2; and a blood culture in another was sterile. No cultures were taken in the remaining 3 patients.

Reports on the pandemic of Asian influenza indicate that it was the leading cause of maternal mortality in Minnesota in 1957; 50% of deaths among women of childbearing age occurred in pregnant women. Routine vaccination of pregnant women with a suitable influenza vaccine may well be indicated in view of the apparently increased susceptibility of such patients to severe pulmonary complications.

Staphylococci in Cheese: Some Public Health Aspects. F. S. Thatcher, R. D. Comtois, D. Ross and I. E. Erdman. Canad. J. Pub. Health 50:497-503 (Dec.) 1959 [Toronto].

Earlier studies in 1956 in the laboratories of the Food and Drug Directorate, Department of National Health and Welfare, Ottawa, had revealed the common occurrence of toxigenic staphylococci in cheese. Since staphylococcic infections in man and in dairy herds have become increasingly important, and since outbreaks of food poisoning have been traced to cheese, a survey was made during 1957 of the distribution of staphylococci in marketed Canadian cheese made from unpasteurized milk and in cheese imported from several countries, most of which was made from pasteurized milk or subsequently had received bacteriologically equivalent heat-processing. In addition, from a particular factory (factory A), some of whose product had been shown to contain an outstandingly large number of staphylococci, a specimen of milk from each contributing herd was examined for the presence of these organisms, and specimens from 166 different vats of cheese from the same factory were tested for enterotoxin.

Cheese identifiable as to factory of origin and date of manufacture was purchased retail or from packaging establishments with a view to obtaining a representative selection from the main production areas of Canada. Three specimens, providing as wide a range as possible in date of manufacture, were bought from each factory source. For the more intensive examination of cheese from factory A, specimens were obtained to the extent available from each vat of cheese made over a 6-month period. In addition, a 100-ml. specimen of milk was obtained from a single shipping container from each of the 53 "patrons" of the factory.

Of the 149 specimens of cheese from factory A which were tested for enterotoxin, 8 evoked emesis in cats. Control specimens caused no reaction. All toxic specimens were from 30 to 60 days old. Numbers of staphylococci present in the emetic specimens ranged up to 1,500,000 per gram. All staphylococcic strains from emetic specimens were of phage patterns containing 42D in association with other phages. The characteristic type 42D alone was not involved. Thus, the studies showed that coagulase-positive staphylococci are common in Canadian cheese made from unpasteurized milk. The presence of chronic or active mastitis in cattle is considered to be a major contributing factor, as shown by the recovery of the same phage types of staphylococci in cheese as were present, often in very large numbers, in milk from the same sources as used in its manufacture. No staphylococci were found among 236 specimens of imported cheese, made for the most part from pasteurized milk or heat-processed after manufacture.

BOOK REVIEWS

Clinical Auscultation of the Heart. By Samuel A. Levine, M.D., Sc.D., F.A.C.P., and W. Proctor Harvey, M.D., Associate Professor of Medicine, Georgetown University School of Medicine, Washington, D. C. Second edition. Cloth. $11. Pp. 657, with 660 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; 7 Grape St., Shaftesbury Ave., London, W. C. 2, England, 1959.

This book merits attention, first, because one of the co-authors, Samuel Levine, is a perceptive physician who has devoted a medical lifetime to discovering what he can learn of the heart by seeing, feeling, and hearing what goes on in the precordium and the places in which peripheral vessels may be examined. Second, here is an honest and effective attempt to encourage physicians to use the commonest tool of their trade, the stethoscope, with skill and imagination. Even the modern physicians who will not accept a diagnosis in which laboratory apparatus and technicians are not extensively involved may agree that listening to the heart, if done expertly, will at least give the earliest clue to what further tests are needed.

One might wonder how so large a volume could be written about the limited part of physical examination dealt with here, but when one considers that the authors attempt to give the auscultatory findings of every normal and abnormal condition that affects the heart, the mystery disappears. There is some repetition which tends toward dull and tedious reading, but on the other hand the book contains some "pearls of great price." For instance, the frequently repeated advice to "inch" over the whole precordium when attempting to discover the timing of a murmur or extra sound is valuable. Recognizing the simple fact that the louder of the two sounds heard in the aortic area is the aortic second sound, one can be sure when systole ends. Then as he listens inch by inch down the precordium to hear such things as a gallop, which may not be heard at all at the base, he usually is able to tell whether it is systolic or diastolic in timing.

The scheme throughout the volume is to present electrocardiographic tracings (usually lead 2) synchronized with phonocardiograms so that the sound effects of the events of the cardiac cycle may be correlated with what one hears. Half of the space is filled with these illustrations, and the other half is the written account of what is heard, together with the explanation of the various sounds. The reader apparently is expected to accept the opinions of the authors as gospel as no references are given. Probably no one has listened to or thought about the human heart more diligently than Dr. Levine. Yet, one would think that in dealing with a subject so sharply circumscribed, some of the experimental evidence beyond phonocardiograms might be briefly alluded to. Even an occasional dissenting opinion might be cited so that it could be knocked down.

In the introductory chapter, the authors point out that the phonocardiogram is not necessarily the last resort in deciding whether or not a murmur is present and how important it is, but when the illustrations are completely confined to the scheme described above and the discussions correlated with them, most physicians will come to the conclusion that differences of opinion regarding murmurs can rarely be resolved without such laboratory aid. As the reader goes through this book, he quickly realizes that its maximum usefulness would be attained by having it open at the bedside as he examined normal and diseased hearts, so that the sounds described could be heard and identified at once. Perhaps Drs. Levine and Harvey will some day prepare a set of records of heart sounds with a running commentary in between, such as Bernstein and the other maestros use to initiate the novice into the nuances of fine music.

The use of "auscult" in place of auscultate or listen, and such phrases as "We certainly can not ascribe to the old teachings that a gallop must be above a certain heart rate to be of significance" are unfortunate. It is also regretted that a simple diagram of the heart pointing out where certain murmurs, split sounds, gallops, etc., are heard was not reproduced somewhere in the book. These are minor criticisms. It is a good book for beginner and expert. Every physician who undertakes to give a patient advice about his heart or to treat disorders of that important organ should profit by reading the book.

Dental Roentgenology. By LeRoy M. Ennis, D.D.S., F.D.S., R.C.S., Chairman of Department of Roentgenology, and Professor of Roentgenology, Thomas W. Evans Museum and Institute, School of Dentistry, University of Pennsylvania, Philadelphia, and Harrison M. Berry Jr., D.D.S., M.Sc., Professor of Roentgenology, Thomas W. Evans Museum and Institute, School of Dentistry, University of Pennsylvania. Fifth edition. Cloth. $15. Pp. 607, with 1282 illustrations. Lea & Febiger, Washington Sq., Philadelphia 6, 1959.

This new edition emphasizes clearly the authors' belief that radiodontia is of major importance in diagnosis. The subject matter of this book is well organized and logical in arrangement. The first seven chapters deal with principles of x-ray production and versatility and effective use of x-ray equipment. A description of the important methods and techniques used for making intraoral and extraoral radiographs is included. The effects and dangers of radiation are evaluated in a rational and unemotional manner. Methods are presented for minimizing harmful radiation doses to which patient and operator may be exposed.

The remaining seven chapters cover the area of radiographic interpretation. Radiographic findings of the developmental processes and variations of normal and pathological conditions are well documented with numerous illustrations and precise descriptions. Radiographs showing obscure and unusual conditions are included, and these findings probably represent the most important and valuable material in the book. The authors make little attempt to appraise or evaluate the relationship of oral radiographic findings to systemic disease. Although the discussions are presented from the viewpoint of the dentist, much of the material should be of interest and value to the medical practitioner.

Metabolic Aspects of Renal Function. By William D. Lotspeich, M.D., Professor and Chairman, Department of Physiology, University of Cincinnati College of Medicine, Cincinnati. Cloth. $7.50. Pp. 214, with 58 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This well-written and comprehensive monograph deals with transport of phosphate, amino acid, organic acids and bases in the cells of the renal tubules, and the tricarboxylic acid cycle in the kidney. The chapter dealing with the effects of phlorhizin is excellent. The author assumes a familiarity with basic ideas in cellular metabolism and renal tubular secretion and reabsorption. The kidney is a remarkable organ which excretes almost completely many phenolic substances such as iodine compounds used in urography and found in para-aminohippurate. Since excretion of these involves work, and excretion parallels blood flow, the renal metabolism varies with blood flow. The progress being made in the study of this organ's curious metabolic behavior is concisely described and fully documented in this book.

Water Supply for Rural Areas and Small Communities. By Edmund G. Wagner, Chief Engineer and Associate Chief of Field Party, Division of Health and Sanitation, Institute of Inter-American Affairs, Rio de Janeiro, Brazil, and J. N. Lanoix, Sanitary Engineer, Division of Environmental Sanitation, World Health Organization, Geneva, Switzerland. World Health Organization monograph series no. 42. Cloth. $6.75; 35 shillings; 20 Swiss francs. Pp. 337, with 85 illustrations. World Health Organization, Palais des nations, Geneva, Switzerland; Columbia University Press, International Documents Service, 2960 Broadway, New York 27, 1959.

Fundamental information on acquisition of a water supply has been put together in a brief and practical form for use by people living in small communities located in remote or rural areas of the world. The authors have intentionally omitted many of the complex details usually included in a book on water supply but have listed references for supplemental information. The purpose of the book is not only to stimulate people to initiate their water development programs but also to serve as a pattern by which to carry out such programs. The book accomplishes this purpose.

The first section deals with the planning which must be done by the people in the community who are to direct the development of a water supply program. The socioeconomic and political difficulties which may be encountered are well stated. Methods by which these problems can be avoided or solved are suggested. The diagrams of the various methods of obtaining either surface or underground water by hand or motor driven pumps can be easily understood. Advice concerning the need for training personnel so that there will be proper administrative and functional operation of a water system during the growth of the community is included. The book is a practical handbook and reference book for any physician practicing in an isolated community which does not yet have a municipal water supply.

Recent Advances in Cardiology. By Terence East, M.A., D.M., F.R.C.P., and Curtis Bain, M.C., D.M., F.R.C.P. Fifth edition. Cloth. $10. Pp. 421, with 133 illustrations. Little, Brown & Company, 34 Beacon St., Boston 6; J. & A. Churchill, Ltd., 104 Gloucester Pl., Portman Sq., London, W. 1, England, 1959.

This new edition is an orderly, thorough, modern, and complete treatise on cardiology. Some chapters may be too complex for men in general practice, but even for them it constitutes a valuable source of widely accepted references. Nothing unorthodox or debatable has been included. It makes good and, as a whole, simple and interesting reading and is recommended without qualification.

Atlas of Rœntgenograpic Positions. Volumes One and Two. By Vinita Merrill. Second edition. Cloth. $32.50. Pp. 291; 295-663, with illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3; Henry Kimpton, 134 Great Portland St., London, W. 1, England, 1959.

The first edition of this work, which appeared in 1949, is recognized as a standard in its field. It might have been more accurate if the publishers had called this recent volume an additional printing rather than a new edition as there have been only minor changes in the text and practically no changes in the illustrations. Anyone owning the first edition would have nothing to gain by purchasing the second. Anyone who does not own the first edition, however, should welcome the opportunity for acquisition which this new printing affords. Most of the text can still be considered up-to-date as there has been little necessity for change in the past 10 years. This is not so in relation to angiographic examinations as here, too, the second edition reprints the original text and illustrations; in 1949, this material, which has as its reference a 1941 publication, was out of date; so, in 1959, it is mainly of historical interest in view of the many developments and accomplishments in this field.

QUESTIONS AND ANSWERS

TERILITY

'o THE EDITOR:—*What diagnostic procedures and treatment can be recommended for a 32-year-old man and his wife who have been married three years and have a sterility problem? The wife has had a complete gynecologic examination which did not indicate any abnormalities. The husband's history and physical examination likewise showed normal findings, and his sperm counts, done on two specimens, were 98,000,000 and 100,000,000 per cubic centimeter respectively. The volume and pH of the samples were normal. Although the morphologic characteristics of the spermatozoa were normal and a testicular biopsy (one side only) showed normal spermatogenesis, all were nonmotile.*

Richard Onofrio, M.D., Los Angeles.

ANSWER.—Total necrospermia in a specimen with count of 100,000,000 spermia per cubic centieter is unusual. It is likely that an error was made the collection of the semen sample through ixture with some chemical substance from a conom, chemical contamination of the receptacle sed for collection, or storage of the sperm at a mperature which was incompatible with their fe span prior to examination. The specimen should e collected in a clean, dry glass jar, stored at a mperature of about 60 to 70 F, and examined ithin one to three hours.

Presumably, the spermatozoa were alive at the rmination of spermatogenesis, in which case a emical alteration in the secretions from the acessory genital glands could kill them; no evidence f this is presented, however. Immobility of sperm ccasionally is due to abnormalities of the centrior bodies and of the caudal extremities, although e sperm heads appear normal. A selective stain hich has a strong affinity for the cytoplasmic omponents of the sperm, such as a 1% aqueous olution of rose bengal, may show structural abormalities. To investigate whether all of the ermatozoa were actually dead one can use a ital red stain or the Blom eosin-nigrosine stain, he latter coloring only the dead sperm.

When sperm motility is less than 30%, fertilizaion of an ovum is not likely to occur, irrespective f the type of therapy given the husband. Since ost of these difficulties are of genetic origin, the dministration of various endocrine substances, inluding thyroid extract or other metabolic stimulators, has no place in the therapy of either male or female sterility of undefined etiology or in a case in which the clinical and laboratory findings fail to signify any significant deficit of the respective hormone.

FIRE ANT STING

To THE EDITOR:—*Is there a new or specific treatment for bites by the fire ant (Solenopsis saevissima richteri)? In my section of Alabama such bites are common, and the patients often have a secondary infection with lymphangitis. Sometimes the lesions become chronic and do not respond to usual measures of treatment. Is the reaction to the bite an allergic phenomenon or due to bacterial invasion?*

Jim S. Phillips, M.D., Butler, Ala.

ANSWER.—The venom of the fire ant is no longer considered to be formic acid, for pure venom is alkaline in reaction and gives a positive nitrogen test result. A crystalline hemolytic principle, with the properties of an amine, which makes up about 90% of the liquid venom, has been isolated.

The ant stings rather than bites, although the mandibles are used to fix its head on the skin. The ant then arches its back at the peduncle and inserts the stinger. It may remove the stinger, and, using the head as a pivot, rotate and reinsert the stinger in two or three additional sites. This clustering of stings is useful in diagnosis. After a victim is stung, a wheal immediately appears in the skin and persists for one hour, regardless of local therapy. Eight to 10 hours later vesicles containing a cloudy fluid, which soon becomes purulent, develop at the puncture site. At this time the vesicles are sterile, but when they rupture, a secondary infection may supervene and cause lymphangitis. An infectious eczematoid dermatitis may develop later, or a more chronic residuum may persist as lichen simplex chronicus.

In addition to the local reactions, the occurrence of febrile or allergic systemic reactions is not infrequent. The fever usually lasts 24 to 48 hours and is rarely more than one to two degrees above normal. The allergic reactions are first manifested by increased local responses in patients to ant stings (larger areas of local edema, erythema, and discomfort); the pustules do not increase in size. Patients may develop generalized urticaria and bronchial asthma shortly after being stung, but more often the victim suffers from a burning sensation, nausea, throbbing in the temples, and apprehension. A few instances of anaphylactic reactions in victims have been recorded.

The answers here published have been prepared by competent auhorities. They do not, however, represent the opinions of any medical r other organization unless specifically so stated in the reply. Anonynous communications cannot be answered. Every letter must contain he writer's name and address, but these will be omitted on request.

There is no satisfactory treatment for the local pustules, which generally clear up in three to seven days. Topical application of steroid, antibiotic, or antihistaminic medicaments is of no value at this time. The allergic reactions are controlled with epinephrine and antihistaminic drugs. Patients can be desensitized against the allergic component of the reaction, but desensitization does not eliminate the formation of vesicles after a sting.

MINCED SKIN FOR GRAFTING

To the Editor:—*Do you have information on a type of treatment for burns which consists of grafts with finely chopped skin?*

A. A. Linington, M.D.,
Sinoia, Southern Rhodesia.

Answer.—Patients who have been burned through the full thickness of skin pose an urgent and difficult problem, because, while early coverage of the lesion is essential to stop bacterial ingress and fluid loss, donor sites from which autoplastic skin grafts can be obtained may be limited.

Various methods have been advocated for making the available grafts serve a wider area. Thick-split grafts have been cut into small "patch grafts" or "postage-stamp grafts," letting intervening areas fill as the graft extends peripherally. Thick-split grafts can be taken repeatedly and periodically from the same donor area but give slow coverage. Temporary homoplastic grafts have been used for immediate coverage, followed by autoplastic grafts when the homoplastic grafts liquefy and disappear. Skin for grafting has been cut into tiny pieces which, with the use of the blunt end of a straight needle, were then pushed beneath the granulation tissue at an angle.

In 1898 Von Mangoldt scraped donor sites with a razor blade to secure a "pulp" of epidermal cells for grafting. The method in question is a "micro" refinement of the pinch graft, which was widely used at one time. In 1956 Najarian used a sterile kitchen food blender to mince a graft consisting of particles no larger than 10 to 100 cells, which were spread on gauze and then applied to the recipient surface. The results of experimental work performed on rabbits are difficult to interpret, because in these animals the loose skin attachment allows an unusual degree of contraction. Cox and Nichol reported in 1958 that, while this method allows coverage of two and one-half times as much wound area as thick-split grafting, it does not prevent early fluid loss or development of infection. They noted severe wound fixation and contraction, whic resulted in an extremely thin epithelium whic deteriorated when subjected to minor trauma.

RETARDED ENDOCRINE DEVELOPMENT

To the Editor:—*Please recommend treatment fo 12-year-old boy whose testes are palpable times in the scrotum and at others in the ingui canal and are smaller than would be normal his age. Results of tests for 17-ketosteroid a ketogenic steroid levels in this boy are in normal range. The radioiodine* (I^{131}) *concent tion of the thyroid gland was 8% of the d administered and 10% in 24 hours.*

Melvin A. Shiffman, M.D., San Diego, Cali

Answer.—If, in addition to his migratory te (Kunstadter, *J.A.M.A.* 148:117 [Jan. 12] 1952), boy shows other evidence of hypogenitalism and tarded growth in his physical development, de mined by the size of his penis, the presence or sence of pubic hair, and radiographic demonstra of his bone age, he should be given 1,000 IU chorionic gonadotropin intramuscularly three ti weekly for four to six weeks. This usually causes largement and permanent descent of the testes and a generalized spurt of body growth, with appearance of secondary sex characteristics. More than one course may be necessary.

The patient's I^{131} uptake is in the hypothyroid range. The results of such determinations may be influenced by previous ingestion of drugs or foods containing iodine, and this possible source of error must be considered. Determination of his bone age will give some information, but determination of the serum butanol-extractible iodine level is a more reliable test and is not influenced by ingested iodine. If the diagnosis of hypothyroidism is confirmed, thyroid therapy should be given.

RARE DISEASE OF LEUKOCYTES

To the Editor:—*What is Chediak-Higashi disease?*

Stephen Mamick, M.D., Williamson, W. Va.

Answer.—The term Chediak-Higashi refers to an anomaly of leukocytes. Whether the condition is hereditary in nature or a degenerative process due to systemic disease such as lymphoma or leukemia remains undetermined. The characteristic features exhibited by patients with the disease are enlargement of spleen, liver, and lymph nodes, with changes in the leukocytes. The condition occurs rarely, and only a few cases have been reported.

SPECIAL REPORT RAPS FORAND LEGISLATION

A report on medical care for the aged, compiled y the National Association of Manufacturers, deared that "There is no justification for imposing ı the entire nation a compulsory program that is ınecessary and hazardous."

Proposals in Congress such as the Forand bill to ovide partial financing of some health care needs the elderly through the social security system epresent another stimulus to the ever-increasing ependency of the individual [person] on the fedal government and to the ever-increasing control individual disposable income by Washington," ıe NAM said.

"Voluntary health insurance provides the answer, ıd within a relatively few years all of our senior tizens who want or need such protection will have ," the report noted.

Not only would the measure be unnecessary, the AM said, but it would add to inflation, costing billion dollars a year to start and 7.5 billion dollars year by 1980. Furthermore, "The Forand proosals would not provide care for most people who eed it, since three out of four recipients of Old ge Assistance—the indigent aged—are not OASI eneficiaries nor would they be eligible for benefits."

Meanwhile, Sen. Hubert H. Humphrey (D., Iinn.), a leading candidate for his party's presidenal nomination, renewed his support for Forandpe legislation. In a six-point program for senior itizens, he included a plan to "extend the social ecurity system to cover costs of hospital and nursıg home care for senior citizens." The Forand bill ould also provide payments for surgical services. ınother Democratic presidential hopeful, Sen. John ennedy (D., Mass.), also has sponsored a wide overnment medicine bill.

The Senate subcommittee on aging, the Demoratic majority of which has urged similar legislaion, was slated to start a new round of hearing Iarch 21, with national authorities in the fields of eriatrics and medical economics called to testify.

NEW SPACE MEDICINE DIVISION SET UP

How man can survive in space and whether life exists on other planets were the tasks assigned the ıew Office of Life Sciences of the National Aeronautics and Space Administration (NASA). Named to head the office was Clark T. Randt, M.D., who had formerly been the agency's chief scientist for space medical research.

The office was established as the result of a recommendation by NASA's bioscience advisory committee which said the agency "should undertake a vigorous program in the life sciences as an integral part of the national space program." The committee said NASA should make the fullest possible use of existing aeromedical facilities operated by the military services, while at the same time developing capability for research peculiar to its own programs in manned space flight and basic biological research.

The prime goals of the new division were the biomedical aspects of manned space ventures, fundamental biological problems of space environments, and the search for extraterrestrial life.

Other recommendations of the advisory committee were that (1) the new office be staffed with assistant directors of basic biology, applied medicine and biology, medical and behavioral sciences, and the life sciences extramural program—sponsored research through grants at universities and private facilities as well as at other federal agencies; (2) provisions be made for training and education in the form of training grants, and fellowships; and (3) exchange of information within the scientific community be emphasized.

Dr. Randt, aged 42, earned his medical degree at Western Reserve University in 1943 and joined the medical faculty of that school in 1950 as associate professor of neurology. He later served as director of the division of neurology at the University Hospitals of Cleveland in 1956. He joined the NASA staff last July.

FOOD CHEMICALS LAW GOES INTO EFFECT

A broad law aimed at protecting consumers against harmful chemical additives in food went into effect March 1, but the average consumer will probably notice no difference in the foods he buys.

The law, stemming from a 1959 measure passed by Congress, requires food processors to submit to the Food and Drug Administration proof of the safety of chemicals used to flavor, preserve, or color foodstuffs. Previously, the burden of proof was on the government, which had to go to court to take challenged products off the market. New additives already had been subject to this regulation for a year.

FDA Commissioner George P. Larrick said no widely known food chemical will be banned immediately and that no crackdowns are expected in the near future, although some chemicals used in food may eventually be barred.

whenever digitalis is needed

'LANOXIN'®
brand
DIGOXIN

formerly known as Digoxin 'B.W. & Co.'®

"If one digitalis agent were to be recommended for its adaptability to the many and varied clinical contingencies, we believe Digoxin would be [a] drug of choice."

Lown, B., and Levine, S. A.:
Current Concepts in Digitalis Therapy, Boston,
Little, Brown & Company, 1954, p. 23, par. 2.

The law states that chemical additives are to be banned unless they are generally recognized a safe by a large committee of government and pri vate experts established by FDA, or have beer cleared by FDA. The food industry has approve the legislation.

Complete approval has been given by FDA to 3S common substances such as salt and sugar as direc additives in food. Temporary approval—for one yea —has been granted an additional 404 products—13 additives, 202 paper and paperboard materials, an 67 packaging materials. Preliminary tests have ind cated these were not harmful.

The major controversy in regulation of chemic additives has been over an amendment prohibitir use of chemicals that in large quantities may pr duce cancer in test animals or human beings, b that in minute quantities might be absolutely saf The FDA has vigorously supported this amendme on grounds that not enough is known yet about t possibility of cancer danger in human beings fr such sources.

STRONG ATTACK URGED ON ENVIRON MENTAL HEALTH HAZARDS

The Public Health Service called for a unifi coordinated attack on what it described as t growing danger to health from polluted or c taminated air, water, and food.

In a special report on environmental health p pared for the House Appropriations Committ PHS said that for the next 10 years hazards fr the environment can be expected to increase.

The report said there is greater pollution of from chemical sources such as factory smoke a automobile exhaust, in addition to higher levels radioactivity. Knowledge of the effects of low-le radiation is grossly inadequate at the present tir according to PHS.

In some areas chronic bronchitis is becoming increasing cause of disability, the report said, w the rate of occurrence apparently related to clim and to pollution of the air.

"Evidence is also mounting that other dise entities such as lung cancer and emphysema a may be related to air pollution."

About three-fourths of all communities of o 1,000 persons in this country use open dumps other unsatisfactory methods of solid waste dispo contributing to air and water pollution, the rep stated. Use of pesticides on crops and chemi additives in food pose still other new probler

"There are strong indications that unrecogniz occupational factors may contribute to the etiolo of disease now considered solely degenerative origin. Social conditions and strains in the occu tional climate have definite bearing on mental a emotional health.

"Less well understood, but pressing for conside tion, are the health implications of noise, spe pressure, crowding, and associated tensions."

As for water pollution, "Research must be carri out to develop methods of preventing pollution, determine the maximum amounts of polluta tolerable, to find ways of treating harmful bacter agents, or chemical substances in solution.

"The Public Health Service is the logical unit direct an attack on environmental health proble as an interrelated system."

VA OPTOMETRY BILL CLEARED BY HOUSE COMMITTEE

Despite objections by the Veterans Administraion and the American Medical Association, the Iouse Veterans Affairs Committee approved a bill llowing federal compensation of optometrists for utpatient care given veterans with service-conected eye conditions.

In a letter to the Committee, Dr. F. J. L. Blasiname, A. M. A. Executive Vice-president, had said hat "Inasmuch as these activities constitute the ractice of medicine, it is our considered opinion at they should be performed exclusively by qualied doctors of medicine."

In a report on the bill, the Committee said that it xpected the measure would allow VA to "material- expand its use of the services of optometrists in its utpatient fee-basis program. At the same time, the ommittee recognizes that the Veterans Administraon must continue to be vested with discretion to ssure that referrals to optometrists will be made nly where there is reasonable assurance that the rvice-connected medical needs of the veteran are eing fully met."

Noting that the VA had contended that service nnection usually involves a disease or basic defect f the eye and the veteran should therefore have e attention of an ophthalmologist, the Commite said that nevertheless it believes "The services f private optometrists should be more widely sed on a free basis on matters they are qualified handle; namely, refraction and prescription of lasses."

The bill would provide for "very limited applicaon, since the bulk of the operation in this field is on inpatient care basis," the Committee said, noting at the VA predicted the measure, if enacted, vould not produce any substantial increase in the st of the medical program."

Meanwhile, the House passed and sent to the enate a supplemental appropriations bill providing extra $8,800,000 for the VA's inpatient care proram for this fiscal year ending July 1.

MISCELLANY

President Eisenhower had some remarks on the eneral subject of health in his economic report Congress. He said, among other things, "There as been remarkable progress in the reduction of fant and maternal mortality; in the prevention, itigation, and treatment of many diseases; in reoring the physically handicapped; in making vailable a better balanced diet at lower cost; and creating other conditions conducive to longer life nd greater efficiency." At another point, Mr. Eisenower noted that in the past 10 years public and rivate expenditures for health have almost doubled from more than 12 to about 24 billion dollars. nnual federal expenditures for health and medical rograms rose from about 700 million dollars to .5 billion dollars, and state and local expenditures icreased from 1.7 to well over 2.5 billion dollars. The assurance of an adequate supply of doctors nd other health personnel will require an expanion of medical training facilities," said Mr. Eisenower.

MONOVALENT ASIAN INFLUENZA VACCINE

EVALUATION OF ITS USE DURING TWO WAVES OF EPIDEMIC ASIAN INFLUENZA IN PARTLY IMMUNIZED PENITENTIARY POPULATION

H. Bruce Dull, M.D., Atlanta, Ga., Keith E. Jensen, Ph.D., Montgomery, Ala.,
Jennie H. Rakich, R.N., Arthur Cohen, M.S., Donald A. Henderson, M.D.
and
Carl I. Pirkle, M.D., Atlanta, Ga.

The effectiveness of a vaccine against Asian influenza was studied in 1,244 volunteer subjects among the 2,600 men in a prison. Hemagglutination-inhibiting antibodies increased to a maximum within two weeks of vaccination. The titers obtained were highest in the group who received the largest doses of vaccine. Detailed epidemiologic and serologic studies were made during two subsequent waves of epidemic influenza. During the first, vaccines containing 200 and 500 chick cell agglutinating units were about 68% effective, while the vaccine containing 50 CCA units was only about half as effective. During the second wave four months later, all vaccinated men demonstrated nearly equal protection at about the same level observed for the higher doses during the first wave.

IN SEPTEMBER, 1957, a study to determine the protective value of single intramuscular injections of monovalent Asian-strain influenza vaccine was undertaken the United States Penitentiary, Atlanta, Ga. Three ses of vaccine, 50, 200, and 500 chick cell agglu- ation (CCA) units per milliliter, respectively, re compared to a formalinized saline placebo in ms of antigenicity and subsequent protection ainst epidemic Asian influenza.

Six weeks after vaccination of 1,244 inmate vol- teers an epidemic of Asian influenza occurred in penitentiary, concurrent with influenza in the mmunity. Clinical, epidemiologic, and serologic dies demonstrated that vaccine with a potency of 0 or 500 CCA units per milliliter induced 68% otection against febrile influenza, whereas vaccine ntaining 50 CCA units was considerably less ective.

When a second epidemic of Asian influenza swept rough the institution six months after execution of e vaccination program, the vaccine's protection rsisted.

From the Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare, and the U. S. Penitentiary. Jensen is now on the staff of the respiratory virus section, Biologics Research Department, Charles Pfizer and Company, Inc., Terre Haute, ; Mr. Cohen is now on the staff of the Department of Statistics, Columbia University, New York.

Material and Methods

The Atlanta penitentiary, a high-security institution, operates with an average inmate population of 2,600 men whose ages range from 18 to more than 75 years, the mean age being 37 years. Housing assignments are most commonly made to cells designed for two to six or more men, although individual units and dormitory arrangements are used in a few areas of the institution. Cafeteria procedure and occupational and recreational programs permit relative freedom of movement, intermixing, and personal contact. Medical care is centralized in a well-staffed hospital and an outpatient clinic.

All inmates were invited to volunteer for participation in the vaccine study by general announcement; the only contraindication to acceptance was known allergy to eggs or egg products. On Sept. 4 and 5, 1,244 volunteers were registered and assigned in rotation to receive one of the three doses of Asian-strain-influenza vaccine or a placebo. All four injections were 1 ml. in volume and identified only by code.

TABLE 1.—*Percentage of Penitentiary Inmates with HI Antibodies Two Weeks, Four Weeks, and Six Months After Administration of One of Three Doses of Monovalent Asian-Strain-Influenza Vaccine or Saline Placebo*

	Interval								
	2 Wk. Titer†			4 Wk. Titer†				6 Mo.* Titer†	
		%, Positive	Geometric Mean	No. Tested	%, Positive	Geometric Mean	No. Tested	%, Positive	Geometric Mean
Placebo	61	2	..	59	2	..	67	3	1

200 CCA Units	63	75	36	63	64	22	64	22	2
500 CCA Units	60	90	85	56	82	50	65	19	2

* Different, randomly selected sample of men bled at six months.

† Positive with initial dilution of 1:20 or greater (all prevaccination serums zero antibodies). Titers less than 1:20 treated as titers of one.

To evaluate the antibody responses stimulated by the vaccine, every fifth man registered (20% of each group) had one blood sample collected prior to injection and was scheduled for collection of additional specimens two and four weeks later. Six months after vaccination (preceding the second outbreak of respiratory disease), serums were again obtained to determine antibody persistence. Although the same men had contributed samples for the two-week and four-week tests, a different 20% of subjects was randomly selected for the six-month collections to equalize the obligations of all volunteers somewhat. Clinical histories were obtained from the subjects at the six-month bleeding time to achieve a more accurate evaluation of serologic evidence of intercurrent influenza infection, particularly in those men who had received placebo.

Daily observations were made of all respiratory illnesses reported either in the penitentiary's regular medical "sick line" or as emergencies. Clinical history, physical findings, and pertinent epidemiologi data were routinely ascertained in each instance Beginning in late October, 1957, when the increase incidence of respiratory illness suggested th *incipience of an epidemic* outbreak, about 2 throat washings were obtained for virus isolatio and serum specimens, in the acute phase and du ing the two-to-three-week period of convalescenc were collected from all patients with respirato illness, both afebrile and febrile, that occurred the population under study. Physicians and nurs from the Communicable Disease Center work daily with the prison medical staff, interviewing patients and organizing records and collection specimens. By early December the outbreak h subsided, and routine daily surveillance was c continued.

A second wave of the epidemic occurred March, 1958, four months after the first. Methods study were more limited in this instance and cluded only collection of throat washings fr about 12 patients and review of all clinic visits a hospital admissions. Thus, in the first wave, di nosis of influenza was based on clinical findi that had been confirmed by virological and se logic study. In the second wave, diagnosis limited to evaluation of the incidence of feb illness during an outbreak of respiratory dise when the Asian influenza virus was prevalent.

The vaccine was an aqueous-type material c taining only formalin inactivated A2/Japan/305 influenza virus and was obtained for this through the Division of Biologics Standards of National Institutes of Health. The stock vacc contained 500 CCA units per milliliter, and other doses were prepared by its dilution with ste isotonic sodium chloride solution. The placebo c tained isotonic sodium chloride solution, formalin, and 1:10,000 thimerosal (Merthiol solution—the latter two compounds being in same concentrations as in the 500 CCA-units cine.

Hemagglutination-inhibition (HI) tests w conducted with serial dilutions of serum and hemagglutinating units of virus in a standa pattern test.[1] The A2/Japan/305/57 strain, wh had been transferred serially in eggs, ferrets, m and eggs, was used to provide an antibody-sensi virus. Serums were treated with potassium perioc to destroy nonspecific inhibitors.[2]

The complement-fixation (CF) technique use standard overnight fixation at a temperature of with two optimal units of the same virus strain infected allantoic fluid as the antigen.[2b]

Results

Vaccine as Antigen.—The relationship of antibody response to vaccine dose is presentec table 1 and figure 1. In general, it was observed the development of antibodies after vaccinat with Asian influenza vaccine was directly related to the dose given. HI antibodies increased to peak levels within two weeks of vaccination and declined considerably thereafter to relatively low levels six months later.

Table 1, which summarizes antibody responses two weeks, four weeks, and six months after vaccination, shows the percentage of each group of vaccinees who developed significant rises in titer (fourfold or greater) and lists the corresponding geometric mean titer for each group. While only 56% of the men who had received 50 CCA units of vaccine demonstrated rises in antibody titer two weeks after vaccination, the groups of men given 200 or 500 CCA units, respectively, showed a considerably greater response, that is, 75 and 90% respectively. Serums collected six months after vaccination revealed a marked decline in antibodies among all groups, indicated by both decreasing geometric mean titers and reduction in the proportion of men with antibodies. Fig. 1, which shows the percentage of each group with antibodies two and four weeks after vaccination, emphasizes the direct relationship of response to vaccine dose.

According to the HI titers shown in table 1, few, if any, inapparent Asian influenza infections appear to have occurred between the time of vaccination and the collection of a blood specimen six months thereafter. The virtual absence of antibodies in the group of men given placebo, and the fourfold decrease in the percentage of men with antibody titers in the three vaccinated groups would not be expected had there been a high rate of infection. Only two persons in the group given placebo demonstrated antibody titers at six months, and single positive reactions had also been noted in both of the previous collections, from a different person in each instance. If subclinical infections had occurred, a significantly greater number of serologically identified cases should have appeared in the group given placebo, and the antibody levels of the vaccinated groups should have been maintained.

To describe more accurately and completely the immune status of each group of volunteers given vaccine, the distribution of HI antibody titers two weeks after vaccination was analyzed on the basis of the cumulative percentage of each group with titers equal to or greater than 1:20, 1:40, 1:160, and 1:640 dilutions of serum. The more concentrated doses produced higher titers throughout the range of serum dilutions.

The Two Waves of Epidemic Influenza.—An epidemic of Asian influenza broke out in Atlanta in late October: Public-school absenteeism showed a fourfold increase; the Georgia Institute of Technology housed the overflow of its ill students in the Naval Armory; Atlanta hospitals reported a sometimes overwhelming increase in outpatient-clinic and emergency-room visits; and Atlanta's influenza-pneumonia mortality increased more than eightfold, reaching its peak in early November. Asian influenza virus was repeatedly isolated in throat washings collected from patients who were ill at various times during the course of the community-wide epidemic.

Coincident with the outbreak of influenza in Atlanta, the penitentiary population experienced a sudden increase in both afebrile and febrile respiratory disease. Daily sick lines were crowded by men reporting a variety of complaints, and the number of emergency medical visits increased rapidly. Febrile cases constituted about one-third of the total and, as will be demonstrated later, accounted for the greatest proportion of serologically confirmed infections. From the perspective of subsequent evaluation, afebrile patients probably had cases of either nonspecific illnesses or "goldbricking," a phenomenon well recognized in institutionalized populations.

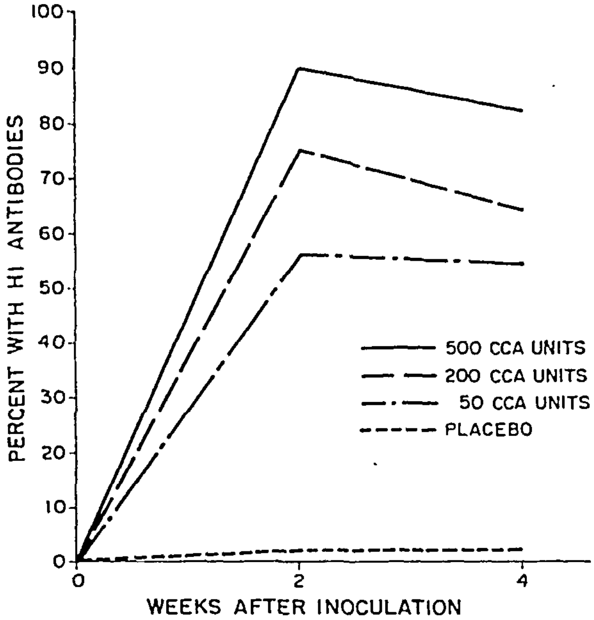

Fig. 1.—Percentage of inmates of U. S. Penitentiary, Atlanta, Ga., with hemagglutination-inhibition (HI) antibodies two and four weeks after inoculation of one of three doses of monovalent Asian-strain-influenza vaccine or saline placebo.

Fig. 2 shows the incidence of respiratory illness in the penitentiary by week during the six-month period after the vaccination program. Two major increases in the amount of reported illness are evident, the first beginning in late October, the second occurring in March. Both waves are compared to the influenza-pneumonia mortality reported in Atlanta for the corresponding weeks. In addition, pertinent newspaper excerpts describing the widespread epidemic that occurred in schools in the area in the autumn have been added for comparison with the penitentiary's first wave of respiratory illness. The peak incidence of illness at the penitentiary in the fall occurred one week prior to the maximum level of mortality reached in Atlanta and coincided with school-wide epidemics.

On the basis of the epidemic curve, the interval from Oct. 26 through Nov. 20 was designated as the "autumn epidemic study period" for evaluating vaccine effectiveness. During these 26 days, 455 men reported respiratory illnesses—189 from the population under study. Sixteen men were hospitalized because of unusually severe illnesses, some of which were complicated by bacterial pneumonia. Only one of the hospitalized inmates had taken part in the vaccination program, and he had received placebo.

The men's illnesses varied considerably in severity. Symptoms reported by a large number of inmates were those of classic influenza: abrupt onset of shaking chills, generalized myalgia, headache, fever, malaise, anorexia, and variable upper respiratory symptoms including coryza, sore throat, and nonproductive cough. The condition of afebrile patients, those having temperatures of less than 100 F (37.8 C), was characterized mainly by malaise, anorexia, and an occasional complaint of feverishness.

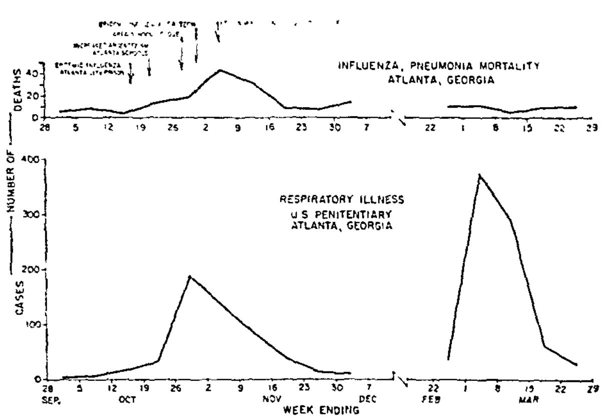

Fig. 2.—Incidence of respiratory illness among penitentiary inmates by week during six-month period after vaccination against Asian influenza, and comparison with influenza-pneumonia mortality during concurrent influenza epidemic in Atlanta community.

Throat washings for virus studies were collected from 23 men, mostly from those with febrile illnesses occurring at the peak of the outbreak. Virus was isolated from 11 of the 23 specimens (48%), 10 of these being from febrile patients. All of these isolates were identified as Asian-strain-influenza virus.

Comparison of focal epidemics in the institution's nine major housing units demonstrated that the earliest outbreak occurred among men in the administrative orientation (A/O) group, which is composed of newly admitted inmates. These men are housed separately from the others for a period of one month while undergoing tests and observation. Four to five men enter the administrati orientation unit daily, and a similar number is leased for assignment to one of the permanent livi areas. The early focal outbreak in this particu group suggests that new arrivals may well ha introduced the Asian-influenza virus and that m discharged from the administrative orientation a then seeded it widely in the general inmate popu tion. Influenza occurred among the several hund guards and other personnel employed by the pe tentiary simultaneously with most of the outbre among inmates. Having contact with both inma and the Atlanta community, employees may have contributed to dispersion of Asian-influe virus in the institution.

In March, 1958, six months after the vaccina program had been completed, an explosive sec epidemic of respiratory disease swept through institution. In late February only 5 to 10 illne had been reported daily, nearly all of them afeb During the first week of March the number creased dramatically to nearly 100 new cases day, almost half of the patients having a temp ture of 100 F or more. The acuteness of the break is illustrated in fig. 2. It is of interest to that no indicators of an epidemic in the Atl community coincided with the penitentiary's ond wave of respiratory disease: the city's i enza-pneumonia mortality remained at seas levels, and school absenteeism did not increase

During the 15 days arbitrarily chosen as "winter epidemic study period," March 3 to M 17, a total of 689 inmates reported a respira illness, 269 of whom were from the popula under study. Symptomatically, the illnesses identical to those which had occurred in the Once again, however, a broad spectrum was served. Fourteen throat washings collected febrile patients early in the course of the epid yielded eight viral agents (57%), all of which identified as Asian-strain influenza.

Effectiveness of the Vaccine.—Although the cine proved to be about equally effective du both actual outbreaks of respiratory illness, i esting variations in HI antibody levels occurre the interval.

During the first wave a total of 189 case respiratory illness occurred in the population u study. Satisfactory serum specimens were obtai during both the acute and the convalescent p and then tested on 166 (88%) of these pati Laboratory confirmation of infection was def as a fourfold or greater rise in antibody levels the acute-phase to the convalescent-phase sp mens, as demonstrated by either HI or complem fixation tests.

Table 2 presents results of the 166 serologic in relationship to the maximum body tempera developed in the patients. Three tempera oups, equal to or lower than 99 F (37.22 C), 2-99.8 F (37.33-37.66 C), and equal to or higher n 100 F were selected to represent afebrile, ermediate, and febrile classifications. Such a ouping of results demonstrates the definite relionship of serologic confirmation of infection to e presence of fever.

While of 42 patients with temperatures of 100 F more 71% (30 of 42) had Asian influenza, only % (7 of 33) with an intermediate temperature crease and 4% (4 of 91) of the afebrile patients d confirmed cases. Thus, a body temperature of 0 F or more proved to be a reliable criterion for e diagnosis of Asian influenza in the first wave, nsidering that nearly three-quarters of all patients th confirmed cases (30 of 41) had such elevations temperature. Twenty-seven of the total of 41 nfirmations (65%) were made by HI tests, 37 %) by complement-fixation tests, and 18 (44%) by th procedures. Because the illnesses of a large mber of men could not be confirmed as Asian luenza, additional serologic studies were underen. Tests with adenovirus and influenza type-B tigens were performed but were uniformly negae.

In view of the direct relationship between fever d serologic confirmation of actual infection, an alysis of the effectiveness of vaccine in prevent; febrile illness was carried out. While the ount of afebrile illness remained relatively connt, the number of patients with a fever of 100 grees or more decreased progressively from 19 in group given placebo (7% of that group) to 12 %) of the group given 50 CCA units of vaccine, d to only 6 (2%) each in the groups vaccinated th 200 CCA and 500 CCA units respectively. Statical analysis at a significance level of 0.05 suprts actual differences in the incidence of febrile ness in relation to placebo. Effectiveness of the ccine in terms of percentage reduction in febrile ness is 38% for 50 CCA units of vaccine and 68% r both 200 CCA and 500 CCA units of vaccine.

An additional evaluation of the effectiveness of e vaccine was made by studying only the laborary-confirmed cases (table 2). Among the total of confirmations, 20 were in the group of subjects ven placebo, 13 were in the group given 50 CCA its of vaccine, and only 3 and 5, respectively, ere in the groups given 200 CCA and 500 CCA its. Because of the small number of confirmed fections in the last two groups, the groups have en combined for analysis at a significance level 0.05. Effectiveness levels are quite similar to ose calculated when the vaccine is considered om the standpoint of protection against febrile lness: 37% for 50 CCA units of vaccine and 75% r 200 CCA and 500 CCA units of vaccine comined.

The immunity of the vaccinated inmates can be further defined. The HI titers of all acute-phase serums that had been collected during the epidemic (166) were grouped according to the vaccine dose received and related to the presence or absence of fever. As might be anticipated, all acute-phase HI titers in the group given placebo were zero, while the vaccinated groups showed a distribution of titers ordered according to vaccine dose. However, within the vaccinated groups it was generally apparent that febrile patients had many more zero or low antibody titers than afebrile ones. Although the number of cases in the groups given 200 CCA and 500 CCA units of vaccine, respectively, is too small to allow completely adequate analysis, the results suggest that the presence of HI antibodies at the time of infection is directly related to protection against developing febrile illness. Moreover, it appears that the relative antibody level is more important than the mere presence or absence of antibodies.

TABLE 2.—*Autumn Outbreak of Respiratory Illness at Atlanta Penitentiary, October, 1957: Relationship of Serologic Confirmation* of Asian Influenza to Occurrence of Fever*

	Maximum Recorded Temperature								
	≤99F		99.2-99.8F		≥100F				
Vaccine Group	Tested	Confirmed	Tested	Confirmed	Tested	Confirmed	Total Tested	Total Confirmed	% Confirmed
Placebo	19	1	8	2	19	17	46	20	43
50 CCA units	26	1	8	3	12	9	46	13	28
200 CCA units	23	0	6	1	6	2	35	3	9
500 CCA units	23	2	11	1	5	2	39	5	13
Total	91	4	33	7	42	30	166	41	25
% confirmed	4		21		71		25		

* Confirmation defined as four-fold or greater rise in HI or CF antibody titers from acute-phase to convalescent-phase serums.

When the second wave of respiratory illness occurred at the Atlanta Penitentiary in March, only 844 of the original 1,244 volunteers were still in the penitentiary, reflecting the more than 30% turnover in the inmate population. During the period of this study, March 3 to March 17, a total of [illegible] respiratory illnesses were reported, 269 ([illegible]) from the group under study.

As anticipated, some of the men reporting an illness in the winter outbreak were also among those who had been ill during the first wave of influenza. It appeared that, of the 269 men who were ill in the winter, 61 (23%) reported illnesses in both outbreaks. What is of interest, however, is the observation that more than 80% of the men who had also been ill in the fall had then been afebrile. Occurrence of febrile illness in both outbreaks was noted in only five instances. (Three of these five men had been confirmed serologically as Asian influenza in the fall, but, because much of the study in the second wave was retrospective, laboratory confirmation was not possible.)

Fever having been shown to be a reliable criterion for confirmation of influenza during the first wave, the occurrence of febrile illnesses among the vaccinated men in the winter outbreak was studied to determine the persistence of protection given by the vaccine. Since 61 of the 269 patients who were considered ill in the winter outbreak had also been ill in the fall, a comparative analysis was made of the cases that occurred exclusively in the winter with the total number. While there were about equal numbers of afebrile illnesses in all groups, there were considerably fewer febrile cases in the vaccinated groups than in the groups given placebo, namely, 19% in the group given placebo but only 8, 7, and 7%, respectively, in the groups that had been given 50 CCA, 200 CCA, and 500 CCA units of vaccine.

The percentage effectiveness of each vaccine dose in preventing febrile illness, based either on winter outbreak cases exclusively or on totals (the latter results being parenthesized), was as follows: 50-CCA-unit vaccine, 60% (50%); 200-CCA-unit vaccine, 62% (63%); and 500-CCA-unit vaccine, 65% (58%). Similar measures of effectiveness were observed (irrespective of whether men who had been ill in both epidemics were included in the analysis). It is of considerable interest to compare the evident protection conferred by the vaccine in the winter to that observed in the autumn. With the exception of the 50-CCA-unit dose, the level of protection in both epidemics was about the same. In the fall the 50-CCA-unit vaccine was considerably less effective than the higher doses, but in the winter it appeared to be of nearly equal value. An immunological explanation of this observation will be suggested later.

Comment

During the past 15 years considerable data on influenza, its clinical, epidemiologic, and laboratory characteristics have been accumulated.[3] Emergence of the Asian variant in 1957[4] presented a unique opportunity for additional investigations. A large portion of the resultant work has dealt with the antigenic character of the virus and the protective value of Asian-strain-influenza vaccines tested under a variety of conditions.[5]

Reports of studies sponsored by the commission on influenza of the Armed Forces Epidemiological Board demonstrated a 42 to 75% reduction in relative rates of respiratory diseases, depending on vaccine dose and the particular conditions of the study. Investigations by the U. S. Public Health Service and a number of clinical and university centers have produced comparable results. The present study, conducted under institutional conditions, demonstrates similar patterns in terms of the vaccine's antigenic character and its protective val
Certain of the procedures, observations, and resu
in the present study deserve additional comm
and discussion.

The accessibility of a penitentiary population
virtue of its routine living and medical progr
favors the choice of such a group for clinical stu
However, these rather obvious benefits are o
accompanied by errors due to overreporting of
ness, or "goldbricking," which occurs in instituti
in which special consideration is available to
sick. Another inaccuracy is underreporting,
counted for by a segment of inmate populat
which is described as refusing medical care
evidence of their resistance to authority. The m
nitude of the reporting errors on either count
not be satisfactorily estimated, but the existenc
inaccuracies must be taken into account in
evaluation of the results of clinical studies. S
definition of a "case" needs, therefore, to be es
lished and respected.

To minimize the anticipated errors in diagn
of influenza, with awareness of both its inhe
clinical variability and the likelihood of repor
errors, fever as the criterion was adopted as
best objective clinical index of infection. On
basis of reasonable confidence in consistent
nosis, the cases of illness established by this
of clinical screening provided a sample in w
to measure and compare the protection afforde
the vaccine.

Considerable support was added to fever as
diagnostic criterion by showing that in nearly th
fourths of the patients with temperatures of 1
(37.78 C) or more Asian influenza infection c
be confirmed serologically while afebrile illn
were rarely confirmed (table 2). On the basis of
evidence, which had been accumulated during
first wave of respiratory illness at the Atlanta P
tentiary, fever was used as the sole criterio
infection during the winter outbreak.

In both waves of respiratory illness most of
patients were essentially afebrile. Although
tempting to explain this observation in term
mild or modified influenza, the paucity of case
laboratory-confirmed infection in afebrile pati
offers little support for such a thesis. It is n
reasonable to consider the afebrile illnesses
occurred among the penitentiary inmates as
specific infections or "goldbricking," which occu
in an epidemic pattern and were superimposed
the actual outbreaks of Asian influenza.

In the autumn, the stimulation of antibody
duction by the Asian-influenza vaccine was
served to correlate with the administered d
Furthermore, there appeared to be a definite

tionship between the level of HI antibodies and he protection given by the vaccine against devel- ping a febrile illness. In the winter, however, the rum specimens that had been collected shortly efore the epidemic demonstrated a marked decline HI antibodies. During the actual outbreak, how- ver, it was observed that all vaccinated men were rotected to about the same degree as in the fall, gardless of whether they had received high or w doses of vaccine.

There may be merit in attempting to explain this pparent paradox in terms of possible immunologi- l mechanisms: In the autumn, the interval be- veen vaccination and the actual epidemic (six eeks) may not have been sufficiently great to low for anamnestic mechanisms to stimulate in- eased antibody production when virus activity gan, and the protection obtained was therefore osely correlated with existing serum-antibody vels. The fact that acute-phase titers among brile patients generally were lower than among ebrile ones adds support to this hypothesis. In ntrast, six months after vaccination, nearly all en in the vaccinated groups had lost most of their culating antibodies. However, the timing was ch that a small amount of antigen was sufficient produce a rapid booster effect in the form of an amnestic recall, thus giving comparable protec- n among all men previously vaccinated.

Summary

Three doses of monovalent Asian-strain-influenza ccine, containing 50, 200, and 500 chick cell glutination (CCA) units, respectively, were com- red to a saline placebo for evidence of antigenic- and protection against epidemic Asian influenza. ngle, intramuscular injections of vaccine were ministered to 1,244 volunteers among nearly 300 inmates of the federal penitentiary in Atlanta, ., in the autumn of 1957. Two outbreaks of spiratory illness, in part Asian influenza, occurred intervals of about six weeks and six months, spectively, after the vaccination program.

The conclusions based on clinical epidemiologic d serologic studies are as follows: 1. The vaccine mulated serum hemagglutination-inhibition(HI)- tibody production in correlation with the dose ministered. Two weeks after vaccination, 56 to % of vaccinated men demonstrated antibody ers. Six months later, there had been a consider- le decline in antibodies among all three groups vaccinees. 2. During the first wave of respiratory ness, a correlation of nearly 75% was observed tween patients with a temperature of 100 F 7.8 C) or more and subsequent serologic confir- ation of Asian-influenza infection; afebrile ill- sses were confirmed infrequently. 3. The vaccine's protection against developing febrile illness was evident in both outbreaks. In the first, protection was roughly related to dose; in the second, all vaccinated groups appeared to be nearly equally protected. The 200-CCA-unit and 500-CCA-unit vaccines were shown to be about 68% effective in the autumn and only slightly less so in the winter. The 50-CCA-unit vaccine was about half as effective as the higher doses during the first wave but almost equally effective during the second outbreak of respiratory illness.

50 Seventh St. (23) (Dr. Dull).

Dr. Alexander D. Langmuir of the Communicable Disease Center, Atlanta, Ga., contributed to the analysis of results and preparation of the manuscript, and Dr. Roslyn Q. Robinson assisted in the completion of laboratory tests. Warden Fred T. Wilkinson of the U. S. Penitentiary at Atlanta and his assistants lent administrative support, and Drs. Kenneth Hyatt and William Wood of the Penitentiary's Medical Department collaborated in the medical administration of the program.

The vaccine used in this study was supplied by Lederle Laboratories, Division of American Cyanamid Co., Pearl River, N. Y.

IMMUNIZATION WITH POLYVALENT INFLUENZA VACCINES

Keith E. Jensen, Ph.D., Allen F. Woodhour, Ph.D., Terre Haute, Ind.
and
Ann A. Bailey, M.D., Gracewood, Ga.

Injection of a single-strain vaccine evokes in the adult person an antibody-recall mechanism previously established by initial childhood antigenic experiences with related influenza viruses. This now bolsters antibody levels against viruses from that family of strains and provides some degree of protection against influenza caused by a new variant. To gain better understanding of age-related differences in antibody foundations in influenza immunization, groups of children and adults were given two different polyvalent influenza vaccines. The six-strain preparation (1,000 chick-cell-agglutination units) produced no greater incidence of undesirable side-effects than those obtained with the standard four-strain formula (500 CCA units) and repeatedly stimulated superior antibody responses. Children generally produced better antibody levels than did adults with use of the six-strain vaccine.

The influenza pandemic which occurred in the United States in 1957-1958 provided an excellent opportunity to determine the efficacy of monovalent vaccines. Even these hurriedly prepared prophylactics were effective, since it was shown that their use reduced clinical influenza in many different populations by as much as 77%.[1] Seroepidemiologic surveys further confirmed the premise that antibody response to influenza vaccines is a reliable index of the protection conferred by a given preparation.[2]

Although influenza infrequently results in death and is usually considered to be a mild febrile illness, severe sequelae and debilitating effects can occur. The United States Public Health Service, in the fall of 1958, recommended vaccination against influenza as the only available means of reducing the incidence of this disease. Several million cases of influenza subsequently occurred during the period January through May, 1959, in the United States, Europe, and elsewhere. These widespread epidemics lead to the usual closure of schools, and mortality due to influenza and pneumonia rose to well above normal for the season.[3] Because viruses isolated during the epidemics of 1958-1959 were shown to be closely related to the strains contained in available influenza vaccines, it is highly probable that much of this disease could have been prevented.

Successful immunization against influenza is complicated by the fact that subgroups of the two epidemiologically important antigenic types are composed of changing antigenic composites. To anticipate future antibody requirements, vaccines should include antigenic mosaics from the types A and B with sufficient breadth to combat any emergent virus variant. The simplest vaccine would be a preparation composed of two strains, one each of the most recent type A and type B isolates. A system of "watch laboratories" has been established for rapid detection of new variants, in the hope that these viruses could be quickly incorporated into vaccine. However, as was shown in 1957, a new variant may spread around the world faster than a countering vaccine can be prepared and distributed. Although our observation period is limited so that the full range of possible variation is not yet known, four sets of type A and two sets of type B viruses have now been isolated. To derive the fullest measure of immunity against the next variants that cause influenza, vaccines should incorporate a gens from each of the six known sets.

It has long been recognized that children h the highest rates of attack in all influenza epid ics. It is also a well-known fact that serum sp mens from adults contain antibodies against stra of virus which were prevalent in the many p epidemics. It is apparent, therefore, that ad derive protection from the antibody comple produced against older viruses which then cr react with the new variant. This phenomenon been examined carefully by Davenport and co-workers,[4] and they have now described in de the antibody-orienting effect of the first antige experience with influenza virus on subseque developed patterns of antibody. The concept "original antigenic sin" has provided a valua hypothesis for an understanding of age-rela variability in antibody responses to vaccination infection. Injection of a single-strain vaccine engage an antibody-recall mechanism that established as a result of the initial childh antigenic experience with related influenza viru which now has the effect of bolstering antib levels against viruses from that family of strains.

From the Biologics Research Department, Charles Pfizer and Co., Inc., and the Georgia State Training School for Mental Defectives.

a contrasting corollary, specific responses to subsequently encountered strains can be inhibited, because much of the antibody that is stimulated is lirected toward the older strain. Immunologically nature persons would appear less sensitive and nay even approach a refractile state when confronted by new antigens. To gain further insight nto the effect of these age-related differences in ntibody foundations on influenza-immunization ractices, groups of children and adults were inected with the two different polyvalent influenza accines that had been used during 1958-1959. The wo preparations differed in formula as shown in ble 1. One was adopted in 1957 for the standard ommercial vaccine, which contained a total of 500 hick cell agglutination (CCA) units per milliliter. he other formula followed the specifications recmmended by the Commission on Influenza of the rmed Forces Epidemiological Board and conained two additional strains, the A/Swine and the /Lee virus, as well as twice as much of the 2/Asian and B1/GL components as did the first.

TABLE 1.—*Composition of Two Polyvalent Vaccines Against Influenza*

Virus Strain	Chick Cell Agglutination (CCA) Units	
	500	1,000
2/Asian/57	200	400
/PR8/34	100	100
1/PR301/54	100	100
/Swine/31	...	100
1/GL/54	100	200
/Lee/40	...	100

The plan of the study was to compare antibody esponses and incidence of febrile reactions after ubcutaneous injections with various dosage schedles. The subjects were children and adults in penal nd mental institutions in Indiana and Georgia.

Methods

All subjects were bled immediately prior to vaccination, and the serums were stored until postvaccination specimens could be processed. Antibody was measured with use of a standard-pattern hemagglutination-inhibition (HI) test, and all serums were treated with trypsin and potassium periodate to destroy nonspecific inhibitors.[5] Solutions of 8 mg. per milliliter of trypsin (1:250) were prepared in M/10 phosphate buffer, pH 8.2. One volume of serum was mixed with one-half volume of trypsin and incubated for 30 minutes at 56 C. After being cooled to room temperature, the specimens were treated with freshly prepared M/90 potassium periodate in distilled water. Three volumes of periodate were mixed with serum and held for at least 15 minutes at room temperature, after which three volumes of 1% glycerol-saline were added. Serial dilutions of serum were prepared in twofold progression in dilutions of 1:10 through 1:320. When results of preliminary tests did not indicate an end-point at the highest dilution of serum, secondary titrations were conducted with dilutions through 1:2,560. The diluent for the virus, chick erythrocytes, and serum was 0.85% sodium chloride with M/100 phosphate buffer at pH 7.2. Titers are expressed as the reciprocal of that dilution of serum (before addition of other reagents) which completely inhibited four hemagglutination units of virus.

Except where noted otherwise, the hemagglutination antigens used were the vaccine strains. To measure antibody against the Asian set of variants, the antibody-sensitive line of A2/Japan/305/57 with an egg/ferret/mouse/egg transfer history was used.[6] The Asian virus used in the vaccine was the A2/Formosa/313/57, which possesses excellent antigenic potency but has low reactivity in the hemagglutination-inhibition test.

Results

Incidence of Febrile Reactions.—A frequently voiced objection to the use of influenza vaccines has been that severe reactions may occur, particularly when high concentrations of virus are used. We have studied the incidence of fever, painful injection sites, and generalized symptoms in 743 persons ranging in age from 2 to 58 years. No subjects with a history of allergy to eggs were included in this study. Only mild reactions occurred, and complaints of sore arms were no more frequent than in subjects who received a formalinized placebo. A summary of the incidence of febrile reactions is provided in table 2.

Although the number of subjects in the group of those aged 2 to 5 years was small, and conclusions regarding those observations must be guarded, the other groups were of sufficient size to provide satisfactory data. Temperatures of all subjects were recorded after 4, 12, and 24 hours, and most of the elevated temperatures were found at the 12-hour interval. In general, fever was not present as long as 24 hours, and all subjects had normal temperatures 36 hours postvaccination. With both vaccines, the highest incidence of reaction was noted in the youngest age groups, in which about 20%

TABLE 2.—*Incidence of Febrile Reactions to Polyvalent Influenza Vaccine*

13-18	1.00	72	4	6	174	19	11
19-58	1.00	57	1	2	89	5	6
Totals		295	38	13	448	60	13

* Recorded temperatures 100F (37.78C) or greater at 4, 12, or 24 hours. None persisted as long as 36 hours postvaccination.

developed transient fevers. In older children and adults, frequency of fever ranged from 2 to 11%, whereas an average value of 13% holds for the entire series of 743 persons. Thus, although twice as much virus was injected with the 1,000-CCA-unit preparation, the incidence of febrile reactions was not greater than that observed with the standard 500-CCA-unit vaccine.

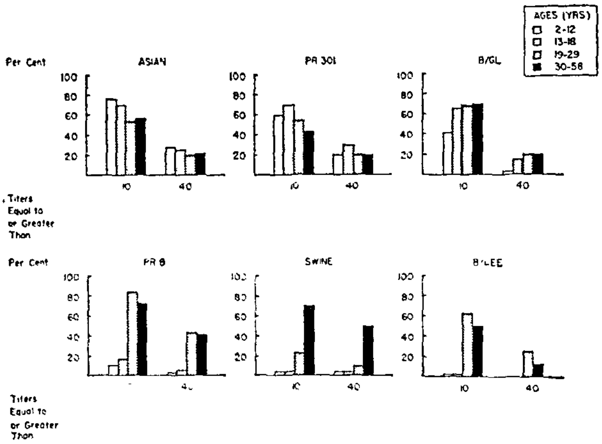

Fig. 1.—Incidence of antibody titers in prevaccination serums obtained from human subjects drawn from four age groups.

Antibody Titers in Prevaccination Serum.—Presence of antibody in prevaccination serums against the six strains of influenza and the relative frequency of various antibody titers in four different age groups are shown in figure 1. Although titers ranging from 1:10 to 1:2,560 were measured, two different levels (equal to or greater than 1:10 or equal to or greater than 1:40) have been selected to simplify presentation of the results. Over 70% of children 2 to 12 years old had antibody against the Asian variant. However, only one-third of those with antibody had titers at 1:40, the level that is usually considered protective and is generally exceeded after convalescence.[2] As expected, we found that older children had the greatest incidence of antibody against PR301, the strain that is closely related to the type A viruses that were prevalent from 1946 to 1957.

The B/GL virus was first isolated in 1954 and is practically identical to the type B strains that have been prevalent during the past seven years. It is of practical interest that the lowest incidence of antibody against the B/GL strain was found in children. That children are particularly susceptible to this variant is supported by the high incidence of type B infection that was seen in children during the early part of 1959.[3]

Age-related differences in antibody patterns are clearly illustrated in the data given at the bottom of figure 1, where it is shown that few children had antibody against older strains. Viruses similar to the PR8 have not been in circulation since 1943; variants similar to the Swine strain were epidemiologically important 40 years ago. The Lee strain was isolated almost 20 years ago and is equivalent to the contemporary type B virus. In sharp contrast to these results, adults often had antibody against the older viruses. It is known that these levels are boosted and maintained by repeated antigenic experiences with subsequently prevalent variants that are only remotely related to those strains encountered in childhood.[4] A greater percentage of subjects in the oldest age group had antibody against the Swine virus, an immunological relic of the type A-influenza strains that circulated in human beings during the decade prior to 1924.

Antibody Responses of Children to Polyvalent Influenza Vaccines.—Keeping the current prevaccination antibody titer foundations in mind, attention will be focused first on the patterns of antibody response in children (age range of 6 to 12 years) that developed after subcutaneous injections of two 0.5-ml. doses of influenza vaccine containing either 500 or 1,000 CCA units per milliliter. The second dose was given one week after the first, and blood samples were obtained two weeks after the last injection. Data from a typical experiment are illustrated in figure 2, with geometric-mean titers plotted in the upper part; geometric mean-fold increases are shown as inverted bars in the lower portion of figure 2. The six-strain preparation with 1,000 CCA units elicited superior results with every antigen. Although the vaccines contained equal amounts of the PR8 and the PR301 strains, greater responses were observed in the children who received the six-strain vaccine. It was of interest to find that the geometric mean-fold increase, when measured against the Asian strain, Japan 305, was about the same in the two groups, although the mean-antibody titer was greater for the subjects who were given the vaccine containing 400 CCA units of Asian virus. With the B/GL strain, greater re-

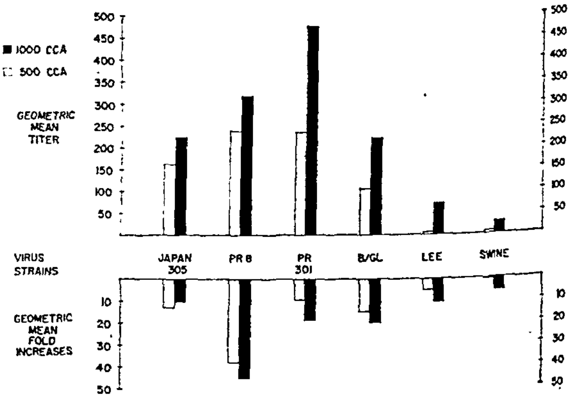

Fig. 2.—Comparison of hemagglutination-inhibiting (HI) titers and average-fold increases in serums obtained from children injected, respectively, with 500 chick cell agglutination (CCA) unit (4-strain) or 1,000-CCA-unit (6-strain) influenza vaccine.

sponses were measured either way in the children who had been given the six-strain product.

In both groups, much of the antibody stimulated against the Japan/305, the PR301, and the B/GL virus was probably of a recall nature, since most subjects had low levels against these strains before vaccination. The titers against both the Lee and Swine viruses are small in comparison with those found for other strains and can be considered as typical primary antibody responses in children who had not been exposed previously to these antigens. The titers are, in fact, quite similar to those obtained in 1957 after injections of monovalent Asian-influenza vaccines, when antibody was produced for the first time against that variant. Curiously, a few persons in the group that was given four-strain vaccine developed antibody against Lee and Swine, strains that were not present in the formula they received.

Relation of Antigen Multiplicity to Antibody Response: Is the greater antibody response to the 1,000-CCA-unit vaccine due to its larger amount of virus, or does it reflect the greater variety of related antigens that are contained in the six-strain preparation? An experiment designed to weigh these alternatives was performed by giving one group of children 1.0-ml. doses of the 500-CCA-unit product, while a comparable group received 0.5 ml. of the 1,000-CCA-unit vaccine. As in previous studies, two doses were given one week apart. By this arrangement, although total virus units were equal, the doses given to one group contained antigens of six trains while those given to the other group conained only four strains, as shown in table 3.

The distribution of antibody titers obtained in his experiment is shown in figure 3. Higher antibody levels of 1:160 or 1:640, as measured against he Asian, B/GL, and PR301 strains, occurred more often in the group that had received the six-strain ormula. The results were particularly striking with he PR301 strain. Although children who had been given six-strain vaccine were immunized with only

TABLE 3.—*Administration to Two Groups of Two Doses of Influenza Vaccine Composed of Six and Four Strains of Antigens Respectively*

Virus Strain	Groups Given CCA-Unit Vaccine (1,000 Units)	
	Six Strains	Four Strains
Asian	400	400
B/GL	200	200
PR301	100	200
PR8	100	200
B/Lee	100	...
wine	100	...
Total CCA units in 2 doses	1,000	1,000

ne-half the amount of this antigen, their responses were greater. The difference may best be accounted for by the presence of a greater variety of type A antigens in the six-strain vaccine. In contrast, when the PR8 strain was used to measure antibody, the response to the four-strain vaccine exceeded that found in the other group, since the larger amount of PR8 antigen in the four-strain formula stimulated a primary antibody response of greater magnitude.

Effect of Dosage Interval on Antibody Response: To investigate the matter of an optimal schedule for maximal response after two injections, a series of experiments were performed in groups of about 25 boys ranging from 12 to 17 years of age in which two, four, or six weeks respectively, elapsed between the first and second injections. The boys were bled prior to vaccination, at the time of the second injection, and two weeks later. As a control, one group received only one dose of vaccine and was bled after eight weeks. The distribution of the antibody titers that were obtained is given in figure 4. The length of the horizontal bar indicates percentage with titers equal to or greater than the values given on the vertical scale. The unshaded portion represents the prevaccination foundation; the lightly shaded area shows the response after one dose, and the heavily shaded portion delineates the increment found in serum specimens drawn two weeks after the second injection. Data are so arranged that the responses of all four groups can be compared with each antigen.

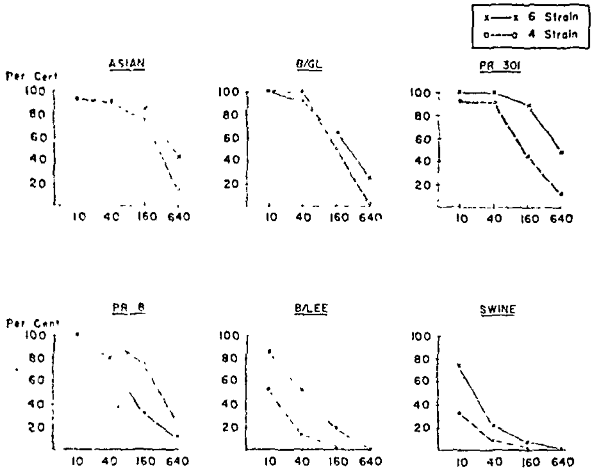

Fig. 3.—Antibody responses in children given two doses of 500 CCA units in four-strain and six-strain influenza vaccines respectively.

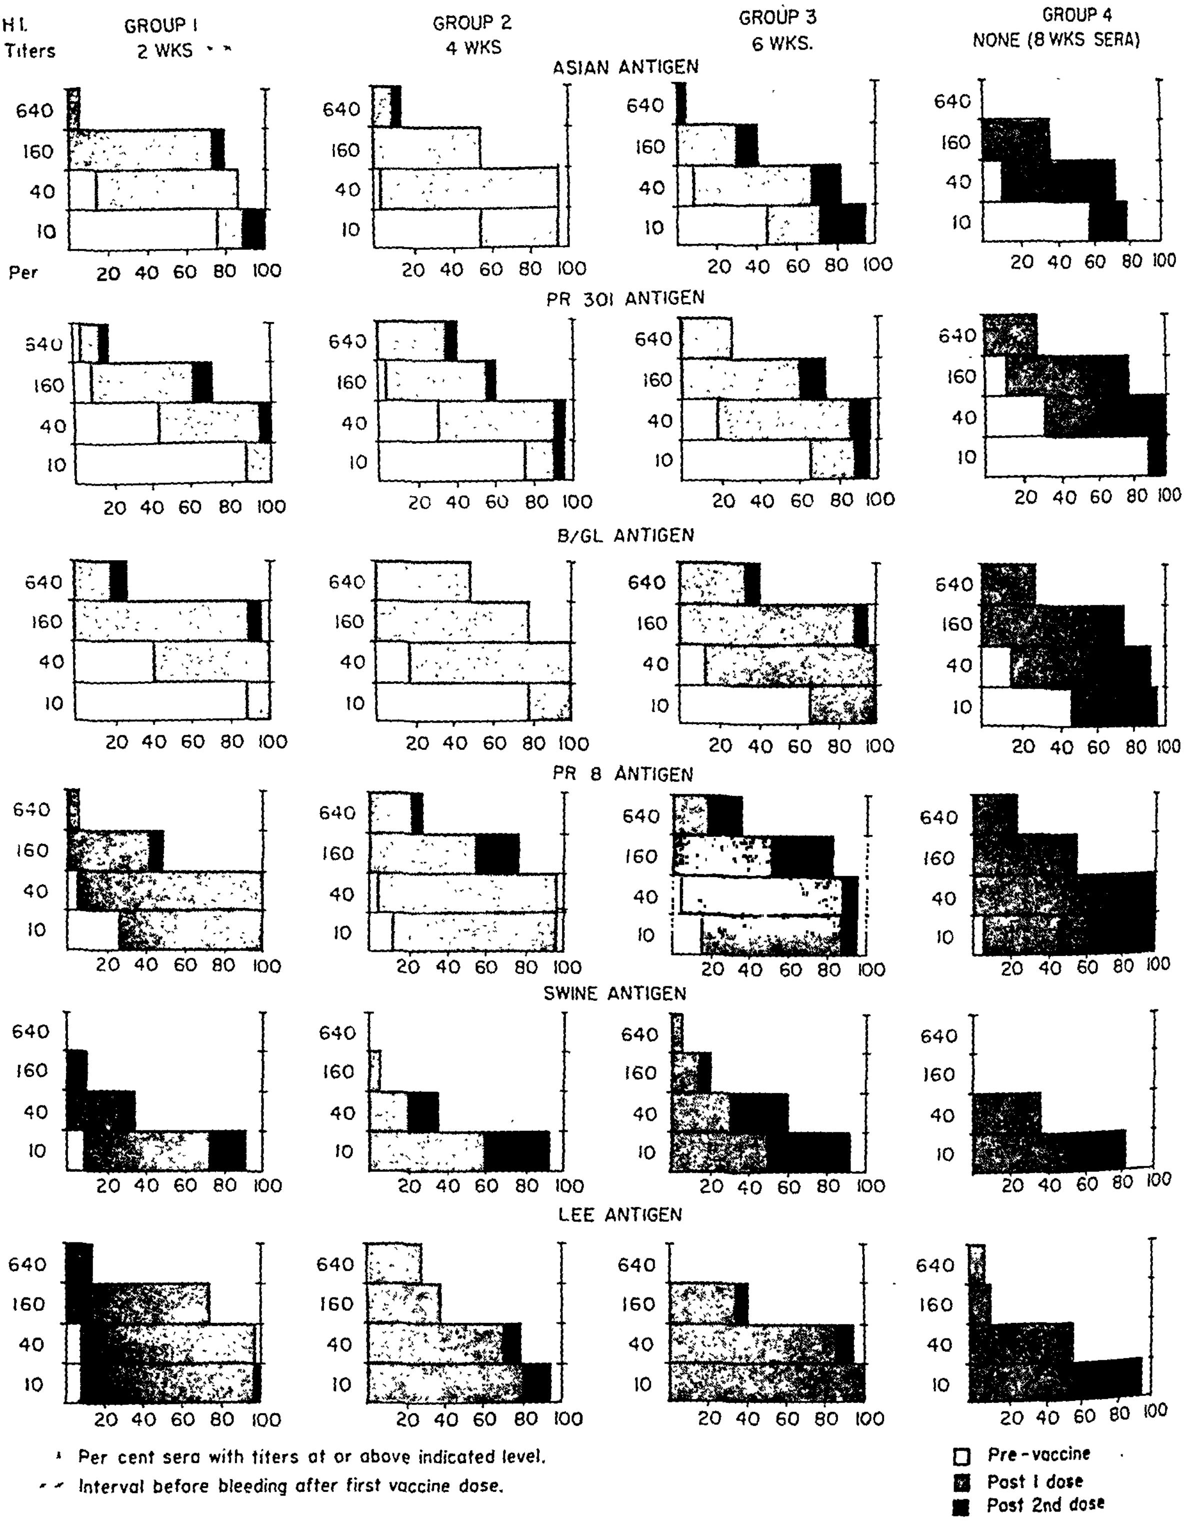
With the Asian virus, the maximum primary response was found two to four weeks after the first dose, and then most of the vaccinees began to lose antibody. When a second injection was given six weeks later, at least 25% responded; nevertheless, the group level was only as great as that found at four weeks after one dose, an indication that little was gained by the second injection. With the PR301 and B/GL antigens, there is little difference between the four groups. It is evident that most vaccinees had responded maximally to the first injection, probably because nearly all had been sensitized previously by experience with closely related viruses. Therefore, the antibody stimulated was due to a recall mechanism, and the subjects were refractory to a second injection at these short intervals.

In the case of the PR8 and Swine antigens, many of the children did derive benefit from a second dose. This is most evident in the responses of the subjects in group 3, in which the interval between



* Per cent sera with titers at or above indicated level.

** Interval before bleeding after first vaccine dose.

Fig. 4.—Distribution of HI antibody titers in serums obtained from children before and after one or two doses of 1,000-CCA-unit (six-strain)-influenza vaccine.

doses was six weeks. However, differences in responses of the three groups were not of sufficient magnitude to warrant a delay in giving the second dose.

Dosage Size Related to Antibody Response: In view of the superior antibody patterns obtained in children when a vaccine dose containing only 500 CCA units of the six-strain formula was injected, we investigated doses as low as 100 CCA units, with use of a 1,000-CCA-unit vaccine that was diluted 1:5 in saline solution and given as a 0.5-ml. subcutaneous injection. For comparison, a second group was given 0.5 ml. of the undiluted vaccine. Injection of these doses was repeated after two weeks, and the serum samples collected two weeks after each dose were tested with the six strains of influenza. Comparisons of the antibody response patterns are presented in fig. 5.

Although somewhat higher levels were found in he group of those who received 500 CCA units of vaccine, it is evident that a large number of chillren given only 100 CCA units developed satisfacory titers, particularly when measured against the Asian, B/GL, and PR301 strains. After receipt of he second dose, titers were, with few exceptions, ssentially like those seen after one dose of either he 100-CCA or the 500-CCA unitage. The concluion is clear that children who had received a total f 100 CCA units and, therefore, only 10 CCA units ach of the Swine, B/Lee, PR301, and PR8 strain ften responded in a satisfactory manner, and that second injection of a similar amount two weeks fter improved the group's response level only lightly.

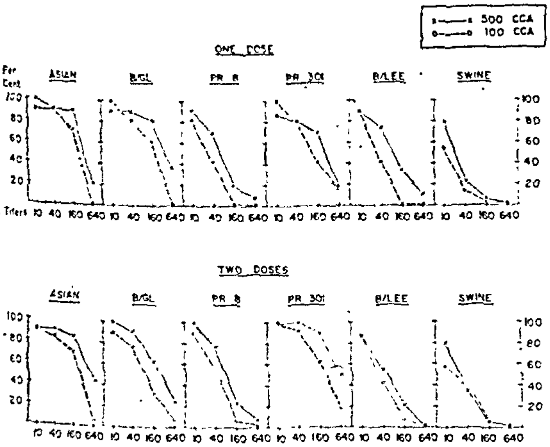


Fig. 5.—Patterns of antibody response in children injected ith 100 or 500 CCA units, respectively, of six-strain influza vaccine containing 1,000 units per milliliter.

Antibody Responses of Adults to Polyvalent Influenza Vaccine: The pattern in adults varied considerably from that found in children. Although, as shown in figure 1, the incidence of prevaccination antibody to all strains was greater in adults, children responded to vaccination more frequently. This effect did not parallel increasing age, except in measurements against the oldest available virus, i. e., the Swine strain. Therefore, to simplify presentation, the data are grouped from all persons who were aged 19 years or older; the median age was 27 years.

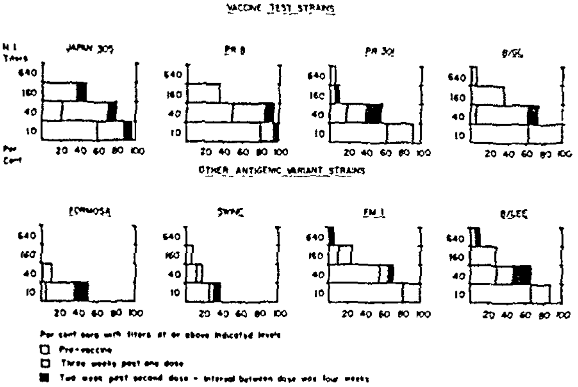

Fig. 6.—Distribution of HI antibody titers in serums obtained from adults before and after vaccination with standard four-strain polyvalent influenza vaccine.

To study the increment that might be gained by giving a second dose of vaccine at a relatively short interval after the first, injections of 1 ml. of four-strain, 500-CCA-unit vaccine were given subcutaneously to 26 adults. They were bled three weeks after the first dose and two weeks after the second, with a four-week interval between injections. The distribution of antibody titers is shown in figure 6, with responses to the strains used in the vaccine illustrated in the upper part and as measured with other different strains in the lower portion of the chart. As was true for children, relatively few adults reacted to the second dose. The best responses were obtained with the Japan 305 and B/GL strains that are representative of the currently epidemic type A and B variants. It is remarkable to find that, although most adults have low levels of antibody against many of the older strains, and can therefore be considered sensitized, vaccination did not elicit hyperimmune responses. It is evident that in many adults antibody titers reach a ceiling or normal maximum, subsequent to which, in a sense, these persons become desensitized after multiple antigenic experiences during the recurrent progression of influenza epidemics.

Results of several experiments with the two polyvalent influenza vaccines in adults indicated that the 1,000-CCA-unit preparation stimulated better antibody responses more often, although the degree of superiority was not as great as that seen in children. The results of two such experiments are illustrated in figure 7. In this case, the effectiveness of vaccination is compared on the basis of the percentage of each group without significant antibody titers before and after vaccination. By this means, attention is focused on that portion of the population which appears to be in greatest need of an effective vaccine.

Prior to immunization, about 50% of each group studied had serum titers of less than 1:10 against the Swine strain, and 65% of the titers were less than 1:40. In the group that had received the 500-CCA-unit vaccine only a few developed antibody, while, in contrast, 80% had detectable levels after vaccination with the 1,000-CCA-unit preparation. This response to the Swine strain is not entirely satisfactory, however, since only 55% produced titers equal to or higher than 1:40. The Lee, GL, and PR8 viruses elicited better group responses. It was only with four strains, namely, Lee, GL, PR8, and Swine, that the group that had been given the 1,000-CCA-unit vaccine showed any degree of superior response, whereas measurements with the PR301 and Japan 305 viruses indicated no difference between the two vaccines. The PR301 strain must be considered a particularly poor antigen in adults, since about 10% of each group remained without antibody levels equal to 1:10 and 50% did not have titers equal to 1:40 after vaccination.

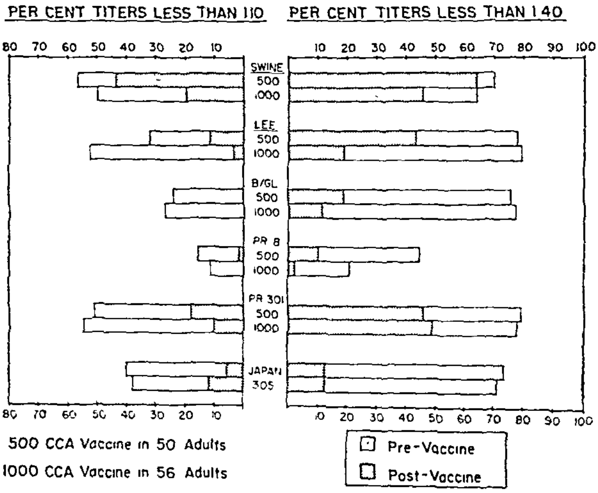

Fig. 7.—Evaluation of polyvalent vaccines by efficiency of conversion of low antibody titer level in adult populations.

About 10% of the adults failed to produce antibody to the Asian component to a level of 1:40 or higher. This was the case regardless of whether 200 CCA units, as provided in the 500-CCA-unit polyvalent vaccine, or 400 CCA units of this component were given.

When one compares the antibody patterns obtained in adults and children with the two different polyvalent vaccines, it is evident that children, in general, responded to influenza antigens in a satisfactory manner more often than did adults (fig. 8). Furthermore, the superiority of the six-strain preparation is most evident in children.

Comment

Since 1947, when the antigenic change amor type A strains to the A1 set was shown to be practical immunological significance, there h been uncertainty as to what degree of differen among antigenic variants is necessary to warra their inclusion in a polyvalent vaccine. The pra tice has been to revise almost yearly the formulati of influenza vaccines. Many serologic variatio among the virus isolates were found to represe "antigenic embroidery" of little significance wi regard to the protection of human population Although influenza viruses have appeared capal of random variations in antigenic structure sin the first isolations three decades ago, it is now p sible to group these variants into families or sel Herein lies the key to successful immunizati since vaccination with one representative of a induces antibody formation and protection agai other members of that group. A new family becon prevalent and completely replaces its ancest group of strains with almost predictable regulari Since new sets of both type A and B viruses can expected to appear in a few years, how can we b prepare for them? What are the mechanisms whi produce the marked shifts in antigenic structu There are as yet no completely acceptable and g erally satisfying answers to either question. optimistic but rational hypothesis is that suffici antigens may be shared by members of the differ sets to provide immunological overlapping in p sons of wide experience with influenza varian who would, therefore, be insensitive to infectio with ensuing generations of influenza strains. Th is supported by the observations that highest rat of attack in influenza epidemics occur among chi dren. This is the basis for compounding a vaccir

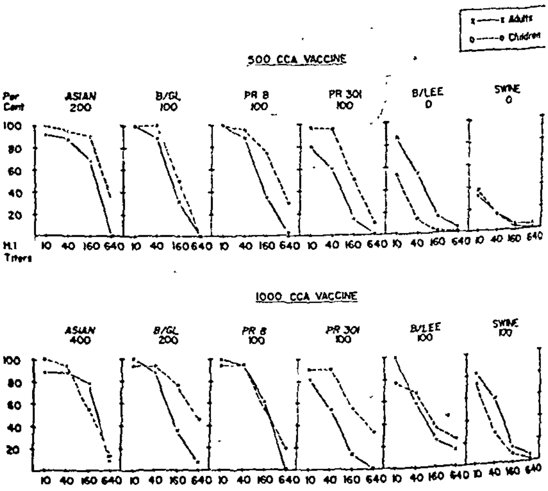

Fig. 8.—Patterns of HI antibody titer distributions serums obtained from children and adults after vaccinati with four-strain and six-strain influenza vaccine respective

that contains representatives from each of the sets of virus known to have been successively prevalent during the past 30 years.

The antibody responses of children and adults to monovalent (single-strain) influenza vaccines have been well characterized in reports on the recent widespread experience with the Asian strain [1] and in such previous studies as those of Davenport and co-workers.[4] The concept that the antibody orientation is the result of the initial influenzal antigenic stimulus in life has provided a valuable hypothesis for understanding the age-related variability in antibody responses to vaccination or infection. Responses to influenzal antigens are governed by antibody-recall mechanisms established as a result of the first antigenic experiences in childhood with related influenza viruses. The most obvious effect is a bolstering of antibody levels measured against viruses from that family of strains. On the other hand, responses to subsequently encountered strains may in some cases be inhibited; indeed, it can be expected that well-seasoned persons will become relatively refractile in producing antibody against the most recently experienced antigens. These aspects of influenza immunization, first observed after injections with monovalent vaccines, clearly affect the results that will be obtained when multivalent preparations are given. However, persons of any age can be immunized to a great variety of influenza variants by the simultaneous injection of several strains.

That the continued use of polyvalent influenza vaccines should be encouraged is supported by recent epidemiologic observations [3] and by our serologic findings that most children, in particular, have little, if any, antibody against the important influenza strains. Our data make it evident that antibody production stimulated by vaccination or natural experience even in the recent past has not been maintained at desirable levels in most subjects. It must be concluded that the greater portion of previously infected persons may be susceptible to reinfection and, therefore, antibody titers should be boosted by additional antigenic experience through vaccination. It is now clear that children can be provided with antibody complexes comparable to those found in older adults by immunization with a six-strain vaccine.

The question of the proper formula for the most successful influenza vaccine has been approached in these studies by a comparison of antibody responses to the vaccines that are now available. Since it is not possible to make an accurate prediction, we must continue the attempt to second-guess the antigenic composition of the next sets of influenza viruses which are likely to appear in the near future. At this point in time, the best recourse is to manufacture polyvalent influenza vaccines that contain a spectrum of efficacy that is provided by the most antigenic representatives of each of the past families of variants. The data obtained from our study indicate that vaccines containing six strains are efficacious and, further, that a new formula for a vaccine which includes from 10 to 100 CCA units each of these strains would be as safe but more potent than the current four-strain 500-CCA-unit standard vaccine. Its use would cause, particularly in children, formation of immunological barriers of greater breadth against new influenza-virus varients.

Summary

Two polyvalent influenza vaccines were given to both children and adults and compared for their safety and potency. Injection of a six-strain preparation, with a total chick cell-agglutination unitage of 1,000, while producing no greater incidence of undesirable side-effects than lower doses repeatedly stimulated antibody responses that were superior to those obtained with the standard four-strain formula of 500 CCA units. Children generally produced better antibody levels than adults with use of the six-strain vaccine. Secondary injections are usually needed to maintain the antibody level and should not be delayed unduly. Use of the six-strain vaccine in the unitage indicated above should provide broader immunological barriers against new influenza-virus variants.

The vaccines used in this study were supplied by the biologics production department of Charles Pfizer & Co., Inc., Terre Haute, Ind.

PNEUMATOSIS CYSTOIDES INTESTINALIS

Howard P. Doub, M.D.
and
James J. Shea, M.D., Detroit

The authors give the histories of four patients with collections of air under the mucosa or serosa of the intestinal tract and its peritoneal attachment. The 4 are representative of 16 patients, observed by the authors, with pneumatosis cystoides intestinalis and a common history of allergic difficulties and asthma. The etiology of the disease has been the subject of many theories, but a complete understanding of the pathogenesis has not yet been attained. The two dominant concepts at present are based on (1) a mechanical theory which assumes that the gas is forced through a fissure in the intestinal mucous membrane and (2) a chemical theory which assumes that gas is produced by fermentation and absorbed by the mucous membrane. Investigation for the existence of a cause-and-effect relationship between allergy or asthma and air in the intestinal wall is suggested as a worthy endeavor.

Pneumatosis cystoides intestinalis is an uncommon disease characterized by submucosal or subserosal collections of air in the intestinal tract and the peritoneal attachments. Pneumatosis coli is the more specific term for its localization in the colon, which is the subject of this report. Koss[1] in 1952 reviewed the world literature and found a total of 255 cases, but only 13 of these were limited to the colon. To the latter group, some 18 cases in adults have since been added.[2] This report is based on a study of 16 cases.

Symptoms and Etiology

Symptoms occur in most patients, but these are nonspecific, being common to any number of conditions involving the colon or small intestine. Bouts of diarrhea alternating with constipation, constipation alone, melena, and flatulence are common. Any of these may occur as an isolated finding, or they may be present in combination. A few cases are asymptomatic initially. In one patient in the present series roentgenograms showed evidence of the disease more than two years before he complained of any symptoms referable to the colon. The onset of symptoms frequently prompts radiologic studies and proctoscopy, leading to recognition of the disease.

Two forms of pneumatosis coli are recognized, the primary, which does not involve the rest of the gastrointestinal tract, and the secondary, in which there is an associated obstructive lesion in the stomach or small intestine. In the latter instance, it is the small intestine which is mainly affected. Koss[1] found that 58% of the patients whose cases he studied had stenotic lesions in the pyloric area, most of which were ulcers.

The mechanical theory of the disease postulates a break in the mucosa through which air is forced under pressure into the submucosa or subserosa, probably by way of the lymphatic channels. It does not, however, explain the separated areas of involvement encountered in the small intestine and certainly does not account for the fact that the

---

Read before the Section on Radiology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

disease is situated solely in the colon. Stienon[3] explained multiple areas of involvement by suggesting that the gas extends retroperitoneally and, having reached the mesenteric insertion of the intestine, either enters the subserosal spaces or follows the perforating blood vessels into the submucosal space. Marshak[2a] has considered the traumatic role of sigmoidoscopy and biopsy in the production of pneumatosis in the left half of the colon. Alford[2d] proposes a chemical theory, attributing the symptoms of diarrhea, flatulence, and abdominal distress to increased fermentation in the large intestine, with an increase in lactic acid and gas-forming bacteria. He postulates an alteration in the normal absorption of gases by the blood stream with retention in the wall of the intestine. The gas bubbles then may lead to the formation of giant cells and connective tissue which encapsulates the gas to produce cysts. There are many theories about this disease, but there is no established cause.

Pathology

Koss[1] outlines the possible sequence of events as follows. The simple endothelial cells with which the cysts are lined have a tendency to coalesce to form large giant cells. An associated inflammatory reaction occurs in the adjacent connective tissue. The giant cells finally slough, the surrounding stroma and the cysts become fibrotic, and the cysts disappear as scarring progresses. The cysts vary from a few millimeters to a few centimeters in diameter. They may occur either singly or in clusters. They apparently do not communicate with the intestinal lumen or with each other. In the colon they are located predominantly in the serosa, but they may be submucosal.

Roentgenographic Studies

The diagnosis of pneumatosis coli can be made from the chest film, in which air cysts (fig. 1) may be seen in the splenic or hepatic flexure of the colon, or from a plain film of the abdomen. Either may be confirmed by barium enema. With involvement of the splenic or hepatic flexure the cysts can be seen as small gas shadows adjacent to or superimposed on the air in the colon (fig. 2). In one of the cases in the present series the diagnosis was suggested by a photofluorogram. Barium enema study demonstrates large polypoid defects in the wall of the intestine. Sometimes the barium practically obliterates the cysts, and they are not well visualized except on the postevacuation film, in which the collections of air are seen at the periphery of the intestine because of the contrast between them and the barium-coated mucosa. At times in the postevacuation film the mucosa appears to be swollen, which suggests ulcerative colitis. Close inspection, however, discloses the air cysts at the margin of the intestine (fig. 3). The gas may also be evident as a linear radiolucent stripe along the intestinal margin.

Roentgenographic evidence of pneumoperitoneum in an asymptomatic patient should suggest pneumatosis intestinalis. A correct roentgenographic diagnosis will prevent unnecessary surgery. No patient in this series was operated on, and there were no complications, though such complications as obstruction from pressure of the cysts, volvulus as a result of the scarring, and pneumoperitoneum have been recorded by others. In one case retroperitoneal air was present beneath the diaphragm bilaterally.[4] It showed no shift regardless of the position in which the films were taken and produced no specific symptoms.

Report of Cases

Case 1.—A 64-year-old man was first seen in August, 1953, because of bronchial asthma. It was fairly well controlled, but exacerbations occurred from time to time, usually precipitated by acute upper respiratory infections. The patient was not seen from April, 1954, until July, 1955. At the latter time a barium enema examination demonstrated pneumatosis cystoides in the sigmoid area and distal portion of the transverse colon. A proctoscopic examination on the preceding day had shown no significant findings. A second barium enema study in August, 1956, showed regression of the previous areas of pneumatosis cystoides in the sigmoid and splenic flexure. The patient died January, 1958, because of an acute attack of asthma followed by congestive failure and ventricular tachycardia. No autopsy was performed.

Case 2.—A 49-year-old man was first seen in 1949 because of asthma which had begun four years earlier. There were repeated visits and admissions to the hospital because of exacerbation of the asthma and superimposed pulmonary infections. In March, 1955, the patient was seen because of his asthma but complained, in addition, of intermittent diarrhea. Chest films at this time showed fibrotic changes in both lungs. There was also noted an unusual collection of gas in the colon beneath the left leaf of the diaphragm.

In May, 1955, the patient reported that he had had diarrhea for five weeks, with five or six stools per day. The stools were watery and contained mucus and occasional blood streaks. Physical examination disclosed an irregular movable mass in the left upper quadrant which did not move with respiration. A barium enema study showed numerous polypoid-like defects involving the splenic flexure and the entire descending colon. Proctoscopy through a distance of 10 in. showed numerous sessile gelatinous-appearing polyps of varied size. An upper gastrointestinal examination showed negative results. The proctoscopic examination was made before the barium enema was given but six weeks after the unusual collection of gas was noted on the chest film. A barium enema given seven months later to check progress showed pneumatosis from the distal transverse colon to the middle of the descending colon. The patient still complained of three or four loose bowel movements per day, two or three times a week.

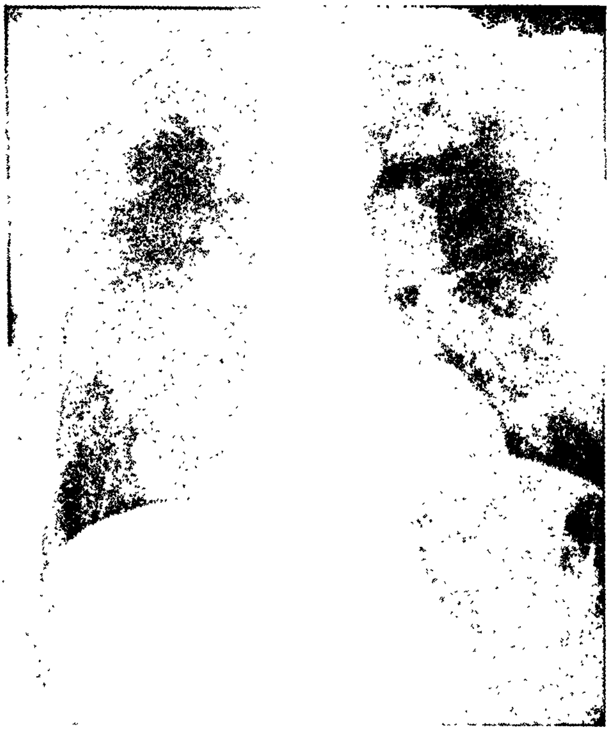

Fig. 1.—Foamy appearance of air in splenic flexure indicating air cysts.

Case 3.—A 67-year-old man had a 20-year history of productive cough with increasing dyspnea. This chronic lung condition was complicated by several acute respiratory infections each year with production of profuse mucopurulent sputum. Pulmonary function studies showed a diffuse airway obstruction, probably with some pulmonary fibrosis, and vital capacity was estimated at 50% of normal.

One and one-half years after his initial visit, the patient returned to the hospital because of blood in the stool and a large amount of flatus. A barium enema examination showed an ulcerative process in the left half of the colon and air cysts. An upper gastrointestinal series showed negative results. On subsequent visits the patient reported no further bowel difficulty. He was admitted six months after the first admission because of sudden onset of epigastric pain with nausea and vomiting. Films of the abdomen at that time showed pneumatosis cystoides in the distal transverse and descending colon. Proctoscopy prior to the earlier barium enema studies had revealed no abnormalities. The symptoms on the last admission were attributed to cholecystitis, and a cholecystogram showed cholesterol stones.

Case 4.—A 62-year-old man was admitted in January, 1953, because of acute pancreatitis. He was next seen in April, 1956, when his chief complaint was shortness of breath. Dyspnea had been present for many years but had become progressively worse, especially since an attack of severe substernal pain a week prior to his admission. An electrocardiogram showed evidence of a recent myocardial infarct. The diagnoses of arteriosclerotic heart disease with atrial fibrillation and chronic bronchitis were made.

The first suggestion of gastrointestinal involvement occurred in December, 1957, at which time he complained of having to evacuate immediately after each meal. In the interim he had had repeated attacks of asthma with superimposed respiratory infections. He was again seen five months later because of diarrhea after meals. He experienced no nausea or vomiting, and no blood was noted in the stools. He returned in June, 1958, still complaining of diarrhea, which was not responding to dietary measures or antispasmodics. At that time an annular irregular mass was felt within 2 in. of the anus, and sigmoidoscopy disclosed a mass involving the entire circumference of the intestine starting at a distance of about 6 cm. and extending

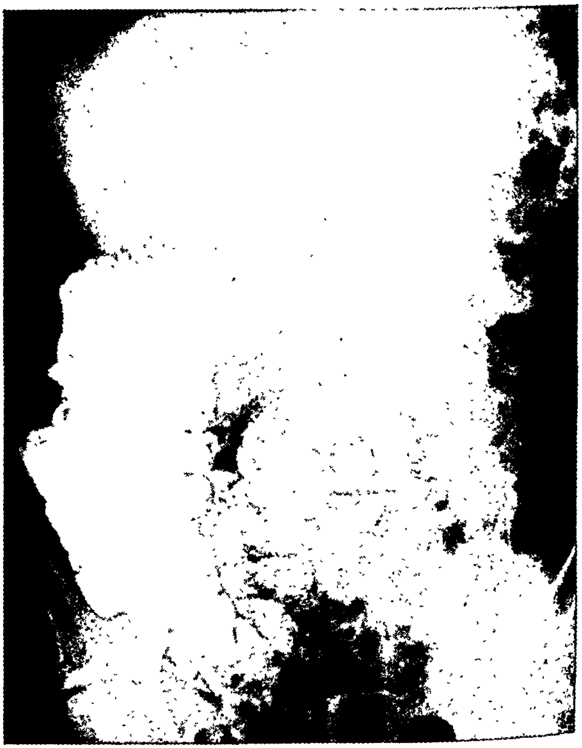

Fig. 2.—Small intestine series. Unusual small rounded air shadows in splenic flexure and descending colon are air-containing cysts.

beyond the limit of the sigmoidoscope. The surface was smooth and soft and looked like blebs. Biopsy specimens were taken of four separate areas, and "each bleb, when biopsied, yielded a report as of a balloon popping, clearly audible through the room." The surgeon's impression was pneumatosis coli involving the sigmoid and rectum. Pathological study showed normal rectal mucosa. A barium enema study a week later confirmed the findings, shown by proctoscopic examination, that there were pneumatosis cystoides involving the sigmoid colon. A study of the small intestine showed negative results.

The patient was readmitted in October, 1958, with pneumococcic pneumonia involving the left lower lobe. There was no complaint of any gastrointestinal trouble at that time.

Comment

The significant feature in 15 of the cases was a history of asthma and allergy. These patients originally and primarily sought advice about these conditions. The other patient had idiopathic pulmonary fibrosis with marked reduction of all categories of pulmonary function. It was only later in the course of the chronic lung disease that symptoms of diarrhea, flatulence, constipation, and blood or mucus in the stools developed. This association is not considered coincidental. Creevey's patient had allergic manifestations including hay fever, asthma, arthralgias, and eczema for 20 years.[2c] Matthew's patient had also been a chronic sufferer from asthma.[2f] In other reports reviewed this association had not been noted.

The exact relationship between the asthmatic and allergic conditions and the pneumatosis is not understood. The cases in this study are all confined to the descending colon except for one case involving the ascending colon. Proctoscopy, usually performed before a barium enema examination, might possibly be a precipitating factor, but in five instances cysts were seen prior to the barium enema, and several cases were diagnosed by proctoscopy initially and confirmed by barium enema. Other cases were detected by chest films prior to proctoscopy. Thus there does not seem to be a constant etiological relationship between proctoscopy and the development of pneumatosis. In none of these cases was there a history or clinical or roentgenographic evidence of obstructive disease of the stomach or small intestine. Symptoms are probably due to the cysts but their occurrence does not necessarily presuppose a complication such as partial obstruction. Symptoms may wax or wane without significant change in the degree of involvement, and pneumatosis may occur without symptoms, though these often develop subsequently. The cysts may regress spontaneously.

Differential diagnosis is not difficult. After recognition of the disease conservative treatment is indicated except in the unusual case of obstruction due to the cysts, volvulus, or uncontrollable hemorrhage.

Summary

A description of 16 cases of pneumatosis cystoides intestinalis involving the colon has been added to the previous reports of this disease. Many of these cases can be recognized or suspected from plain films of the abdomen or chest and then confirmed by means of barium enema. The diagnosis may occasionally be made by proctoscopic examination.

No cause of this lesion has ever been proved, although many theories have been advanced. It is of interest that in 15 of the 16 cases it was allergy and asthma which led the patient to seek medical care. While it is impossible at this time to establish a definite causal relationship between these conditions and pneumatosis coli, it is believed that further study should be made with this possibility in mind.

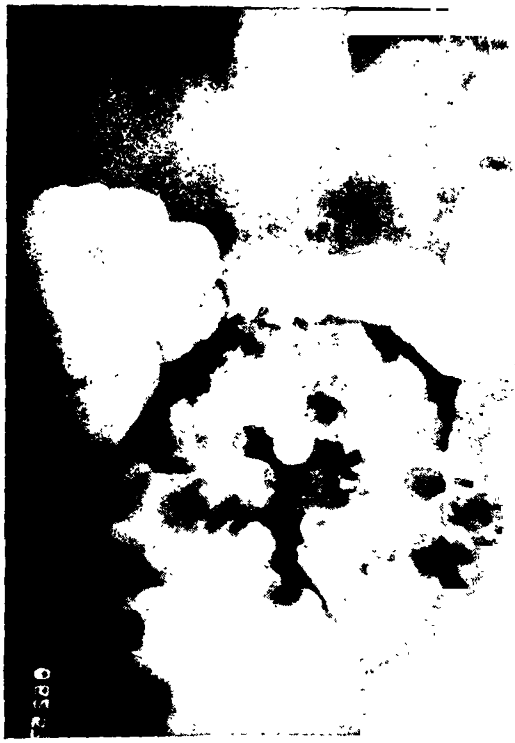

Fig. 3.—Large polypoid defects resembling polyposis. Air density at margin of intestine is well seen in splenic flexure. Pneumatosis cystoides intestinalis is proved by biopsy.

TREATMENT OF CALCANEONAVICULAR BAR

James I. Kendrick, M.D., Cleveland

A calcaneonavicular bar, when complete, seems to join the whole of the lateral aspect of the os naviculare to the calcaneus; it replaces the calcaneonavicular ligament, produces rigid fusion of the corresponding joint, and generally causes pain. Another anomaly, a talocalcaneal bridge, is commonly associated with it. In a series of two girls and five boys with feet made painful by these anomalies, there were four feet with complete and seven feet with incomplete bars. In the younger patients in whom the bar was incomplete, simple resection was successful and good motion returned to the subtalar joint. When the bar was complete, neither conservative measures nor simple resection relieved the pain, so that triple arthrodesis was necessary.

A calcaneonavicular bar is a congenital anomaly consisting of bony bridging between the calcaneus and the navicular bone. This unusual bone formation replaces the calcaneonavicular ligament, producing a rigid fusion, which causes foot strain d associated symptoms.

Reports on the treatment of peroneal spastic flatot due to calcaneonavicular bar in children have een few, and I should like to bring this subject to your attention and to discuss it in the light of my experience in treating a number of such patients during the past 10 years.

Jack,[1] in 1954, pointed out that the papers of Slomann,[2] in 1921, and of Badgley,[3] in 1927, have been neglected, and that the important role of the calcaneonavicular bar and the talocalcaneal bridge in peroneal spastic flatfoot received attention and much-needed emphasis from the report of Harris and Beath[4] in 1948. Anatomists had described these anomalies, but the correlation of anatomic with clinical findings was due to better roentgenographic techniques and the exact visualization of the nature of these structural variations.

On the basis of my experience and the reports of others, it should be emphasized that any child who has a painful foot with peroneal spasm should undergo proper roentgenographic examination to confirm the presence or the absence of one of these anomalies as the cause of the complaint. It should also be pointed out that, since the anomalies coexist more often than not, the roentgenographic study should include the special oblique-lateral and superoinferior views of the os calcis so that exact evaluation can be made.

Nature of Anomaly

Incidence.—The condition is more frequent in boys than in girls. In the group reported here there were five boys and two girls. Three boys and one girl each had both feet involved. Two of the boys had both talocalcaneal bridge and calcaneonavicular bars bilaterally. The girl who had both feet involved had the combination bridge and bar in

one foot and only a calcaneonavicular bar in the other. The ages of the patients at onset of symptoms ranged between 9 and 12 years; the earliest age was in a girl. Trauma was an uncommon cause of the onset of the symptoms, which developed insidiously and seemed to be associated with the process of skeletal maturation.

Symptoms.—Pain was the most common complaint. Of the 11 feet, all but 2 were painful. Restriction of motion was the most common finding. Eight feet showed peroneal spasm; one foot showed anterior tibial spasm, and the two painless feet showed no restriction of motion. Local tenderness over the region of the calcaneonavicular bar was a frequent finding but was not present when there was a complete bar. The tenderness was just distal to and below the sinus tarsi. All patients experienced fatigability and aggravation of the symptoms by activity. None had obtained relief by either arch supports or rest. None had had manipulations performed or been given walking casts.

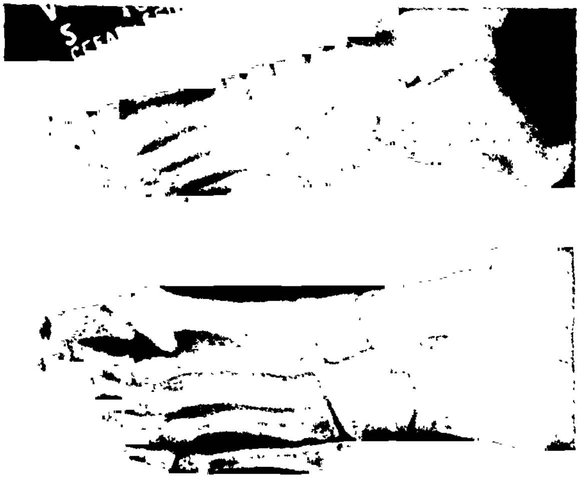

Fig. 1.—Roentgenogram showing bony bridge between calcaneus and navicular bone.

Roentgenographic Findings.—Complete diagnostic roentgenographic examinations were made of all 11 feet. The appearances of the calcaneonavicular bars varied widely. In 4 of 10 feet the bar was broad, complete, and bony throughout (fig. 1). The complete bars seemed to join the whole of the lateral aspect of the navicular bone and to flow to the inferior surface to form an extensive attachment. The other seven feet contained bars of variable structure, but all showed a radiolucent interval of either cartilage or fibrous tissue.

Pathology.—It is my belief that in early life the calcaneonavicular bar exists as a cartilage or a fibrous mass. This tissue is flexible, and its structure is adapted to movements with the joints of the midfoot. As age advances, the character of the tissue changes, and the bar becomes evident. One of the boys in this series, whose symptoms developed insidiously at the age of 11 years, had injured his foot two years earlier. A routine roentgenogram was made at that time, and I was able to review the film without finding in it any evidence of the bar that subsequently developed. The injury had been treated as a sprain, and the foot had recovered and remained painless for two years, until the onset of the peroneal spasm. This bar was removed en bloc from the youngest patient, a girl who had combination bars in both feet but pain in only one foot; she also had anterior tibial spasm. In the gross specimen (fig. 2), bone, cartilage, and fibrous tissue are recognizable, and the appearance is that of a synchondrosis. The microscopic section (fig. 3) shows bone, cartilage, and fibrous tissue on both sides and a space lined with

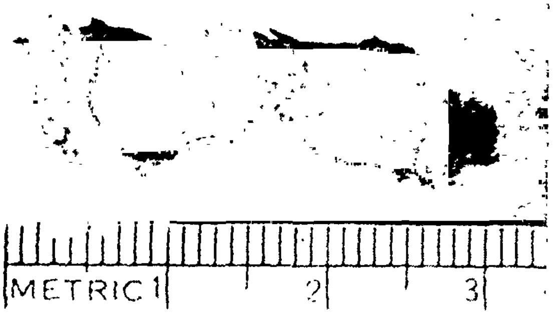

Fig. 2.—Gross appearance of resected specimen of incomplete bar, showing bone, cartilage, and fibrous tissue.

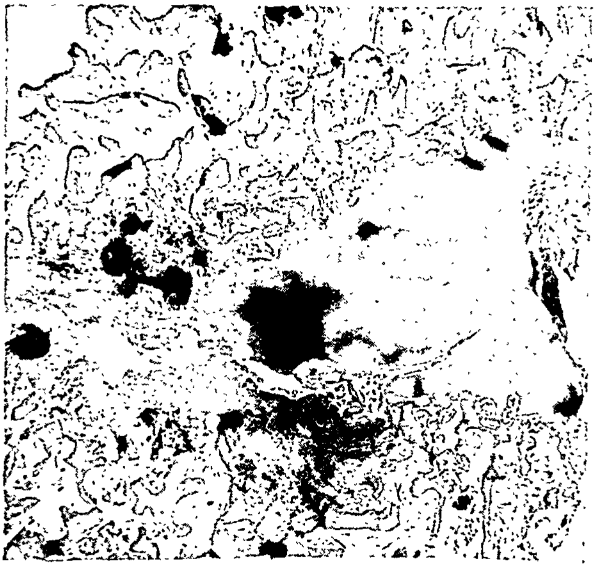

Fig. 3.—Photomicrograph of incomplete bar, showing bone, cartilage and fibrous tissue (× 12).

cells that are similar in appearance to synovial cells. This morphologic appearance is similar to that of the specimen shown by Webster and Roberts[5] in their report in 1951. The tissue noted in their case seemed more mature, and there was no evidence of a space that simulated a joint space like that seen in this case.

Treatment

In describing the treatment, I shall present the material as an analysis of the treatment of the 11 feet rather than of the seven patients. In the four feet with the broad complete bars, two of the bars were resected, and fat was interposed in the defect. Neither patient obtained relief from the operation, and one bar had re-formed completely within one year after the operation. Among these four feet, relief of symptoms was achieved in three by triple arthrodesis, but one foot remained painful and unimproved by resection of the bar. Of the seven remaining feet in which the calcaneonavicular bars were incomplete, two were painless and required no treatment. One bar was in the foot of a child who had had poliomyelitis, and the symptoms were controlled by a brace that was worn of necessity. Of the four remaining feet, all obtained prompt and complete relief of symptoms by resection of the bar, and all had subsequent return of good motion to the subastragalar joint.

Comment

Calcaneonavicular bar is not a common condition. I have examined hundreds of children's feet to gather together the seven cases presented here.

Although the number is small, I believe that the analysis of the results obtained from treatment, gives some indication of the results to be expected and which type of patient will respond to simple resection with effective relief of symptoms. In the younger patients in whom the bar was incomplete, simple resection was successful and good motion returned to the subastragalar joint. In the patients in whom the bar was complete, the pathological changes apparently were more extensive, and simple resection was not successful in either relieving the symptoms or effecting improvement in subastragalar motion. In these patients, triple arthrodesis was necessary to relieve the pain.

Summary and Conclusions

Calcaneonavicular bar is a rare condition, but nevertheless it should be considered when a preadolescent or early adolescent child has pain in the foot or feet, with evidence of either peroneal or anterior tibial muscle spasm.

If a bar exists and symptoms are well established, conservative treatment seems to be ineffective in giving lasting relief of pain. It is best to identify the bar early and to recognize that symptoms can develop in preadolescence; in those patients in whom the bar is incomplete, it can be successfully resected.

In patients in whom the bar is complete, the pathological changes are more extensive, and simple resection of the bar may not result in relief of pain.

LEPROSY IN JAPAN.—There are 15,000 leprosy patients in Japan, as contrasted with 30,000 in 1904. I visited the National Leprosorium, Zama Zensho-En, near Tokyo, a 50-year-old institution which has been gradually enlarged but hardly modernized. At present it has a capacity for 1,570 patients. It spreads over 97 acres and the patients are living in 257 houses, all surrounded with pretty gardens. The houses are extremely simple but scrupulously clean wooden structures. In addition, there are hospital buildings for the acutely ill. Strangely enough, in some wards the sexes are not separated. There are facilities for agricultural work, all kinds of handicraft, and sport facilities. Among the 32 full-time resident physicians, all specialties are represented. The medical care is at highest modern standards. The plastic surgeon, who happened to be my guide through the premises, showed me marvels in reconstruction of mutilated ears, noses, hands, and feet. Seventy per cent of the patients had lepromatous leprosy, but only 20% were active. The preferred sulfone preparation is glucosulfone (Promin); sulfoxone (Diasone) is thought to be less effective.—S. Rothman, M.D., A Dermatologist's Trip to Japan, *A. M. A. Archives of Dermatology,* July, 1959.

CONGENITAL DISLOCATION OF THE HIP

STUDIES IN THE EARLY WALKING GROUP

Edward A. Nalebuff, M.D.
and
Paul L. Norton, M.D., Boston

The authors analyze their experience with 31 cases of congenitally dislocated hip occurring in 21 patients. In all cases treatment began with closed reduction between the ages of 1 and 3 years. Twenty-two hips were immobilized in the so-called frog leg position and nine in the position of abduction and internal rotation. The frog leg position was effective only in 8 cases; the other 14 hips were changed to abduction with internal rotation, and 7 of these changes were accompanied by open reduction. Six case histories illustrate the occasional success of the frog leg position, the advantages of abduction and internal rotation, and the plan of treatment now recommended by the authors. This consists of an initial closed reduction followed by immobilization in abduction-internal rotation, combined with rotation osteotomy in selected cases.

In spite of an increased awareness of congenital dislocation of the hip by the medical profession, patients with this crippling condition are still being discovered late and are starting treatment long after they start to walk. This paper is a review of our experience with this group at the Lakeville State Sanatorium during the period 1949 through 1958. It was undertaken in order to develop an improved and more logical method of management of future cases.

This report is limited to our experience with an early walking group, between the ages of 1 and 3 years. The greatest variety of opinions exists about treatment of this particular group. Problems such as closed reduction versus open reduction; immobilization in the "frog leg" position versus abduction and internal rotation; the importance of anteversion and its management by rotation osteotomy; and the place of shelf stabilization procedures are all controversial. By excluding cases of congenital dislocation of the hip associated with other skeletal deformities such as spina bifida, arthrogryposis, and cerebral palsy, which alter both the prognosis and the treatment, we were able to study 21 patients, with a total involvement of 31 hips. All of these patients began treatment between the ages of 1 and 3 years.

Material and Methods

Description of Group.—There were 17 girls and 4 boys in the group investigated. The average age at time of diagnosis was 17 months. The average age at admission of patients initially treated at Lakeville was 21 months. Patients admitted to Lakeville for final treatment averaged 26 months of age. There were 11 patients with unilateral involvement and 10 patients with bilateral dislocations, making a total of 31 hips available for study.

Treatment.—Every hip had an initial closed reduction. Figure 1 illustrates the position of immobilization used. Twenty-two hips were immobilized in the so-called frog leg position. Nine hips were immobilized in abduction and internal rotation and required no alteration in position. However, only 8 of the 22 hips treated in the frog-leg position were successfully stabilized. The remaining 14 hips required an alteration in treatment to achieve stability. The position of immobilization was changed to abduction with internal rotation for this entire group, half of them associated with open reduction. This alteration in treatment was usually initiated because of failure of prolonged immobilization in the frog leg position to achieve stability. In two hips initially reduced in the frog leg position the position of immobilization was changed intentionally, after a short period, as part of their planned treatment. In the patients whose hips had redislocations, x-ray examination showed excessive anteversion as measured by the true lateral view, and several of these patients underwent rotation osteotomies in association with the change of position of immobilization. Excessive anteversion was visualized in each hip which underwent open reduction and in five of these hips the redislocation was anterior. Several shelf procedures were performed and rotation osteotomy for anteversion was often carried out.

Resident in Orthopedic Surgery, Veterans Administration Hospital in affiliation with Lakeville State Sanatorium, Middleboro, Mass. (Dr. Nalebuff), and Chief of Orthopedic Surgery, Lakeville State Sanatorium, and Visiting Orthopedic Surgeon, Massachusetts General Hospital (Dr. Norton). Dr. Nalebuff is now a National Foundation Fellow in Orthopedic Surgery.

Read before the Section on Orthopedic Surgery at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

It should be noted that in no patient whose hip was either initially immobilized in abduction and internal rotation or treated in this position after failure of the frog leg position was open reduction required. Preliminary traction, usually skeletal, with a wire through the distal femur, was used in most cases.

Results

In our evaluation, a patient was considered to have an excellent result when both the clinical examination and the roentgenographic appearance were normal. With only a slight deviation from normal in either the clinical examination or the roentgenographic appearance, the result was rated good. When a hip maintained its reduction but had abnormal roentgenographic appearance or mild loss of function, the result was considered fair. Patients in these three groups were classed as having satisfactory results. When there was moderate limitation of function or the reduction was not maintained, the result was considered poor.

Fig. 1.—Summary of treatment in 31 hips.

Of the 31 hips treated there were 27 satisfactory results and 4 failures. The results according to the various types of treatment used were as follows: group 1 includes those patients with hips in which closed reduction in the frog leg position was used and continued throughout the period of immobilization. This period ranged from 7 to 18 months, with an average immobilization of 9 months. No surgical attempt to correct anteversion was carried out in these patients. Although the eight hips included in this group were rated satisfactory (three excellent and five good), it should be emphasized that there were 14 other hips initially treated this way which had to have an alteration in treatment, and these failures represent groups 3 and 4.

Treatment with the frog leg position alone has not been used at Lakeville since 1954, because of the frequency of redislocation even after prolonged immobilization in a plaster cast. Our present method of treatment was used in the patients in group 2. Their nine hips were initially reduced and maintained in abduction and internal rotation. There were eight excellent results and one good result. In seven of the nine hips, a rotation osteotomy was performed in the subtrochanteric area to correct excessive anteversion. Internal fixation with a four-hole plate and screws was used to maintain the correction. The period of immobilization in this group ranged from four to eight months; a shorter period was used when immobilization was combined with corrective osteotomy.

Group 3 represents those patients in whom the frog leg position was used initially and then altered to abduction–internal rotation after failure of reduction. Five of the seven hips in this group had satisfactory and two unsatisfactory results. The two failures in this group occurred in a patient with bilateral recurrent dislocations, who has been treated in both frog leg and abduction–internal rotation positions and who continues to have dislocations anteriorly. During the past year this patient has undergone rotation osteotomies and a shelf stabilization procedure. It is too early to evaluate the results of these procedures; therefore, this patient is still considered to have a failure.

Those patients who underwent open reduction after failure of the frog leg position constitute group 4. Of their seven hips there were five satisfactory results and two failures. One patient died postoperatively, with acute pulmonary edema, and the second was transferred to a mental institution before completion of treatment.

Complications.—There were three postoperative varus deformities of the femoral neck after performance of rotation osteotomy and two failures of rotation osteotomy, one of which required a repeated correction before a satisfactory result was obtained. The second case was one of overcorrection due to a shallow acetabulum. There was one superficial postoperative wound infection in a patient after rotation osteotomy which healed without further complication. One patient developed a deep wound infection after a shelf procedure but subsequently did well and underwent another shelf operation and two rotation osteotomies without further incident. There were three cases in which the hip continued to dislocate. Two patients with such hips are undergoing treatment at the time of writing. There were three hips with mild aseptic necrosis.

Other orthopedists have used and recommended abduction with internal rotation for the position of reduction and immobilization in these cases.[1] The importance of excessive anteversion in the etiology of this condition has been previously described.[2] We have learned the hard way—by trial and error.

Report of Cases

Case 1.—A 26-month-old girl was admitted to another hospital in November, 1953, with a diagnosis of bilateral congenital dislocation of the hips. A closed reduction was successful, bilaterally, and the patient was immobilized in the frog leg position. After five months of hospitalization the patient was referred to Lakeville, with instructions to continue the immobilization for an *additional four months.* The patient was then allowed up and several months later the hips were noted to be unstable.

Examination under fluoroscopy showed the left hip to dislocate and the right hip to subluxate on external rotation, but both hips were well reduced on internal rotation. We felt that additional plaster-cast immobilization in abduction–internal rotation was needed, but the referring orthopedist insisted we repeat the frog leg position for an additional nine months. This was carried out and after ambulation was started the hips were again unstable. The treatment was then altered. After reducing the hips in abduction–internal rotation in December, 1955, a rotation osteotomy of the left femur was carried out. After five months of immobilization the patient was again allowed to walk. Her hips were stable in all positions and she was discharged from the hospital almost three years after her *initial reduction* (*fig.* 2).

Case 2.—A 17-month-old boy had a congenital dislocation of his left hip initially treated elsewhere in April, 1954. A successful closed reduction was done and the patient was immobilized in the frog leg position. Three weeks later he was transferred to Lakeville, where he was kept in a plaster cast for eight months before walking was allowed. His left hip was then found to be clinically unstable on weight-bearing and roentgenography showed progressive subluxation laterally. Excessive anteversion was proved roentgenographically. The hip was stable in abduction–internal rotation, and in May, 1955 (*at the age of 30 months*), he was again immobilized in a plaster cast, this time in abduction–internal rotation. After several months, he began physical therapy in a bivalved cast. He maintained his reduction but showed evidence of mild aseptic necrosis of the capital femoral epiphysis.

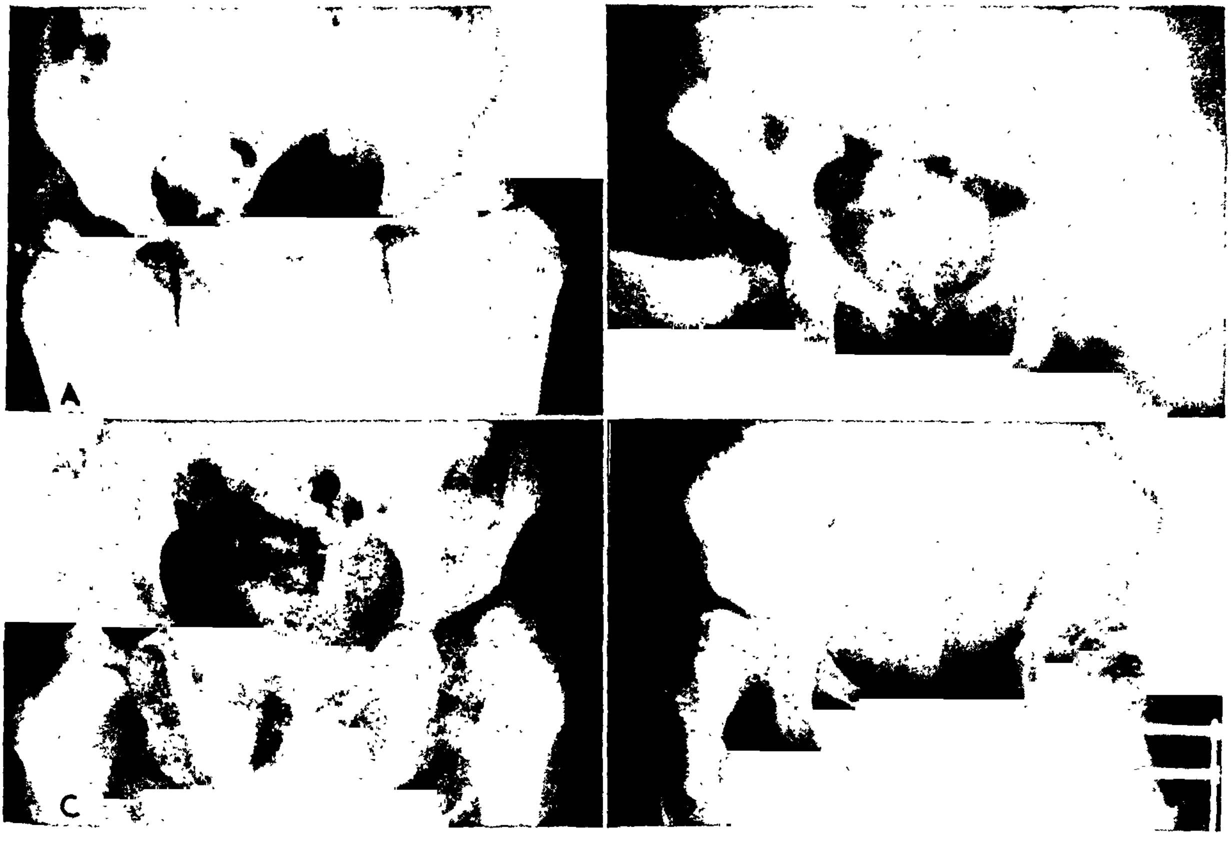

Fig. 2 (case 1).—*A*, bilateral dislocation of hips in November, 1953; *B*, successful closed reduction in frog leg position; *C*, left hip unstable on external rotation. Fluoroscopy revealed bilateral instability. Roentgenogram made after nine months' immobilization in plaster cast; *D*, alteration of treatment to abduction–internal rotation, with subtrochanteric rotation osteotomy of left femur. Hips had continued to subluxate after 18 months' immobilization in frog leg position, now are stable.

Comment.—These two cases are typical of group 3, in which patients who had failure of the frog leg position were successfully treated by changing to abduction and internal rotation. We believe the presence of excessive anteversion played an important role in these cases, and until it was managed by abduction–internal rotation and corrective osteotomy (case 1) a stable hip could not be achieved. The length of treatment could have been shortened considerably if this method of treatment had been used initially.

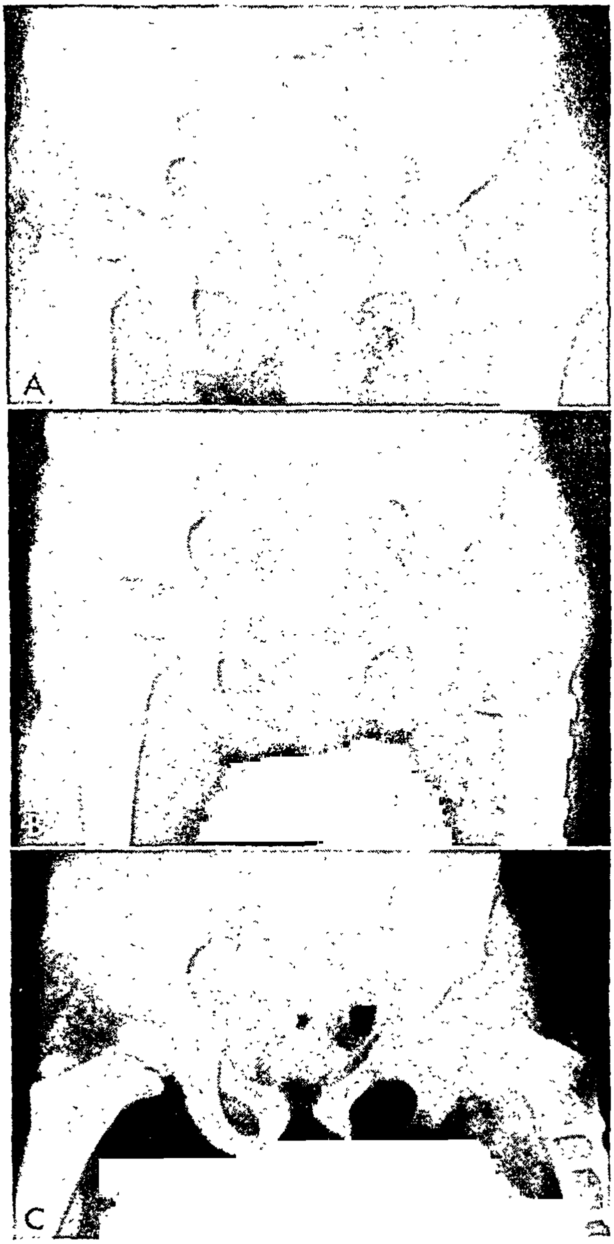

Fig. 3 (case 3).—*A*, dislocation of left hip in September, 1953; *B*, open reduction and rotation osteotomy were performed after hip redislocated, in spite of prolonged immobilization in frog leg position. Hip was still unstable in neutral position, indicating anteversion had not been corrected; *C*, after repeat rotation osteotomy with 90 degrees of correction. Anterior dislocation of hip is now stable.

Case 3.—A 15-month-old girl was given a diagnosis of congenital dislocation of the left hip after investigation of her waddling gait. In September, 1953, she was admitted to another hospital where a closed reduction and immobilization in the frog leg position was carried out. However, this was unsuccessful and another closed reduction was attempted in November, 1953. The hip continued to be unstable and in October, 1954, the patient was admitted to Lakeville, with a dislocation of the left hip still present. An open reduction was performed and at operation the anteversion was estimated to be 60 degrees. The next month a rotation osteotomy was done and the leg was immobilized in abduction–internal rotation. Several months later, however, it was noted that the hip redislocated on external rotation. This was studied by fluoroscopy and it was seen that the anteversion had not been corrected by the osteotomy. In spite of several additional months of plaster-cast immobilization in abduction and internal rotation, the hip continued to be unstable. The patient had a waddling gait but was discharged from the hospital against advice in September, 1955.

On follow-up visits the clinical and roentgenographic examination showed the hip to be unstable in neutral position but well reduced in internal rotation, which indicated that the anteversion had not been corrected. In December, 1957, the patient was readmitted to the hospital with no change in the status of the left hip. An arthrotomy was performed, with the full intention of performing a shelf-stabilization procedure, but examination under direct vision clearly demonstrated that the hip reduced easily when the leg was rotated internally. The dislocation was anterior and the anteversion was 90 degrees. A rotation osteotomy was then redone and the leg was immobilized in the appropriate position. The patient was discharged several months later with a stable hip and has continued to do well (fig. 3).

Comment.—This case is typical of group 4, in which patients were treated by open reduction after failure of frog leg position. A failure of closed reduction in the frog leg position was handled by open reduction and immobilization in abduction and internal rotation, followed by subtrochanteric rotation osteotomy. An incomplete correction of the marked femoral torsion, however, was responsible for continuation of the dislocation, necessitating a second rotation osteotomy before a stable hip was achieved.

Case 4.—At the age of 14 months a girl had a waddling gait and often fell. One month later a diagnosis of bilateral dislocation of the hips was made. The patient was admitted to Lakeville for her initial treatment in July, 1953. Reduction was possible in both frog leg and internal rotation positions. However, the patient was immobilized for seven months in the frog leg position after an excellent reduction was achieved. The follow-up roentgenograms over a three-year period showed excellent hips bilaterally. However, comparison of the neutral anteroposterior view with an anteroposterior view in internal rotation showed more stability in the latter position, indicating increased anteversion (fig. 4).

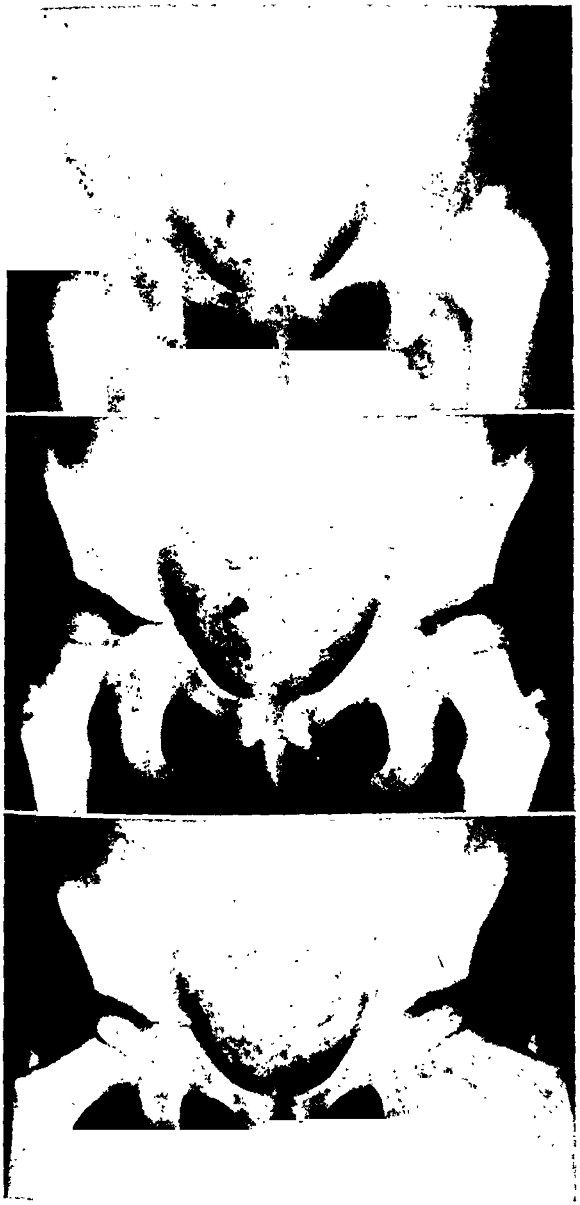

Fig. 4 (case 4).—*A*, bilateral dislocation of hips, reduced and immobilized in frog leg position; *B*, roentgenogram made on follow-up examination in neutral position; *C*, on internal rotation hips are better seated, indicating presence of uncorrected anteversion.

Comment.—This case is typical of group 1, in which the frog leg position alone was successful in achieving stable hips. This was possible only because the increase in anteversion was slight in these cases. When the increase in anteversion was moderate or excessive, this method of treatment failed. The roentgenographic appearance of the hips in group 1 is characterized by an apparent coxa valga on the neutral anteroposterior view which, in these hips, is due to uncorrected increase in anteversion. Our present method of treatment is illustrated by the following cases from group 2.

Case 5.—A girl was given a diagnosis of bilateral dislocation of the hips at the age of 30 months. Two months later, in August, 1955, she was admitted to Lakeville. Roentgenograms (true lateral view) showed excessive anteversion, especially on the right (estimated at 60 degrees). A closed reduction with the hips in abduction–internal rotation was successful. Several months later a subtrochanteric rotation osteotomy of the right femur was performed. After an additional four months in a plaster cast the patient was permitted to walk. The hips maintained the reduction, and it was decided that osteotomy of the left femur was not necessary in this case. The patient had normal hips when last examined three years later (fig. 5).

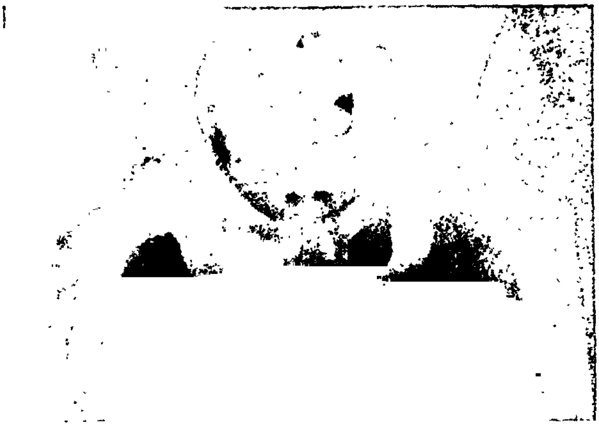

Fig. 5 (case 5).—Follow-up roentgenogram showing stable reductions in patient initially treated at the age of 32 months with closed reduction and immobilization in abduction–internal rotation. Rotation osteotomy was performed on right.

Case 6.—A boy started walking at the age of 15 months. Roentgenograms taken to evaluate his waddling gait revealed bilateral congenital dislocation of the hips. A 45-degree cephalad view showed the dislocations to be anterior. After several weeks of preliminary skin traction the hips were reduced under anesthesia in abduction and internal rotation. Five months later a subtrochanteric rotation osteotomy with 90 degrees of correction was carried out on the right. One month later, a similar procedure was done on the left. After several months he was permitted to walk and has continued to do well. Figure 6 demonstrates the original anteroposterior view and the 45-degree cephalad view which was originally described by Martz and Taylor.[3]

Comment

Anteversion and Rotation Osteotomy.—Anteversion is an important factor in the evaluation of these hips and must be considered in the management of each case. An estimate of its severity can often be made by comparing the neutral anteroposterior roentgenographic view with the anteroposterior view on internal rotation. The measurement of anteversion with use of the true lateral view alone was inaccurate in this series when compared with findings at open operation.

Patients with mild (less than 45 degrees) increase in the degree of anteversion can be satisfactorily treated in either the frog leg position or abduction internal rotation. A second group with moderate (45-60 degrees) anteversion will continue to have instability even after prolonged immobilization in the frog leg position but may be successfully treated by abduction–internal rotation. There are hips with severe degrees of anteversion (over 60 degrees) in which rotation osteotomy is necessary to achieve a stable hip.

The use of rotation osteotomy to correct anteversion is mandatory in the severe group but may also be used in the moderate group to shorten the period of postreduction immobilization. Failure to correct excessive anteversion is the most common cause of redislocation in these patients.

We prefer subtrochanteric to supracondylar osteotomy, because more correction can be obtained at this site and we believe that this is important, especially in anterior dislocations which are associated with severe anteversion, even in excess of 90 degrees.

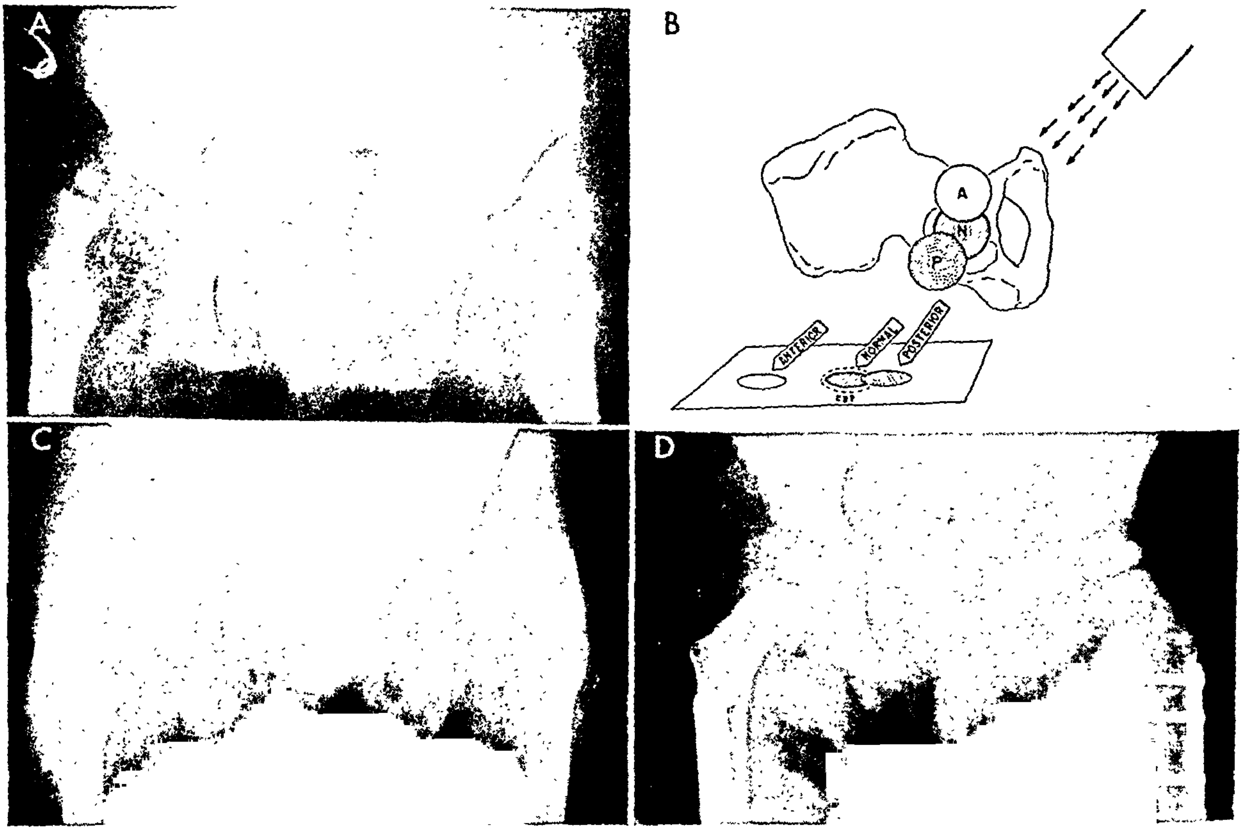

Fig. 6 (case 6).—*A*, bilateral dislocation of hips; *B*, 45-degree cephalad view; *C*, roentgenogram of 45-degree cephalad view. Hips are projected anteriorly, indicating anterior dislocation; *D*, stable hips after closed reduction and rotation osteotomies.

Position of Immobilization.—The position of immobilization after closed reduction is controversial. We believe that abduction–internal rotation is preferred, because it not only achieves a stable reduction but also gives a good estimate of the anteversion as indicated by the amount of internal rotation necessary to achieve stability. With moderate or severe increases in anteversion, corrective osteotomy should be performed to prevent recurrent dislocation and to shorten the period of immobilization.

Occasionally, reduction will be achieved only in the frog leg position, and this should be used initially with a plan to change gradually to internal rotation when the cast is changed. The need for osteotomy in these cases may be determined by the same criteria as described above after the final position of internal rotation is achieved.

Initial Examination.—The initial examination of these patients should follow some orderly pattern, because the x-ray exposure for many of these children was excessive. The following views would provide the necessary information on initial roentgenographic examination: an anteroposterior view in neutral and internal rotation, a true lateral view to aid in the measurement of anteversion,[4] and a 45-degree cephalad[3] view to determine whether *the dislocation is anterior or posterior.* The frequency of anterior dislocations was not appreciated by us until we began using this view. This roentgenogram is easy to interpret, because a superior projection of the femoral head indicates an anterior dislocation, while an inferior projection indicates a posterior dislocation (see fig. 6*B*).

Open Reduction.—Recently Somerville and Scott[5] have stressed the advisability of early open reduction in these cases. Although almost one-quarter of the hips in this series had open reductions, they represent our early efforts. With our present method of treatment, open reduction has not often been necessary. We believe that it is indicated only if a closed reduction is not possible.

Summary and Conclusions

We hope that the day is near when the group of patients with congenital dislocations of the hip, a potentially crippling condition, will be diagnosed during infancy before they begin to walk. Until then it is the responsibility of the orthopedist to treat this group of patients well. An initial closed reduction followed by immobilization in abduction-internal rotation and combined with rotation osteotomy in selected cases has consistently given us a high percentage of satisfactory results. Therefore, we recommend this treatment as the preferred method in this age group.

LABORATORY ANIMALS FOR THE STUDY OF OSTEOARTHRITIS.—Osteoarthritis is a widely prevalent disorder in man and bulky mammals, and has been noted in large fossil reptiles. Its occurrence in small laboratory animals was not recognized until recent years. In a survey of wild mammals, Fox studied the joints from 173 rodents. In none was arthritis apparent. This investigator cited a communication from Dr. Hamerton of the London Zoological Society, in which he stated that he had had a similar experience in a study of arthritis over a period of 15 years. Nevertheless, Silberberg and Silberberg demonstrated that osteoarthritis of microscopic proportion does indeed occur in mice under certain conditions. Osteoarthritis is generally believed to arise from mechanical erosion of the articulating surfaces of the movable joints and, for this reason, to be a wear-and-tear phenomenon—whether from the insidious abrasion of everyday weight-bearing or, in its acute form, from trauma or mechanical disadvantage. If this is true there would appear to be little prospect for preventing or ameliorating this exceedingly common and economically destructive disease of man and livestock. . . . Osteoarthritis of small laboratory animals closely simulates its counterpart in man and livestock. The studies indicate that local factors profoundly affect its development. Genetic factors also are important, although it is not clear whether they operate at a local level or in some more general constitutional manner. The observations provide encouragement and a tool for examining the possibility that environmental factors contribute appreciably to the development, and therefore potentially to the control, of this economically destructive rheumatic disorder.—L. Sokoloff, M.D., Osteoarthritis in Laboratory Animals, *Laboratory Investigation*, November-December, 1959.

VESICOURETERAL REFLUX IN CHILDREN

Victor A. Politano, M.D., Durham, N. C.

Vesicoureteral reflux, the regurgitation of urine from the bladder back into the ureters, is considered abnormal regardless of the age group in which it appears. The author believes that, if it is allowed to continue, it will inevitably destroy the kidney and that, once the diagnosis has been established, the process should be eliminated. The more conservative methods of urethral dilatations, multiple voidings, indwelling catheters, or various modifications of the vesical outlet should be tried if indications for such measures exist. Ureteral reimplantation by creation of a submucosal tunnel was found necessary in 17 girls and 9 boys in the author's series. All had had recurrent urinary tract infections, and several had progressed to various stages of uremia. These operations have given excellent anatomic and clinical results.

Vesicoureteral reflux, the regurgitation of urine after it has entered the bladder back into the ureter, has been a topic of intense interest and speculation. Pozzi,[1] in 1891, noted urine coming from both ends of a cut ureter. Modlinsky[2] noted cessation of urine passage through the urethra and passage of urine through the lumbar incision after nephrectomy for hydronephrosis. Kelly[3] described reflux of air on several occasions during air cystoscopy in patients with inflamed ureteral orifices. These observations resulted in extensive investigations into the frequency with which ureteral reflux occurred and the conditions necessary for its occurrence. Graves and Davidoff[4] demonstrated reflux in 86% of rabbits studied. Wislocki and O'Conor[5] made similar observations. Most of the early experimental studies were done in rabbits, and conclusions from these studies about the competency of the ureterovesical sphincter in animals were thought to apply to man. Sampson,[6] in an exhaustive treatise on urinary infections and the role of reflux in ascending infections, theorized that the length and obliquity of the intramural ureter was an important factor. It was left for Gruber[7] to do a comparative study in animals and human beings and illustrate that the percentage of ureteral reflux varied inversely with the thickness of the bladder and length of intravesical ureter. In rabbits reflux occurred in as many as 80%, but the rate rapidly decreased toward zero as animals with thicker bladders, more prominent development of the trigonum vesicae and the muscli pylari of the ureters (Bell's muscle), and increased length of the intravesical ureter were used. The human bladder showed the highest development of these structures and did not demonstrate reflux. Gruber observed that the intravesical ureter is not a sphincter dependent on muscle tone or muscle contraction but acts passively and serves as a true valve, one flap only being mobile, the other being the bladder wall itself. An increase in intravesical pressure presses the valve more closely against the bladder wall and prevents reflux of fluid.

With the passing of many of the early investigators, interest waned, and for many years vesicoureteral reflux was treated rather passively. In recent years there has been a resurgence of interest in this problem. It is becoming more evident that ureteral reflux in the presence of infection and progressive ureteral dilatation will lead to impairment of renal function and ultimate total renal destruction. In spite of this fact, a direct positive approach to correction of the problem is often tempered by conflicting opinions about whether reflux may occur in a normal child. Graves and Davidoff suggest that the contraction force of the bladder may produce reflux in the presence of normal ureterovesical valves in man. Gibson[8] studied 43 children without urological complaints by cystograms and observed reflux in 2. From this study he concluded that "ureteral reflux may occur in children who have apparently normal urological tracts." This conclusion was drawn without further explanation or investigation of the two children that demonstrated this condition. Bumpus[9] stated, "I have not known it to occur if the bladder was normal, except in children." No reference was made to any studies conducted in children or to any other basis for such a statement. Others[10] do not share this opinion.

Occurrence

Campbell[10a] surveyed 722 cystograms done in infants and children and was unable to demonstrate reflux in the absence of other associated urologic problems. Jones and Headstream,[11] in a study of 100 normal children ranging in ages from 14 days to 14 years demonstrated reflux in only 1. The one child with reflux was found to be carrying 180 cc. of residual urine and was treated by transurethral resection of the vesical neck. Bunge[12] examined 24 normal children and adults ranging in age from 9 months to 74 years. Ureteral reflux did not appear in any of the examinations. In our own study of over 50 normal children, ureteral reflux was not demonstrated in a single case. The absence of reflux in normal children is impressive when com-

pared to the frequency with which it occurs in persons with other urologic lesions. Bumpus observed reflux in 8.6% of cystograms showing other urologic problems. Twelve per cent of the cystograms reviewed by Campbell demonstrated reflux in children with coexisting urologic diseases. St. Martin, Campbell, and Pesquier [16] noted reflux in 13.5% of children investigated because of urologic symptoms. Roughly 10 to 12% of children with urologic complaints can be expected to demonstrate vesicoureteral reflux.

Diagnosis

The diagnosis is usually simple to make and is demonstrated by cystography. Talbot and Bunts,[13] in 1949, emphasized the importance of delayed cystograms for demonstrating ureteral reflux. Voiding cystourethrograms will increase the incidence by which reflux can be demonstrated. The cystogram is obtained by injecting from 30 to 90 cc., depending on the size of the child, of methiodal sodium (Skiodan) or a similar contrast substance through a small urethral catheter./The catheter is removed, and in 20 or 30 minutes the child is instructed to void. An x-ray film is taken while he is voiding. In the very young or unco-operative child the same results can be expected if he is made to cry. It is important to repeat the cystograms on several occasions if ureteral reflux is suspected and is not demonstrated in the first cystogram or if reflux is demonstrated in one side only. Not infrequently, even in the presence of large, patulous ureteral orifices and dilated ureters, reflux may not be demonstrated or may be visualized in one side only at any given examination. Cystograms are essential to any complete urologic study in a child, and vesicoureteral reflux must be suspected in any child with repeated urinary tract infections, residual urine, unexplained fevers, flank pain, or vague abdominal complaints. There is a tendency to eliminate this valuable diagnostic procedure when intravenous pyelograms show normal findings. It must be remembered that about 60 to 70% of patients that demonstrate vesicoureteral reflux, even with advanced changes, will show essentially normal results in intravenous pyelograms.

Etiology

Several factors may produce or be responsible for the occurrence of vesicoureteral reflux. Infection, which is present in many instances and is often the presenting complaint, may produce fibrosis and fixation of the ureter with loss of elasticity of the intramural portion, thus interfering with its normal function. Ureteral reflux is frequently seen with neurological disorders of the bladder and especially in cord injuries. Congenital anomalies, such as ectopic ureteral orifices or developmental deformities of the trigone, may be a cause. Trauma to the intramural ureter incident to surgery of ureteroceles, meatotomies, or transurethral resections is a well-recognized cause for reflux. It is commonly seen in children with obstructions to the vesical outlet—such as contractures, median bars, posterior urethral valves, or strictures. Yet reflux is not a frequent observation in adults with obstructive disease. It is often extremely difficult and at times impossible to clinically demonstrate any evidence of obstruction to the bladder outlet in children that demonstrate ureteral regurgitation. This strongly suggests some intrinsic defect or weakness of the intravesical ureter or vesicoureteral valve such as a thin-walled bladder with a short intramural ureter or poorly developed muscli pylori of the ureters or trigonum vesicae, or any combination of these. The defect, whatever it is, is sufficient to prevent the valve from withstanding normal intravesical pressure variants.

Management

Once the diagnosis has been established, every effort should be made to eliminate the process, which if allowed to continue will inevitably destroy the kidney. Infections should be eradicated. This may be difficult or even impossible in the presence of large, dilated, tortuous ureters or with residual urine. Neurogenic disorders should be corrected or modified with appropriate drug therapy when possible or modified by surgical methods when feasible. Residual urine secondary to vesical neck obstructions must be eliminated. Some children may be improved by multiple voidings, others may improve with urethral dilatations, while still others may need transurethral resections or open modifications of the vesical outlet. Every conservative effort to eliminate reflux should be attempted first. If these measures fail to resolve or improve the problem and if there is progressive loss of renal function due to either repeated infections or progressive dilatation, a direct attack on the intramural ureter may be necessary. The creation of a submucosal tunnel described by Politano and Leadbetter[11] has been most successful in correcting vesicoureteral reflux without producing obstruction to the efflux of urine.

Ureteral Reimplantations and Results

Ureteral reimplantations by creation of a submucosal tunnel has been performed in 26 children with vesicoureteral reflux during the past four years. Reimplantation was considered essential in these patients for one of several reasons. All had recurrent urinary tract infections lasting for periods ranging from six months to as long as four years. Many showed signs of impaired renal function as evidenced by a depressed phenosulfonphthalein test value, elevated blood urea nitrogen level, or radiographic changes consistent with pyelonephritis. Several had progressed to stages of uremia. All had been given antibacterial drug therapy for varying lengths of time, several over protracted periods, only to relapse with discontinuance of drug therapy. Surgery, either in the form of urethral dilatations or modification of the vesical neck, had been done on a few of the patients without improvement in symptoms. Nephrectomy without relief of symptoms had been performed on one child. It was necessary to do nephrectomies on two other children after correction of reflux in the better kidney. Of the 26 children treated there were 17 girls and 9 boys. In eight boys and in nine girls both ureters were involved. In one boy and in three girls the right ureter alone was involved. In seven girls only the left ureter was involved. No boys had involvement of the left ureter only. Ten children have previously had or had at the time of their reimplantation transurethral resection or YV-plasty of the bladder outlet. Of these, six were boys and four were girls.

Modification of the vesical outlet was not considered necessary in the remainder. Eight of nine boys had bilateral reflux, and surgical modification of the vesical neck was considered necessary in six. Only 3 of 17 girls were thought to have a degree of bladder neck obstruction. Unilateral reflux occurred about as commonly as bilateral in the girls.

There has been one complete failure and one partial failure in the 26 children in whom reimplantation for vesicoureteral reflux was done. The complete failure was in a boy who had undergone several surgical procedures prior to reimplantation of his ureters. These consisted of transurethral resection of posterior urethral valves, suprapubic cystostomy, bilateral nephrostomies, and mobilization and resection of a long segment of large, dilated, tortuous ureters with a direct reimplantation. During the submucosal reimplantation the ureters were found to be thick, fibrotic, and partially rigid. This child has been given constant suprapubic catheter drainage since reimplantation, and there has been improvement in the degree of reflux with the lapse of time. The partial failure was in a child with advanced bilateral pyelonephritis and a four-year history of repeated infections. After reimplantation ureteral reflux persisted on the right side for about six months but has since disappeared. Reimplantations by creation of a submucosal tunnel have been done for conditions other than ureteral reflux. These conditions include segmental resection of the bladder in which the trigonum vesicae has been sacrificed, low ureteral strictures, ureterovesical strictures, congenital megalo ureters, and reflux secondary to trauma of the intravesical ureter. It is not within the scope of this paper to cover these conditions, many of which occurred in adults.

In the successful reimplantations there have been no evidences of obstruction to the upper tract, which indicates free efflux of urine through the newly-created intravesical ureter. All children have remained asymptomatic, in most of them renal function has improved, and urine samples are sterile.

Increasing experience with this problem strongly suggests that vesicoureteral reflux is an abnormal finding which children do not outgrow. Bumpus found reflux present in 19% of patients with pyelonephritis. A number of adults which I have studied with advanced or terminal pyelonephritis have demonstrated a free regurgitation of vesical contents to the kidneys. Had these adults had undiagnosed or unrecognized vesicoureteral reflux when they were children? One can only speculate about the answer.

Report of a Case

A 4-year-old girl was admitted with a five-month history of intermittent fever with temperature elevations to 105 F (40.6 C) occurring every three to four days. She had mild irritative symptoms on voiding, consisting of burning and frequency. Her fever was controlled with sulfisoxazole (Gantrisin), which she had been taking for six weeks prior to admission.

On physical examination her temperature was 100.2 F (77.8 C) pulse rate 90 per minute, respirations 25 per minute, and blood pressure 98 mm. Hg systolic and 76 mm. Hg diastolic. She was a small but normally developed child. Laboratory studies showed a hemoglobin level of 12.6 Gm. with a white blood cell count of 11,000 per cubic milimeter. Urinalysis showed 20 to 25 white blood cells and 10 red blood cells per high-power field. The nonprotein nitrogen level was 34 mg. per 100 cc.

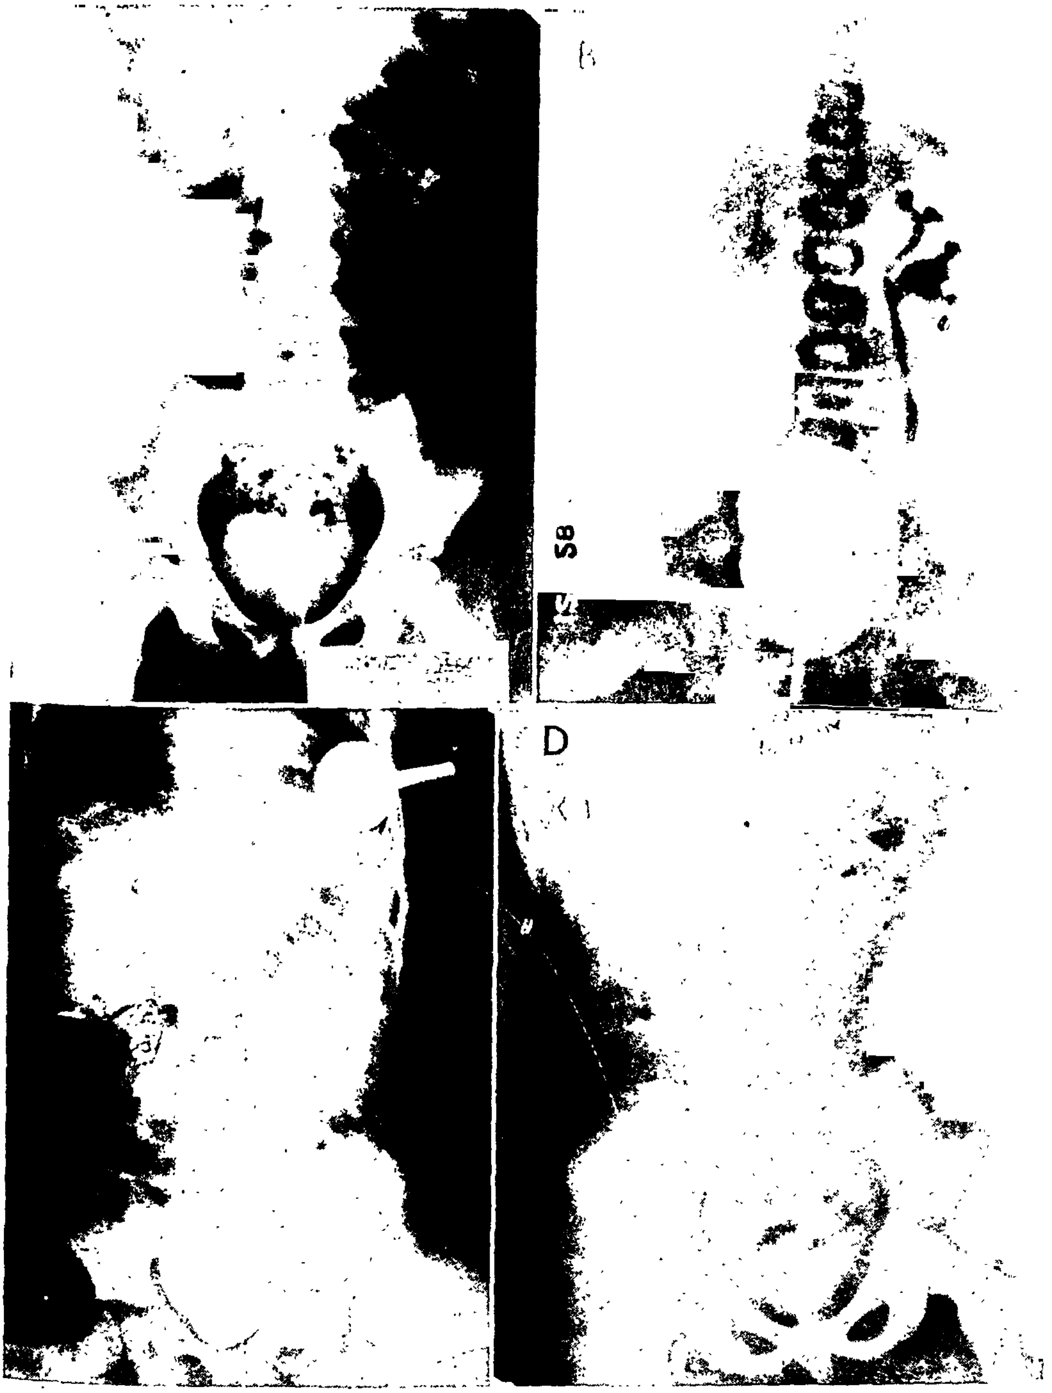
Intravenous pyelograms (see figure, part *A*) showed slight hydronephrosis of a double left kidney with blunting of the calyces. There was partial reduplication of the left ureter. A cystogram (see figure, part *B*) demonstrated immediate ureteral reflux on the left. On cystoscopic examination the left ureteral orifice was found to be lateral to the trigonum vesicae high on the left lateral portion of the bladder wall. The right ureteral orifice was in its normal anatomic position. The bladder outlet was considered normal. The diagnosis was ectopic ureteral insertion with ureteral reflux and pyelonephritis on the left side.

Treatment consisted of reimplantation of the left ureter by creation of a submucosal tunnel. This successfully corrected the vesicoureteral reflux (see figure, part *C*). Postoperative intravenous pyelograms showed good excretion from the left kidney without evidence of obstruction (see figure, part *D*). The child has remained asymptomatic for a period of 40 months. Microscopic examination of urine showed negative results, and cultures have been sterile.

Summary

Vesicoureteral reflux is an abnormal finding regardless of the age group in which it appears. This condition, if unrecognized and untreated, may lead to severe renal damage and ultimate renal destruction because of repeated infections and progressive dilatation. Cystograms should be a part of every complete urologic investigation in children. Once the condition is recognized, immediate treatment should be instituted to eliminate this problem. The more conservative methods of urethral dilatation

tiple voidings, indwelling catheters, or various ifications of the vesical outlet should be tried indications for such measures are present. If these nservative methods fail to correct the problem, a direct attack on the intravesical ureter should be de. There probably exists some inherent defect or weakness in the vesicoureteral valve which permits reflux to occur *with normal or slightly elevated* intravesical pressures. Reimplantation of the ureter through a submucosal tunnel performed in 26 children has given excellent anatomic and clinical results.



Findings in 4-year-old girl with vesicoureteral reflux. *A*, preoperative intravenous pyelograms show blunting of calyces *on left with bifid kidney and ureter*. *B*, preoperative cystogram shows reflux on left, and contrast medium in right pelvis represents continued excretion from contrast medium after intravenous pyelograms had been made. *C*, postoperative cystogram demonstrates absence of reflux. *D*, postoperative intravenous pyelogram shows essentially same calyceal pattern as preoperative films.

DEVELOPMENT OF URINARY CONTROL IN CHILDREN

SOME ASPECTS OF THE CAUSE AND TREATMENT OF PRIMARY ENURESIS

S. Richard Muellner, M.D., Boston

A study of the development of urinary control in 1,000 children confirmed the belief that bladder control is a self-learned skill, which most children acquire by the age of 4½ years. In the acquisition of urinary control the child learns to coordinate the use of the levator ani, the thoracic diaphragm, and the abdominal musculature, which constitute the "voluntary mechanism" of urination in the adult. Through the use of the "voluntary mechanism" the child doubles its bladder capacity by the age of 4½ as compared to what it was at the age of 2 years. The enlarged bladder capacity insures night control of the urine. Children who fail to enlarge their bladder capacity become enuretic. The author believes that a potential enuretic can be recognized by the age of 3 years. A simple program which can be used to prevent and to eliminate bedwetting is described.

An infant starts life with an automatic bladder. By the time a child is 4½ years old, it has acquired complete urinary control both by day and by night. Our studies show that if this maturation process, which occurs between the ages of 2 and 4½ years, is incomplete, the child will be left with a bladder which retains some of its infantile characteristics and will have improper urinary control or enuresis. What, precisely, happens in this short span to bring about this profound change in the function of the bladder is important if we are to understand the genesis of enuresis and its rational treatment.

The impression is widely held that the acquisition of normal urinary control is due to parental training, whereby conditioned reflexes are established by means of some mysterious maturation of the autonomic nervous system. This theory and similar theories about the nature of the development of urinary control in children are quite vague and leave many questions unanswered. My recent studies of the physiology of micturition by means of the fluoroscope—a technique which by now has been employed in over 1,000 cases, encompassing all sorts of micturition problems as well as measurements of the capacity of the bladder in the infant, in the normal child, and in the enuretic child—have clearly shown that the acquisition of adult bladder

---

From the Department of Surgery (Urology), Harvard Medical School, and Department of Urology, Beth Israel Hospital.

control is due to a self-learned skill in the use of large skeletal muscle groups with which the child manipulates its intra-abdominal pressure.

Klackenberg,[1] in a careful study of 315 children, aged 1 to 7 years, showed conclusively that there is no correlation between parental "training" efforts and the development of urinary control. Others have offered similar proof that urinary control is not something that the child is taught by its parents but that, on the contrary, it is a process which each child develops at its own pace, irrespective of parental travail.

Steps in Development

A review of the steps which the child must take to change from an infantile to an adult type of bladder control will show the nature and the complexity of this process, which is usually taken for granted. It will then become apparent why things can and do go wrong with this process.

The infant voids automatically, i. e., the detrusor contracts spontaneously when its limit is reached and maintains this contraction until the bladder empties. The child appears to have no sensation of bladder fulness nor does it manifest any sign that it is about to void. Many a new mother has been surprised by a warm jet while her baby boy smiles at her, giving no indication that he has to void or that he is about to do so. At this stage, the infant can neither initiate nor stop the urinary stream at will. This type of micturition can be termed "detrusor micturition" in that it is based mainly on the stretch reflex and activity of the detrusor.

The next step in the development of urinary control is the child's ability to indicate that his bladder is full or that micturition is imminent. This occurs between the ages of 1 and 2 years, during which time the child gradually also acquires day control of its urine. By the age of 2 years important changes have already occurred in the developmental process: first, awareness of the full bladder and, second, the ability to "hold" urine for a brief period beyond this point. The child still cannot initiate its urinary stream at will, nor can it void when the bladder is less than full. The ability to hold urine gradually becomes more pronounced, so that in the 3-year-old child the bladder capacity steadily increases and day control becomes quite well established. By the age of 4½ years most children are able to control their urine during the night as well. Bloomfield and Douglas[2] have shown that 87.8% of 4½-year-olds have complete urinary control and 12.2% still have enuresis.

Most children aged 4½ years can stop the urinary stream at will, but they may still have some difficulty in initiating micturition at any degree of bladder filling. The exact age at which a child is able to do so varies considerably, although as a rule it will occur somewhere between the ages of 3½ and 6 years.

By the age of 4½ years, then, the following significant changes have occurred. The child no longer has an automatic bladder. The bladder capacity has become double what it was at the age of 2 years, and the child has acquired the ability to stop and to start its urinary stream at will. (All the time data given here are relative and not absolute, because children vary in the speed with which they acquire specific skills, grow, and mature.)

To understand how this remarkable process came about, it will be necessary at this point to review the mechanism of voluntary control of micturition in the adult, for that is precisely what the child has now achieved (fig. 1).

Man's ability to void at any degree of bladder filling is a unique biological phenonemon which no other mammal manifests. An apparent exception is the male dog (and other canines) who is able to deposit small amounts of urine at each pillar and post. The mechanism of micturition in the dog, however, is entirely different from that in man. In the male dog the frequent squirting of small amounts of urine is a sexually linked and hormonally controlled act that is more closely related to the sex drive than to the ordinary function of micturition.[3]

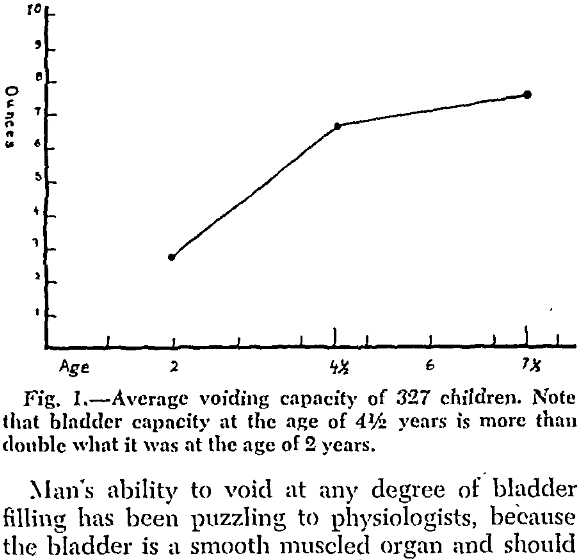

Fig. 1.—Average voiding capacity of 327 children. Note that bladder capacity at the age of 4½ years is more than double what it was at the age of 2 years.

Man's ability to void at any degree of bladder filling has been puzzling to physiologists, because the bladder is a smooth muscled organ and should not respond to the whims of the will. It had been established that the detrusor must contract for micturition to begin, but how the detrusor is made to do so by man's will was not clearly understood.

Physiology of Bladder Control

In the past, man's ability to void at any time was explained by the theory that the detrusor will automatically contract, once the acquired inhibition to its contraction is removed.[4] Studies of micturition by means of the fluoroscope, however, have shown that contraction of the detrusor is the second step in voluntary control and that it is not brought about by the direct exercise of the will over the detrusor. We found that the first step in the voluntary initiation of the urinary stream consists of the descent of the vesical neck, after which the detrusor contracts.[5] The descent of the vesical neck is brought about in the following manner. The diaphragm is fixed at the end of a brief inspiration; the lower abdominal musculature is contracted and the pubococcygeus (the anterior half of the levator ani) is relaxed. By means of the manipulation of these three large muscle groups, the intra-abdominal pressure is directed precisely toward the vesical neck and since the vesical neck support (the pubococcygeus) is relaxed, the vesical neck descends in the pelvis. It is this downward push on the vesical neck that is the stimulus for the contraction of the detrusor. The wave of contraction starts at the vesical neck and then spreads upward to the sides and dome of the bladder. The contraction of the detrusor results in the opening of the internal sphincter and micturition proceeds.

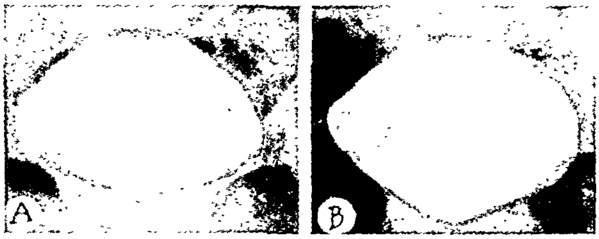

Fig. 2.—*A*, bladder at rest; *B*, first step in voluntary micturition. Note descent of vesical neck.

These findings mean that man does not have direct control over his bladder but that he uses large skeletal muscle groups over which he has full control to influence a smooth (involuntary) muscled organ. The child, therefore, must acquire the necessary skill to manipulate its intra-abdominal pressure. It is not sufficiently appreciated that, by a different application of these same muscles, man directs his intra-abdominal pressure toward the rectum to defecate and upward to the diaphragm to clear his air passages, and that he steadies all three muscle groups when he must lift heavy objects so that he will not lose his urine or his stool in doing so. I have termed the three muscle groups (diaphragm, abdominal musculature, and levator ani) with which man initiates a detrusor contraction his "voluntary mechanism" (see fig. 2, 3, and 4).

In the child the excursion of the vesical neck to initiate the urinary stream is small and rapid, and the contraction of the detrusor occurs promptly, so that the bladder quickly assumes a spherical shape in contrast to the scutiform shape it had during repose.

The first step away from infantile bladder control is the development of the cognizance of the full bladder, i. e., the desire to void, which is clearly the function of the maturing autonomic nervous system. Before long the child is able to communicate this sensation as well. The second step in the development of urinary control is the ability to hold urine for a brief period "beyond" the desire to void. To do so, the child learns to inhibit a detrusor contraction through the use of the levator ani. This, then, is the second step in the maturation process, although it constitutes the first attempt which the child makes to use one of the large skeletal muscle groups. The third step is the ability to start the stream when the bladder is full or nearly so. Here the diaphragm and abdominal muscles are first used to create and direct the intra-abdominal pressure toward the bladder. Being still quite sensitive to stretch at this stage, the detrusor requires little intra-abdominal pressure for contraction. *At this stage, the child cannot as yet start* his urinary stream at any degree of bladder filling. This comes much later, for to do this, he must now develop the coordinate use of all three muscle groups; i. e., the diaphragm, the abdominal muscles, and the levator ani, including the separate use of the pubococcygeus. The child must contract the former two and relax the latter at the same time, in order to get the detrusor to contract at any degree of bladder filling. This last step is the most difficult and is the final step in the change-over from the infantile to the adult type of bladder control.

Just as the child's initial efforts at walking are uncertain and awkward, so are his early attempts to manipulate his intra-abdominal pressure. The small boy at first stands at the toilet bowl, arches his back, and balloons out his abdomen, without being able to initiate the reflexes of micturition. After a considerable effort to do so, he announces he cannot, only to wet spontaneously a few minutes later. Through trial and error he learns that ballooning his abdomen is not the way to start his stream, and only gradually does he acquire the skill to direct his intra-abdominal pressure toward the bladder neck. The ability to stop the urinary stream comes easier. To do this, he does not simply contract his external sphincter, as has been taught in the past. Instead, he contracts the entire levator ani, including the pubococcygeus, and lifts the bladder neck away from the membraneous urethra, thus coapting the urethral walls over an area longer than the height of the external sphincter alone. In this manner the child shuts off his stream while the detrusor relaxes. It is only when he has learned to use his voluntary mechanism with skill and precision that he achieves complete mastery over his detrusor (fig. 3*B*).

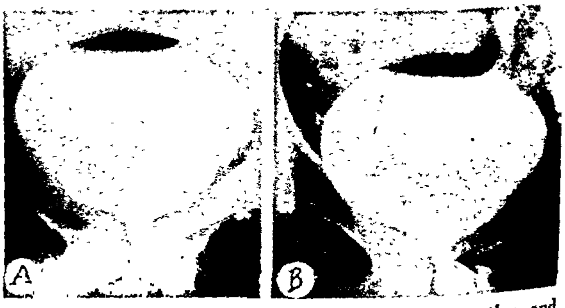

Fig. 3.—*A*, bladder during micturition; *B*, urethra and bladder at moment of voluntary inhibition of urinary stream.

Parental training constitutes at most an artificial urinary frequency which succeeds in catching the urine in the toilet bowl before the child wets its diaper. It is not possible for any parent to teach the child the complex use of the various muscle groups or to coordinate them in such a fashion as to develop mastery over the voluntary mechanism. Klackenberg's conclusion that there is no correlation between the development of urinary control and parental training is, therefore, borne out in this study.

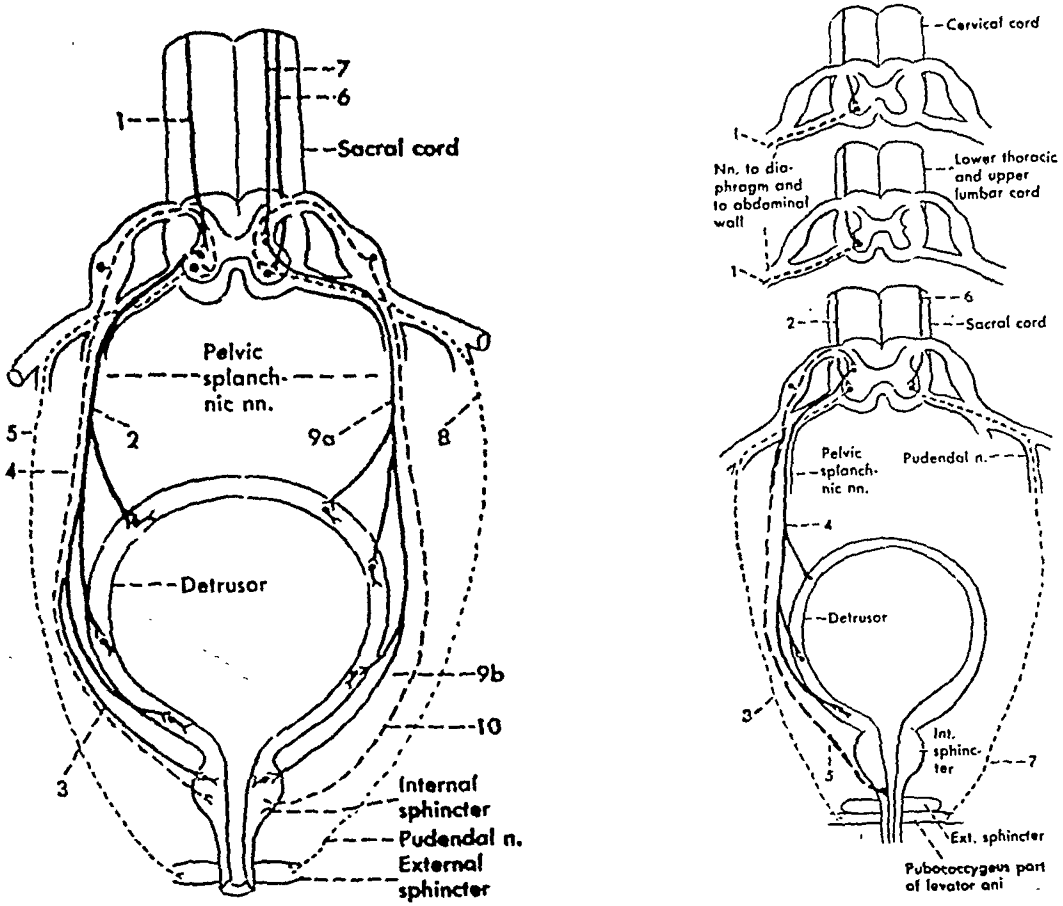

Fig. 4.—*Left,* Schema of neuromuscular mechanism for voluntary control of micturition implied by, *left,* concept of direct voluntary control over detrusor of bladder and of voluntary and reflex contraction but no inhibition of external sphincter. Initiation of micturition (*far left*): Impulses from cord, *1-2,* activate preganglionic neurons to detrusor and cause it to contract. Urination is stopped (*right*), through direct voluntary fibers, *6,* in spinal cord which activate lower motor neurons, *8,* to external urethral sphincter. Solid lines indicate descending fibers; heavy broken lines, afferent fibers; light broken lines, voluntary motor fibers. *Right,* neuromuscular mechanism for voluntary control of micturition implied by author's concept. Comparison with *left* shows that while same branches of sacral nerves are involved, mechanism is otherwise quite different. Initiation of micturition (*left side*) through voluntary contraction of abdominal musculature and thoracic diaphragm through their nerves: *1,* pubococcygeus is relaxed through descending fibers, *2,* acting on lower motor neurons, *3,* resulting in downward movement of vesical neck and initiation of detrusor contraction. Micturition is stopped (*far right*) through pyramidal tract fibers, *6,* which act on lower motor neurons of pudendal nerve, *7,* thus producing contraction of levator ani (see text for manner in which this inhibits urinary stream). (Reprinted with permission from Hollingshead, W. H.: Anatomy for Surgeons, New York, Paul B. Hoeber Inc., 1956.)

Having achieved voluntary control over his bladder, the child now can control his bladder capacity as well; he has the means at hand to enlarge this capacity to the point where the bladder will be able to hold the total output of night urine. Earlier he has achieved the ability to inhibit a detrusor contraction when the bladder is full during the day so that he can reach the toilet in time.

Elimination of Enuresis

Cause of Enuresis.—Measurements of the bladder capacity of 327 children aged from 2 to 7 years (fig. 1) have shown that when the child can hold 10 to 12 oz. (284 to 340 Gm.) of urine he will not wet at night once complete mastery of the "voluntary mechanism" has been achieved. (The term "bladder capacity" as used here denotes not the absolute volumetric capacity of the bladder, but rather the amount the child will void when it has the normal desire to do so.) The bladder capacity measurements of 30 enuretic children have confirmed previous reports[6] that the enuretic child has a much smaller than normal bladder capacity, in effect retaining the bladder capacity of a 2-year-old child, which is much too small to hold the entire output of night urine of a child aged 4½ years or older.

Primary enuresis, therefore, is due to the improper development of bladder capacity of a child through the inadequate use of its voluntary mechanism. Many children correct this at a later age, which accounts for the fact that they "outgrow" their enuresis. In a study of 4,294 children, Bloomfield and Douglas[2] showed that the 12.2% incidence of enuresis in 4½-year-old children drops to 7.3% among children aged 7¾ years. Those who continue to be enuretic during puberty and into adolescence or even adulthood, have, as our studies show, simply retained an infantile bladder capacity. Some children compensate for it by automatically reducing their fluid intake and by frequency of micturition by day and by night.

While observers have noted that enuretics have smaller bladders and increased urinary frequency, the precise reason for these conditions seemed to have escaped them. The implication was that this departure from the normal was due to some congenital anomaly or a mysterious quirk. Actually, all children start life with a small bladder which they must enlarge as they grow older. For some the transition is easy, for others quite difficult, and for still others impossible, without intelligent medical help. All children are thus potential enuretics. They can grow into enuresis as well as out of it. The critical stage for them is the period in their life between the ages of 2 and 4½ years. It is at this stage that steps to foster proper development of the bladder and to prevent enuresis must be taken. When it is realized that there are about 2 million enuretics in the United States (calculated on the basis of the 1950 census), the magnitude of the problem from the point of view of prevention becomes clear. These studies suggest that the potential enuretic can be spotted by the age of 3 years and that it may be profitable to take steps at that age to prevent the development of enuresis.

In a series of 30 enuretics it has been possible to eliminate the enuresis by enlarging their bladder capacity to a size commensurate with their age and stature. The treatment of enuresis, therefore, can be placed on a rational basis. Past efforts, which were primarily designed "to benefit the bed and not the child," are futile and should be abandoned. In this category belong such suggestions as dehydration, the strict forbidding of fluids after 4 p. m., dragging the child out of his bed at night to void, clocks to wake him, and gadgets to shock him out of his sleep once involuntary leakage of urine has occurred. Equally futile are rewards and punishments for something a child cannot control without help.

Training Program.—In our hands the bladder capacity of the enuretic could be increased by a simple program which can be carried out by children who are mature enough to cooperate and whose parents are intelligent enough to follow the training scheme.

For a few days before any therapy is starte the child, with the mother's help, is asked to kee a "voiding chart" to record the fluid intake an urinary output. The time and the amount of eac micturition should be noted by asking the child t void into a glass measuring cup which will measur at least up to 14 oz. The very fact that the chil takes an active part in his training program i beneficial psychologically, especially, when he made to understand that his bladder is as yet to small and that he will have to try to make it large to become cured of the nuisance of bedwettin The "voiding chart" will show that the child voic in amounts of 2, 4, or 6 oz. (60, 120, or 180 cc. An occasional 8-oz. (240 cc.) voiding is not goo enough to cure enuresis. The child is now instructe to force fluids during the day and to hold his urin as long as possible. This is precisely the reverse what is being practiced today. It will take an where from three to six months, depending on th initial capacity of the bladder and the cooperatio of the patient and parent, before a satisfactor bladder capacity is reached. During the trainin period, the wet bed is strictly ignored.

The use of anticholinergic drugs during the da and at bedtime is often helpful to accomplish more rapid distention of the bladder. Atropin sulfate, propantheline (Pro-Banthine) bromide, oxyphencyclimine (Daricon) hydrochloride are helpful in relaxing the detrusor and in the distentio of the bladder with its own urine so that graduall larger amounts are voided.

Sometimes it is necessary to overcorrect a smal bladder. While a 12-oz. capacity and a voidin volume of 8 to 10 oz. during the day can be sufficient to eliminate enuresis in most instances, for permanent cure it may be desirable to reach th higher capacity of 14 oz. (420 cc.). It should b emphasized that the cure of enuresis is not a simpl matter of ounces held or voided. Each child i highly individualistic and the "normal" (nonenuretic) bladder capacity of one child may be to small for the next one, for there is no such thin as a standard child. It is perhaps trite to say tha they vary tremendously in weight and height a any given age and that their water metabolisn varies as well.

Summary

The infant has an automatic bladder and empties it by means of "detrusor micturition." Within a short span of 4½ years, most children acquire an adult type of control over their bladders and are able to hold urine and to start the urinary stream, at will, at any degree of bladder filling. In the course of this development the child first acquires the cognizance of the full bladder through the maturation of the autonomic nervous system. Next, it learns to inhibit a detrusor contraction and to hold its urine through the use of the levator ani and its pubococcygeus. The third step in this progressive development is the ability and skill to manipulate the intra-abdominal pressure through the use of

the diaphragm and of the abdominal musculature. The next and most difficult step in this process is the ability to stop and start the urinary stream at any degree of bladder filling. This is carried out through the contraction of the diaphragm and of the abdominal musculature and the simultaneous relaxation of the pubococcygeus. The development of urinary control in a child, therefore, is essentially the development of the skill in creating and manipulating intra-abdominal pressure. When complete mastery of this voluntary mechanism is achieved, the child is in a position to enlarge its bladder capacity and to double this capacity by the age of 4½ years, compared with what it was at the age of 2 years. When this has occurred, the bladder is large enough to retain the total output of night urine and the child will no longer wet the bed.

Primary enuresis is due to the improper development of adult urinary control which leaves the child with a bladder capacity too small for its age and stature. Enuresis can be cured by controlling the child's urinary output during the day to enlarge and to distend its bladder. This is done by forcing fluids during the day and by teaching the child to hold the urine as long as possible. Anticholinergic drugs can be useful in the treatment of enuresis.

SHORT-TERM STUDY OF CORONARY HEART DISEASE IN A NORTH DAKOTA COMMUNITY

Robert C. Painter, M.D., Lloyd S. Ralston, M.D., Grand Forks
Robert M. Fawcett, M.D., Devils Lake, N. D., William J. Zukel, M.D.
and
Robert H. Lewis, M.D., Washington, D. C.

The authors studied data on heart disease obtained between Jan. 1 and Dec. 31, 1957, from an area containing an estimated population of 100,000. This area was taken as typical, geographically and economically, of the situation usually dealt with by the general physician. There were 40 cases of angina pectoris, 45 of definite or probable coronary insufficiency, 157 of definite or probable myocardial infarction, and 49 of sudden, unattended death. Eighty-seven patients were women and 204 were men. There were 143 deaths. Of every five serious episodes of coronary heart disease three terminated in death during the given episode. The prognosis was better if the patient lived long enough to receive medical attention and still better if he survived the first 24 hours thereafter. Except for those in the category of angina pectoris, most patients had no prior known symptoms of coronary heart disease.

This report attempts to present a cross section of the clinical picture of coronary heart disease as it occurs in a general population in North Dakota. Since this epidemiologic study of coronary heart disease was based on the reports of cases by the practicing physicians in the area, one would assume that the incidence of the different manifestations of coronary heart disease presented here might be expected to be reproducible in the practice of any general physician in a similar population.

Methods and Procedures

Early in 1956, in response to the interest shown by Dr. Paul D. White and the United States Public Health Service, plans were begun for an epidemiologic study of coronary artery heart disease in North Dakota. A six-county area in the northeastern corner of the state was selected as being the most geographically and economically suitable for such

a study, the counties so selected (Cavalier, Pembina, Ramsey, Walsh, Nelson, and Grand Forks) containing an estimated population of 100,000. The physicians in this area fortunately were all members of the Grand Forks District Medical Society or, as in the case of those in Ramsey county, of the Second District Medical Society. Both of these societies expressed enthusiasm for the study and appointed three physicians, all qualified internists, to supervise the program on the local level and to work with the North Dakota State Health Department, the North Dakota Heart Association, and the United States Public Health Service. The latter appointed a medical officer to help in the collection and correlation of the necessary data.

The physicians in the area were requested to report all new manifestations of coronary disease which they encountered in their practice. To assure a uniform reporting sequence for at least one year, the reporting began Oct. 1, 1956, and was carried through Dec. 31, 1957. Only cases occurring between Jan. 1, 1957, and Dec. 31, 1957, are included in this analysis, since it was considered that reporting was most complete for this period.

Card Used for Reporting Cases of Coronary Disease.

Each case was reported by the physician on a simple reporting card (see the figure), on which it was grouped under one of several general categories such as angina pectoris, coronary insufficiency, myocardial infarction, or other manifestations of coronary heart disease. He also was encouraged to list additional data when available. Each physician was visited monthly by the medical officer, who obtained all clinical data available in all reported cases. An attempt was made to obtain a clinical description of symptoms, progress of the patient, and laboratory data. When an electrocardiogram had been made, this was obtained for photostatic reproduction by the North Dakota State Health Department. These monthly visits helped in obtaining data on some cases, the reporting of which the physician otherwise might have overlooked. In addition, all the hospitals in the area were cooperative in reporting cases of coronary disease which might have been overlooked in the busy practice of the local physician. Physicians practicing in the areas bordering the six-county area were visited every two months, and similar data were collected on any cases in residents of the six counties who might have been cared for by these physicians.

Other sources of information included morticians, coroners, registrars of vital statistics, public health nurses, and newspapers. In addition a 24-hour autopsy service was offered to the physicians in outlying areas to help in the diagnosis of deaths of unknown cause. Gross and microscopic study of this material was made in the pathology department of the medical school at the University of North Dakota in Grand Forks.

Classification of Cases

Each case was reviewed by a committee made up of the medical officer and supervising physicians, all of whom were also qualified internists. After careful perusal of clinical history, laboratory data, electrocardiogram, and progress, each case was placed in a suitable category. The diagnostic categories of coronary heart disease were as follows: angina pectoris, coronary insufficiency, myocardial infarction, and unattended deaths. Congestive heart failure, arrhythmia, and embolic phenomena also were reported if coronary heart disease conceivably provided the etiological basis.

Angina Pectoris.—The category of angina pectoris was defined as the occurrence of transitory, substernal pain with characteristic radiation to the neck, jaw, or arms, usually precipitated by some inducing factor such as effort or emotion, and amenable to prompt relief by rest or the use of nitroglycerin. Findings of physical examination and laboratory examination in these cases were normal. The electrocardiogram may have shown normal results or changes indicative of myocardial ischemia without acute change.

Coronary Insufficiency.—The category of coronary insufficiency included those cases in which the substernal chest pain was more prolonged, occurred either with effort or at rest, and was associated with acute electrocardiographic changes which might last several days or weeks. These consisted of ST-segment elevation or depression, with or without inversion of the T wave, and without presence of a Q wave. While there might have been mild fever and some elevation of white blood cell count and erythrocyte sedimentation rate (not over 20 to 30 mm. per hour), the heart sounds, lung fields, blood pressure, and pulse rate were normal.

Myocardial Infarction.—The category of myocardial infarction included those cases in which there was a more clear-cut history of sustained chest pain associated with electrocardiographic evidence of and/or a subsequent clinical course indicative of a more severe myocardial injury (fever;

elevation of white blood cell count, sedimentation rate, and transaminase level; perhaps pulse and blood pressure abnormalities; or in some instances death ensuing before such a clinical course could be established). The reviewing committee of internists interpreted all electrocardiograms, along with the clinical and laboratory data, and was the final judge as to whether a given case was classified as myocardial infarction or otherwise.

The reporting physicians were requested to report each patient as having a definite or probable case in each category. Each case was reviewed by the reviewing board, and every attempt was made to obtain sufficient criteria to place the case in a definite diagnostic category. However, in some instances, even though clinical judgment seemed to indicate a case should be in a definite category, it was necessary finally to place it in the probable diagnostic category.

Unattended Deaths.—As the study progressed, it became apparent that there was a large number of ases in which the patient died unexpectedly and without the attendance of a physician in the interal between the acute onset of his immediate anteortem symptoms and death. These deaths were rouped into the following three categories: first, nattended death due to definite coronary disease with (1) autopsy showing acute changes or (2) history of coronary disease and symptoms immediately prior to death, which were indicative of coronary disease; second, unattended death due to probable coronary disease consisting of either (1) no history of coronary disease but symptoms immediately prior to death which were suggestive of coronary disease or (2) a history of coronary disease but no known symptoms of coronary disease immediately prior to death; and third, unattended death, unknown cause, in persons with no history of coronary disease and no known symptoms of coronary disease immediately prior to death.

An attempt was made to group those cases in which angina pectoris and coronary insufficiency were secondary to other disease processes such as acute arrhythmia, anemia, congestive heart failure, and others into a separate category to be evaluated later. These cases are not included in this presentation. Likewise, in some instances the information was more suggestive of pulmonary embolism or noncoronary cardiac disease and the case therefore was eliminated.

Data

Table 1 shows all the cases collected in the study which were classified, as listed above, in the categories considered to constitute coronary heart disease. There were 291 cases in all, 70% of the patients being men. This proportion of about two men for each woman was fairly uniform in each category, except in coronary insufficiency where it was 4:1. In the six-county area the number of men and women 35 years of age and over was determined by a census to be about the same.

Fourteen per cent of the cases were listed as angina pectoris. The reviewing committee believes that this figure does not represent a true incidence of this condition in the population. These patients were ambulatory for the most part, and reliability of reporting rested entirely on the reporting physician. There was no way to check hospital records and/or death certificates and thus be able to remind the physician of a forgotten case, as was done frequently in the other categories. As a result, it is our impression that this figure is far too low.

In 17% of the total number of reported cases unattended deaths were listed; the patients died suddenly or at least before they could obtain medical attention. This, of course, represents a group of patients who ordinarily would be included neither in an analysis of coronary heart disease in a physician's practice nor in a hospital service. Rather, most of them might well be coroner's cases. Among the total of 291 subjects classified as having coronary heart disease, there were 143 (49%) "deaths." Of the latter, 49 (17% of the total number of cases) were "unattended deaths," leaving 94 deaths (32% of the total number of cases) as occurring among those patients who had myocardial infarction and received medical attention.

TABLE 1.—*Data on 291 Patients with Coronary Heart Disease*

	Diagnostic Categories,* No. of Cases								
		CI		MI		Unattended Deaths			
Patients, No	Angina Pectoris	Definite	Probable	Definite	Probable	UDD	UDP	Total Cases, No.	Deaths, No.
Male	27	32	3	79	28	10	25	204	95
Female	13	8	2	29	21	2	12	87	48
Total		40	5	108	49	12	37		
Grand total	—							—	—
No.	40	45		157		49		291	143
%	14	15		54		17		100	49

* CI: coronary insufficiency; MI: myocardial infarction; UDD: unattended death, definite coronary heart disease; UDP: unattended death, probable coronary heart disease.

In addition to the 291 cases of coronary heart disease shown in table 1, there were 51 cases (35 men and 16 women) placed in the category of "unattended deaths, unknown cause." These cases were not included in table 1, because, by definition, there was no clinical or pathological evidence to indicate that death was due to coronary heart disease, and it was believed that a clearer picture of the definite or probable coronary heart disease diagnosed in this population would be obtained by their omission. However, one cannot ignore the fact that, if postmortem examination could have been performed on all 51 of these persons, some of them certainly would have been reclassified in the group "unattended death from coronary heart disease." (A preliminary report on the men in this study who had coronary heart disease was presented at the American Public Health Association Annual Meeting, St. Louis, Oct. 30, 1958. Since these data were evaluated, 30 additional cases which are classified as "unattended death from coronary heart disease" have been collected on the basis of additional death certificate data.)

In table 2, the 157 cases of myocardial infarction are presented in regard to sex, age, and survival or death. Among those of all ages who survived the attack, men predominate in a ratio of 3:1 as compared to a ratio of 2:1 among those who died. However, if one excludes patients aged 75 years and over, there is a definite rise of the ratio of men over women to 3:1, whether surviving or not. Among those aged 75 and over who survived there are only three men and two women, while among those in this same age group who died there are almost twice as many women as men (18 and 10 respectively). The women with infarction are fairly consistently seven years older than the men in this series. If those over the age of 75 years are excluded, this difference drops to five and three years respectively. The average age of men and women who die of myocardial infarction is exactly 10 years above the average age of those who survive the attack. It is important to note, however, that there was no appreciable difference in age at death between men and women in the older age group (82 versus 80 years).

TABLE 2.—*Sex and Age Distribution in One Hundred Fifty-seven Patients with Myocardial Infarction*

	Age, Yr					
	All Ages		Under 75		75 and over	
Patients	No	Average Age	No.	Average Age	No.	Average Age
Living						
Male	47	57	44	55	3	80
Female	16	64	14	60	2	76
Total	63	...	58	..	5	...
Dead						
Male	60	67	50	64	10	82
Female	34	74	16	67	18	80
Total	94	...	66	...	28	...

The fact that 94 (60%) of 157 patients with myocardial infarction died is noteworthy. This high fatality rate would suggest that there might have been under-reporting of nonfatal cases of myocardial infarction by physicians or that persons with less severe clinical symptoms did not seek medical attention and were not all recognized. In spite of this fact, the members of the reviewing committee, who are acquainted with the practitioners and the standard of medical practice in this area, believed this to be an accurate reflection of clinically manifest coronary heart disease as seen in the private practice of physicians in this population.

Further analysis of these deaths from myocardial infarction as compared to all other deaths is presented in table 3. If we consider only those d ceased persons who obtained some medical atte tion and whose cases were thus classified myocardial infarction, it is interesting to n that 27 died within the first hour after obtaini medical attention and that a total of 56 (60% the myocardial infarction deaths) died within t first 24 hours after obtaining medical attenti However, one can obtain a different perspective surveying all the deaths in the study, that is deat presumably all secondary to coronary heart disea There were 143 such deaths, 49 (34%) being u attended deaths in persons who did not, or co not, obtain medical attention prior to death. Twe ty-seven persons died within one hour after c taining medical attention, and 105 (73% of deaths) died before or within 24 hours of obtaini medical attention.

---

* UDD: with definite coronary heart disease; UDP: with prob coronary heart disease.

† Total of 143 deaths occurred: 49 (34%) died before they could tain medical attention: 56 (39%) died within 24 hr. after obtai medical attention; and 105 died (73%) died before or within 24 hr. obtaining medical attention.

In table 4 the deaths have been analyzed in co parison with cases of survival. No deaths occurr among patients reported to have had angina pe toris alone. If we consider all of the patients in t study, with the exception of those given a diagno of angina pectoris, as having a serious episode coronary heart disease, and if we also exclude t 51 cases listed as "unattended death, unknow cause" for the reasons already discussed, there ar a total of 251 such cases. In this group, 45 patient with coronary insufficiency and 63 with myocardia infarction survived, i.e., a total of 108. Thus, abou three of every five cases of a serious episode o coronary heart disease terminated in death. If w consider only the patients who received medica attention, i. e., the coronary insufficiency and myo cardial infarction groups, there were 202 patient

TABLE 4.—*Survival Statistics of Patients with Serious Episodes of Coronary Heart Disease*

	Total No. of Cases	Survivals, No.	Death No.
Coronary insufficiency Myocardial infarction Unattended death, definite Unattended death, probable	251	108	143
Coronary insufficiency Myocardial infarction	202	108	94
Surviving 24 hr. after medical attention	146	108	38

lived long enough to receive medical attention 146 who were still alive at the end of the first 24 hours. Applying the figure of 108 surviving patients to these totals. It would appear that, if a patient survived a serious episode of coronary heart disease long enough to receive medical attention, he had a somewhat better than even (108 survivals s compared to 94 deaths) chance to survive that pisode. Furthermore, if he survived the first 24 ours, his chances of surviving that episode rose to bout 3:1 (108 survivals as compared to 38 deaths).

In table 5 all cases in the study are analyzed ith regard to the known occurrence of symptoms r attacks of coronary heart disease prior to the eported episode. Of the 40 patients given a diagnosis of angina pectoris in this population in 1957, 4 (85%) had experienced symptoms from one eek to seven years prior to diagnosis. Six patients 15%) had consulted a physician and had been given a diagnosis of angina pectoris on the first appearance of symptoms. In the categories of coronary insufficiency, myocardial infarction (deaths); unattended death, definite coronary heart disease; and unattended death, probable coronary heart disease, there were no known previous symptoms in 50 to 60% of all cases. However, among those patients with myocardial infarction who survived the episode, 46 (74%) had not previously experienced symptoms. The types of prior coronary heart disease experienced by patients included angina pectoris, coronary insufficiency, myocardial infarction, and congestive heart failure. Analysis of those cases that terminated in death during this episode (myocardial infarction; unattended death, definite coronary heart disease; and unattended death, probably coronary heart disease) revealed that the prior incidence of angina pectoris and myocardial infarction was identical in each category. There was a wide range in the length of time from the first symptom or attack until death ensued. In some cases this time was reported by the attending physician or the patient's family as being "many years." To establish an approximate average, it was arbitrarily decided to use 10 years to replace this term in an individual case for the purpose of estimating duration of symptoms. If this is done one finds that, among the myocardial infarction deaths, those patients who had had angina pectoris developed this symptom an average of two years before death, while those having had a prior episode of myocardial infarction first experienced the symptom an average of 5.2 years before the final episode. This difference was not present in the category "unattended death, definite coronary heart disease," and since there were only two cases of each, no real conclusion can be drawn. In the category "unattended death, coronary heart disease probable" there were eight cases of angina pectoris and eight of myocardial infarction, with a survival time of 3.2 years for each category.

Among patients surviving the reported episode (coronary insufficiency and myocardial infarction), there is a greater incidence of angina as compared to any other type of coronary heart disease existing prior to the reported episode. Thus, in the coronary insufficiency group there are 12 patients who had had angina pectoris previously as compared to 4 who had experienced previous myocardial infarctions. In contrast to this, however, the prior infarctions had occurred on the average almost six years before, as compared to a duration of two and one-half years of angina pectoris. In the myocardial infarction (living) category the frequency of prior angina pectoris as compared to infarction was less marked, and the time of prior occurrence for both was about two years.

TABLE 5.—*Prior Manifestations of Coronary Heart Disease*

		No Known Prior Symptoms		History of Prior Symptoms		Prior Symptoms or Attack		Duration of Time Between First Occurrence of Prior Symptoms and Reported Episode

Summary

A study was made of the clinical spectrum of coronary heart disease in the population of six counties of North Dakota over a period of one year, as seen through the eyes of the practicing physicians serving that area. The clinical findings of this unique study, which was made possible through the interest and participation of all practicing physicians in the area in cooperation with public health agencies, are as follows.

Of the persons in this population who developed manifestations of coronary heart disease of sufficient severity to result in their being seen by a physician, 14% had manifestations diagnosed as angina pectoris, 15% had coronary insufficiency, 54% had myocardial infarction, and 17% died from coronary heart disease before they could receive medical attention.

When all diagnostic categories are considered as a whole, the incidence of coronary heart disease among men was twice that among women. At ages under 75 years, a ratio of 3:1 was found for the incidence of myocardial infarction among men as compared with women. However, at ages 75 years and over the ratio became two men to three women.

Men under 75 years of age with a diagnosis of myocardial infarction were, on the average, four years younger than women of the same age group in this diagnostic category. The average age of me and women in this age group who died of my cardial infarction is nine and seven years, r spectively, above the average age of those su viving the attack. However, in the patients 75 yea of age and over there is no difference between th sexes in regard to average age at death.

Sixty per cent of all patients with myocardial i farction died during the particular episode whic occurred in the course of this study.

Analysis of death and survival rates reveals th three of every five cases of a serious episode coronary heart disease terminated in death duri that episode. If the patient survived long enou to receive medical attention, his chances of survi ing that particular episode were about even. Ho ever, if he survived the first 24 hours after obtai ing medical attention, this ratio rose to 3:1 in fa of his survival.

Except for those in the category of angina pe toris, most patients had no prior known sympto or manifestations of coronary heart disease. Amo those that did, angina pectoris and myocardi infarction occurred most frequently. Among tho who died during this reported episode, angina pe toris and myocardial infarction had occurred wi equal incidence, while in those surviving the ported episode angina pectoris had previously c curred more frequently than myocardial infarcti

CLINICAL NOTES

REPORT OF A CASE OF BOTULINUS POISONING

Harold P. Sutherland, M.D., Idaho Falls, Idaho

A 41-year-old woman was first seen at 5 p. m. on July 29, 1959, about 28 hours after ingestion of four or five slices of odd-tasting prepared beets. Earlier in the day she had noted difficulty in reading the newspaper and had had some diplopia. Her husband and daughter, who had also eaten the beets, had vomiting and loose bowel movements during the day, in addition to the visual symptoms. They had difficulty in forming words, and their legs felt like wooden sticks. On examination, the woman's blood pressure was 128/64 mm. Hg, body temperature 98.2 F (36.8 C), pulse rate 72 per minute, and respiration rate 20 per minute. Findings of laboratory studies, ordered at the time of admission, were as follows: hematocrit, 40% volume of cells; hemoglobin level, 12.3 Gm. per 100 cc.; white blood cell count, 6,900 per cubic millimeter, with a differential of 67% segmented and 6% band cells, 24% lymphocytes, and 3% monocytes. Findings of urinalysis were specific gravi 1.008, pH acid, and urine negative for sugar a albumin.

A diagnosis of botulinus poisoning was made the emergency room. The patient noted that s and her family had eaten slices of odd-tasting bee at the last noon meal. Several of the children in t family had not eaten the beets, but the patie her husband, her daughter, and her father-in-la had ingested the beets and had a marked similari of symptoms. The diagnosis could not be prove at this time but was felt to be suspicious enough warrant an order for polyvalent antitoxin. The re of the jar of beets had been discarded prior to a mission, and the only specimen available for stud was a jar processed at the same time by the da gerous open-kettle method. This sample of bee showed marked spoilage, and there were some gra positive, spore-forming rods on the smear. On fu r testing, however, the material in the second jar of beets was not poisonous when injected into unprotected guinea pigs. Nevertheless, I believe that, inasmuch as there were three deaths in the two families and two other members exhibited the classic symptoms of botulinus poisoning, there is no doubt concerning the diagnosis. Polyvalent botulism antitoxin was obtained by air transport from Portland, Ore., Los Angeles, Denver, and Pearl River, N. Y.

The patient was given 1 oz. of castor oil, and administration of 1 oz. of a compound containing dihydrostreptomycin sulfate, polymyxin B sulfate, and pectin, with activated attapulgite (Claysorb) as the adsorbent agent (Polymagma, plain), was ordered after successful administration of an enema; it was believed that the Polymagma would absorb any poison remaining in the gastrointestinal tract. Chloral hydrate was given for sedation on the night of admission.

The next morning the patient suffered from extreme lassitude, weakness, and vomiting, and she continued to complain of visual symptoms. Her speech had become thicker. An infusion of 5% dextrose in isotonic sodium chloride solution, with 40 mg. of potassium chloride, was started at 7:30 a. m. The initial dose of 80,000 units of polyvalent botulism antitoxin was given on July 30, at 11 a. m. This was diluted 1:10 with 10% dextrose in water. The total 2,400-cc. volume of infusion solution was given during the next 18 hours. The antitoxin was given after the initial dose of infusion solution, at the rate of 10,000 units diluted to 300 cc. with 10% dextrose in water, every four hours for the next five and one-half days. On Aug. 4 there was improvement in the patient's speech, control of nuscles of swallowing, breathing, and vision.

Shortly after administration of the antitoxin had een started, the patient complained of increased lifficulty in swallowing and breathing and became yanotic. On July 30, at 3:30 p. m., she had comlete paralysis of the respiratory muscles and was laced in a Drinker respirator. To obtain sedation nd analgesia, she was given 50 mg. of promethazine Phenergan) hydrochloride and 75 mg. of meperiline (Demerol) hydrochloride every four hours. This losage was later decreased to 25 mg. of promethaine and 50 mg. of meperidine every four hours.

The patient was administered oxygen 4 to 6 liters er minute, first by nasal catheter and later by asal cannula. She was placed also on Levine-tube suction for the first two days.

During the second day in the respirator she developed a temperature of 102.6 F (39.2 C) and was given 3 cc. of Bicillimycin, which contains 600,000 units of benzathine penicillin G, 300,000 units of buffered crystalline penicillin, 300,000 units of procaine penicillin G, and 1 Gm. of streptomycin sulfate. Administration of this combination of antibiotics was repeated for four days.

On the third day in the respirator the patient's speech improved. Tenacious sputum was a problem, and on the fifth day in the respirator she was started on continuous administration of Tergemist, a mucolytic, detergent aerosol solution, which made the secretions less tenacious. On the seventh day in the respirator, therapy with botulism antitoxin was discontinued, as she was regaining her speech and had only minimal visual symptoms.

On Aug. 5, a roentgenogram showed increased bilateral markings in the lungs. The white blood cell count was 11,000 per cubic millimeter, with a differential count of 68% segmented cells, 4% band cells, and 28% lymphocytes. Her body temperature was 101.4 F (38.6 C) on the morning of Aug. 4 and 101 F (38.33 C) on the morning of Aug. 5. In addition to the intramuscularly given penicillin-streptomycin combination, 0.5 Gm. of oxytetracycline (Terramycin) was given intravenously.

On Aug. 7 another x-ray film supported the diagnosis of "early diffuse bronchopneumonia." Chloramphenicol, 1 Gm. intravenously and 0.5 Gm. intramuscularly, to be repeated every six hours, and oleandomycin phosphate, 0.5 Gm. intravenously, were given.

Sensitivity tests showed the incriminated organism to be a coagulase-positive staphylococcus, which was sensitive to erythromycin, chloramphenicol, kanamycin sulfate (Kantrex), oleandomycin phosphate, and ristocetin. On Aug. 9, chloramphenicol therapy was discontinued, and 150 mg. of erythromycin was given intramuscularly every four hours until Aug. 15. Oleandomycin phosphate, 1,000 mg., was given intravenously, and kanamycin sulfate, 0.5 Gm. four times daily, was given intramuscularly. Because the culture showed considerable yeast overgrowth, a suspension of nystatin, containing 400,000 units, was given every four hours by mouth. The patient was afebrile on Aug. 13; erythromycin and kanamycin sulfate therapy was discontinued on Aug. 15, but Ilosone (propionyl erythromycin ester) in capsules of 250 mg. was given four times daily.

When removed from the respirator on Aug. 8 and given oxygen by nasal tube, she developed a rash over her back. There were no other symptoms of serum sickness, but since this was a definite possibility she was given 80 units of ACTH as a prophylactic measure.

The patient was discharged to her home on Aug. 21, 1959, 23 days after admission. Her eye movements, swallowing, and general strength improved markedly during the week after discharge, but two weeks later she had severe diarrhea which necessitated hospitalization.

The patient's husband required levarterenol (Levophed) bitartrate therapy to maintain his blood pressure, and intravenously given amobarbital (Amytal) sodium and intramuscularly given phenobarbital to control convulsions. The husband, the daughter, and the husband's foster father died from botulinus poisoning. The foster father died before the respirator or antitoxin could be used. The husband had hypotension, bilateral pneumonia, and complete renal shutdown a day before his death, on the 10th hospital day. The daughter died on the third hospital day.

Summary

A 41-year-old woman was admitted to the hospital 28 hours after having eaten beets contaminated with botulism toxin. Therapy consisted o administration of 350,000 units of botulism poly valent antitoxin, eight days in the Drinker respi rator, antibiotics, and supportive measures. Thi patient recovered. A total of 1,050 cc. of hors serum was used without apparent toxic effects.

1050 Memorial Dr.

The polyvalent botulism antitoxin used in this study w furnished without charge by Lederle Laboratories, Divisic of American Cyanamid Co., Pearl River, N. Y.

CONSTANT TENSION SPRINGS ON LONG LEG BRACES TO ASSIST THE QUADRICEPS FEMORIS

Harold M. Sterling, M.D., Brighton, Mass.
and
Frederic J. Kottke, M.D., Minneapolis

Patients with weakness or paralysis of the extensors of the knee, especially when this is associated with weakness or paralysis of the hip extensors, have great difficulty standing and walking. Many devices have been designed to support the knees, ranging from simple gutter splints, plaster splints, and nonjointed bars to jointed knee braces with knee locks. Ambulation with a stiff knee is difficult for a person who has normal strength and is a great problem for a person with paresis or other disabilities. For this reason many attempts have been made to design a brace which allows flexion during sitting and flexion and support during walking. A knee joint allowing 2 to 4 degrees of extension beyond 180 degrees offers fairly good support to the patient with moderate weakness in both hip and knee when he is standing or walking, but it requires active muscular force, either in the knee extensors themselves or in the hip extensors, to extend the knee.

Where there is weakness of somewhat greater degree in both of these groups of muscles, such a brace becomes less satisfactory, and the patient often resorts to using the mechanical knee lock on the brace to obtain stability. More than 50 years ago mechanical knee extensors in the form of rubber bands or springs appeared, but they have bee of limited use[1] because the contractile force rubber bands and coil springs diminishes linear with shortening, so that at full extension of t knee (the point at which the patient would li maximum extensor force) these devices offer the least resistance to flexion. If the tension is increase at full extension, the patient becomes unable flex his knee.[2]

Prosthetic equipment research[3] has recentl turned attention to the use of constant-tensio springs[4] in many devices.[5] This report concerns th design and manufacture of long leg braces wit constant-tension knee-extension supports for pa pients who are unable to stand and walk becaus their quadriceps are too weak when the knees ar extended.

Construction

The brace itself (fig. 1) is a light double-bar lon leg brace with high and low thigh bands and high calf band. The ankle joint is prescribed t compensate for the disability of the specific ex tremity. In several of our cases a freely movin ankle joint with no stops or springs was adequate In others, posterior stops or dorsiflexor spring were necessary because of weakness of the dorsi flexors of the ankle. The knee joint is a freely mov ing nonlocking joint, allowing extension to abou 183 degrees. Both thigh bars are extended 2 to 3 in below the knee joint. A constant-tension spring i

Read before the Section on Physical Medicine at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

mounted on a ball-bearing pulley at the end of each extension arm, and the end of the spring is attached to the bar of the lower leg section to provide a constant tension extending the knee joint. It is necessary to keep the extension arm of the brace as short as possible, since the projecting points will limit flexion inside a trouser leg and may damage clothing.

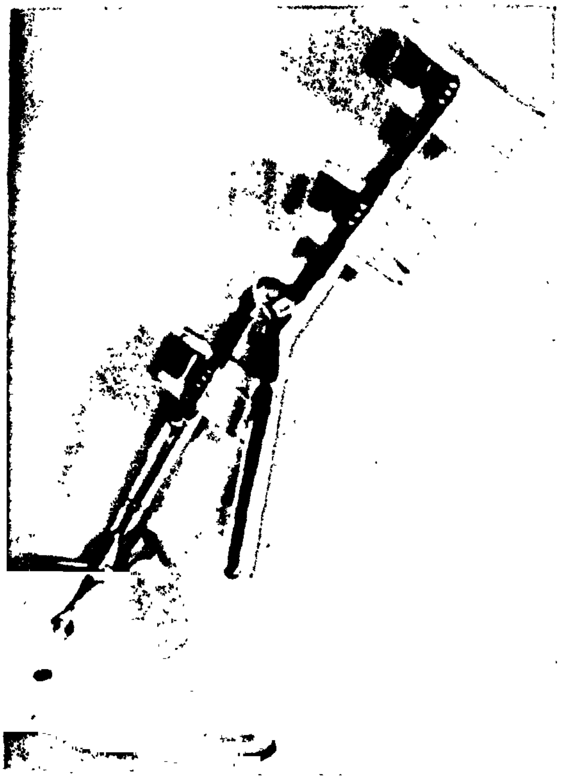

Fig. 1.—Brace before attachment of springs.

The strength of the springs to be used can be estimated easily by applying a scale or strain gauge[6] to the brace at the proposed point of attachment of the springs and noting the force necessary to extend the lower leg with its brace and shoe when the patient is seated. When the patient has some strength in his knee extensors, he should assist in this process, thus lowering the necessary spring strength. A spring which can exert one-half of the necessary force is mounted on the freely moving pulley on each of the extension arms (fig. 2). The knee joint of the brace is centered at the center of flexion of the knee but lies posterior to the line of the thigh bar and its extension arm so that the knee joint can extend slightly beyond 180 degrees.

Report of Cases

Case 1.—A 6-year-old boy with moderately severe general weakness due to amyotonia congenita was able to walk five or six steps without braces with Kenny sticks. He was fitted with lightweight long leg braces with spring-extension knee joints in December, 1957. He found that he could stand and balance immediately. Within one month he was able to walk with a 4-point gait and to walk up and down small stairs unassisted, with the braces and Kenny sticks. For the past six months he has been able to walk using sticks, but no braces, and attend public school. His gait continues to improve.

Case 2.—Another 6-year-old boy had extreme weakness of the left leg as a result of having poliomyelitis in the fall of 1957. He was originally fitted with a long leg brace with a drop lock, but he was unable to walk with the knee unlocked in spite of several months' of physical therapy and gait training. In July, 1958, he was fitted with a brace with spring knee extensors. By January, 1959, he was able to walk quite well without the brace and, at the time of this writing, walks with an almost normal gait without the brace or sticks.

Case 3.—A 60-year-old man with weakness due to compression of the spinal cord at L-3 and L-4, with weak hip extensors, no quadriceps action on the right, and fairly good action on the left, was fitted with two long leg braces with knee extensors in November, 1957, and was able to walk 60 ft. using a 4-point gait in December. Because he has not become stronger, he has continued to use the braces but can walk without assistance.

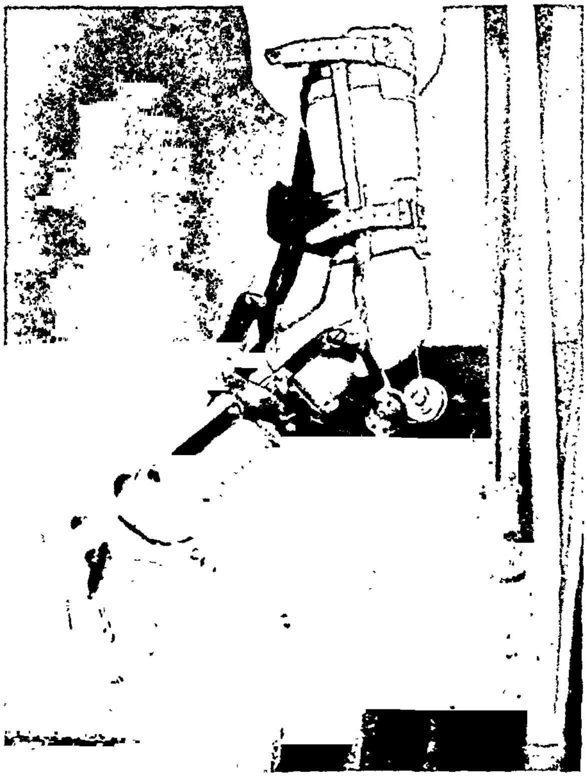

Fig. 2.—Brace completed.

Case 4.—A 3-year-old child with nonprogressive muscular atrophy which caused general weakness, most marked in the hip and knee, was unable to stand or walk without support. He was able to walk 100 ft. with gutter splints[7] and Kenny sticks.[8] In May, 1958, he was fitted with two long leg braces with knee extensors. He was able to walk with knee flexion and extension almost immediately after the braces were applied and now walks without assistance, using Kenny sticks for a swing-to and a 4-point gait.[9]

Two other patients have been fitted with similar braces too recently for a progress report.

Summary and Conclusions

A brace with constant tension throughout the range of knee motion has been described. Proper tension allows the quadriceps to participate in walking where residual strength is present, and thus the muscle can become stronger through use. Patients require less hip-hiking (elevating the pelvis on the affected side as the leg is swung forward) for walking and walk with a more normal gait. The freely flexed or extended knee joint offers greater ease in sitting and standing. In two patients, ambulation with braces developed quite rapidly and the braces were soon discarded, although both had had unsuccessful gait training directed at independent ambulation previously. Two continue to use these braces because of pe weakness.

ANAPHYLAXIS.—In the course of about a 5-month period, I had several episodes of folliculitis of one or the other nostril, and each of these episodes responded nicely to oral penicillin and bacitracin ointment topically. The day of this occurrence, another such episode had begun in the early afternoon. Bacitracin was used right away, but the soreness was increasing and when I got to my quarters, I took 4 oral penicillin tablets (800,000 u). At about 2130 hours, I took 4 more, the last of my supply. . . . I decided to go to the hospital and take penicillin intramuscularly, thus eliminating the need to awaken for oral medication. 600,000 units of procaine penicillin were administered at approximately 2235 hours. In past years, some 8 to 12 such injections had been received, none of which caused an allergic reaction. . . . Returning to my quarters I prepared for bed. While in the bedroom, about 2300 hours, moderate tenesmus was experienced. This was followed rapidly by a violent pounding sensation at the top of my head and . . . by a sensation of extremely heavy radial pulsations. Added to these symptoms was the sensation of a generalized erythema. Although these symptoms appeared successively, I doubt that the total elapsed time was more than 1½ minutes. It was probably at this point that I realized what was taking place, and told my wife to call the hospital O. D. and tell him I was having anaphylaxis and to please hurry. I lay down on the bed, vomited suddenly and uncontrollably about three times, and for the next few minutes the account can no longer be one of personal observation. There is no recollection of dashing to the bathroom, which I am told I did, and which is where I was when the medical officer arrived. . . . His case report: . . . "Patient was pulseless and unresponsive. Apex beat 50-60 per minute. 05 cc. of adrenalin was administered subcutaneously and response began in a few minutes. A second injection was given 5 minutes later." I regained consciousness. . . . Recovery was rapid after this and the adrenalin side-effects gradually subsided.—Lieut. Col. Martin Putnoi, MC, U. S. Army, Anaphylaxis—A Personal Experience, *Military Medicine,* June, 1959.

COUNCIL ON DRUGS

Report to the Council

The Council has authorized publication of the following report.

H. D. Kautz, M.D., *Secretary.*

This report, prepared by the Subcommittee on Breast and Genital Cancer, is the result of a 12-year collaborative undertaking to study the effect of androgen and estrogen therapy in the treatment of disseminated mammary cancer. As one of the earliest projects of this type, it has served to blaze a trail for a number of studies which have followed. It will undoubtedly serve as a base line for comparative evaluation of studies which are under way in the field of cancer. A great deal could be said about the devotion of the two men who originally headed the project and who have since died, namely, Drs. Ira T. Nathanson and Earl T. Engle. The enthusiasm and effort of the collaborators and the members of the subcommittee speak well for the participants. Credit should be given to those firms in the pharmaceutical industry which cooperated and so generously provided the products used by the investigators. The present members of the Subcommittee on Breast and Genital Cancer, headed by Dr. Ian Macdonald, are to be congratulated on their integrity and resolution in assuming the responsibility for the follow-up and reanalysis and in discharging their duties to the medical profession by assembling and interpreting the data from which this report is derived. Copies of the data and statistics used in preparing this report ("Accumulated Statistology") are available on request from the Secretary, Committee on Research.

Norman De Nosaquo, M.D.,
Secretary,
Committee on Research.

ANDROGENS AND ESTROGENS IN THE TREATMENT OF DISSEMINATED MAMMARY CARCINOMA

RETROSPECTIVE STUDY OF NINE HUNDRED FORTY-FOUR PATIENTS

In the fall of 1947, the Therapeutic Trials Committee (later designated the Committee on Research) of the American Medical Association undertook the sponsorship of a co-operative investigation of the effects of steroid hormones in the treatment of advanced or disseminated carcinoma of the breast. This investigation was co-ordinated by a Subcommittee on Steroids in Cancer including Drs. Ira T. Nathanson (deceased), Frank E. Adair, Willard M. Allen, and Earl T. Engle (deceased). In 1956, the subcommittee was reconstituted and redesignated the Subcommittee on Breast and Genital Cancer. Members of the Subcommittee on Breast and Genital Cancer of the Committee on Research are Drs. Ian Macdonald (Chairman), Los Angeles; Alfred Gellhorn, New York; B. J. Kennedy, Minneapolis; and Samuel G. Taylor, III, Chicago. With the support of the Committee on Research, and especially of its chairman, Dr. Stuart Mudd, the subcommittee has brought to completion the study which started a decade ago. The material consists of pooled data contributed by the following 60 collaborating investigators, without whose original and continued co-operation this report would not have been possible: Drs. Paul D. Abramson, Frank E. Adair, T. J. Anglem, Lionel S. Auster, H. C. Ballon, R. W. Begg, Frederick Hardy Bowen, A. J. S. Bryant, William Y. Burton, Franz Buschke, L. R. Chauncey, R. L. Clark, William A. Cooper, A. R. Curreri, Charles Eckert, Lucille Ellison, George C. Escher, Louis A. Eshman, Barry Friedman, L. H. Garland, Leonard B. Goldman, L. W. Gorham, Robert C. Grauer, Robert B. Greenblatt, Charles B. Hanna, Margaret Hardie, Joseph A. Hepp, Roy Hertz, Robert Huseby, B. J. Kennedy, Morton Kligerman, Edwin A. Lawrence (deceased), George Q. Lee, Henry Lemon, Edward F. Lewison, Champ Lyons, Ian Macdonald, S. S. Marchbanks, E. Perry McCullagh, Barton McSwain, John M. Modlin, Paul J. Murison, Ira T. Nathanson, H. E. Nieburgs, Kenneth B. Olson, Robert J. Parsons, Karl E. Paschkis, R. W. Postlethwait, Rieva Rosh, W. C. Sealy, Reginald A. Shipley, Joseph Silverstein, Arthur G. Siwinski, James A. Stapleton, Augustus Street, Samuel G. Taylor, III, G. M. Tice, Keene M. Wallace, Grant E. Ward, and Benjamin

B. Wells. The consultants in radiology included Drs. L. H. Garland and Leo G. Rigler. The consultants in pathology were Drs. Lauren V. Ackerman, Fred Stewart, and Arthur Purdy Stout. Dr. Stanley C. Harris served as consultant in biometrics.

At intervals, usually every two years, a conference of the collaborating investigators was held at the headquarters of the A. M. A. in Chicago. At the 1956 conference, the subcommittee determined the necessity of a complete reanalysis and recoding of the information which had been contributed concerning 1,983 patients. The successful completion of this laborious project was facilitated by Dr. Alex Sahagian-Edwards, College of Physicians and Surgeons, Columbia University and Francis Delafield Hospital, New York City, who served as Research Associate to the subcommittee for a 15-month period, 1956 to 1958.

Objectives of Study

TABLE 1.—*Cases Submitted for Analysis*

Cases complying with criteria for inclusion in study:		
Androgen-treated	580	
Estrogen-treated	361	
Total accepted for study		944
Cases not complying with criteria for inclusion in study:		
Not mammary cancer	19	
Male breast cancer	2	
Information lacking	372	
Not disseminated disease	309	
Radiation-treated	105	
Castrations	69	
Combined treatment	25	
Not sex steroids	22	
Ancillary treatments	14	
Inadequate dosage	101	
Miscellaneous	1	
Total rejected from study		1,039
Total submitted for analysis		1,983

The original objectives of this investigation, as established by the parent subcommittee, were outlined at the First Conference on Steroid Hormones and Mammary Cancer in Chicago, April 4-7, 1949.[1] It soon became apparent in a study of this magnitude that certain objectives could not be achieved practically or accurately. Specifically, some of the objectives were to establish which morphologic types of breast cancer were affected by androgen and estrogen therapy, the dosage necessary to achieve favorable effects, the duration of palliation, and the criteria by which improvement could be judged. Arrangements were made with the Armed Forces Institute of Pathology for a central registry, through which surgical and autopsy specimens could be reviewed by a group of consultants. Histological changes in responsive cases were comparable to the effects of irradiation, in both epithelial and stromal elements. No histological criteria for recognition of responsive tumors were apparent, nor did these studies provide any explanation of the mechanism of hormonal action.[2] Serial roentgenograms submitted to the consultants i radiology were impossible to evaluate, due to variations in techniques. Effort directed toward th elucidation of hormonal action was considered impractical in a group study. Such *areas as th* metabolic aspects of hormonal therapy, cytochemical effects, and the morphologic and *functiona* changes induced in various tissues were not investigated.

It was the current subcommittee's *opinion* tha the data available were sufficient to allow the following analyses: (1) determination of the objectiv responses of the neoplasm to estrogenic and androgenic hormones when administered to women wit disseminated mammary carcinoma, (2) compariso of the effectiveness of androgens and estrogen (3) clarification of the criteria for selection of patients and indications for hormonal treatment b estrogens and androgens, and (4) elaboration o certain aspects of the natural history of the diseas

Methods and Materials

Reports of 1,983 patients with mammary carcinoma treated by steroidal hormones were submitte to the subcommittee by the 60 investigators. Thi report is concerned with 944 cases (table 1) whic fulfilled the following criteria: 1. The diagnosis o mammary carcinoma was established histologicall in every patient. 2. Unequivocal evidence of distan dissemination of the disease was present, which wa unsuitable for radiotherapy or surgical palliation Specifically, it was required that spread beyond th regional (axillary) nodes be demonstrable in multiple foci, or be of such extent in dominant area that irradiation was impractical, or both. Each patient represented genuine, distant dissemination s advanced as to require a systemic approach i treatment. 3. The patient must not have bee irradiated or castrated within the six-month perio immediately preceding hormone therapy. This di not exclude patients with multiple lesions who received x-ray therapy to a single symptomatic area unless such irradiation resulted in any possibilit of ovarian exposure, e. g., treatment to lumba spine and pelvis. 4. No more than one hormone wa administered during a single period of observation. 5. The hormone was administered for at least one month. 6. The patient received hormones designated by the subcommittee, with dosages in reasonable accordance with established protocols. 7. A completed initial case report was submitted and was followed by progress reports at suitable intervals.

The material consisted of an initial case report of the patient, with historical data concerning (1) diagnosis and treatment of the primary disease, (2) menstrual history, (3) past illnesses and operations, (4) treatment of metastases prior to admission to this study, (5) description of size and location of lesions as indicated on appropriate diagrams, and

(6) specification of compound and dosage schedule to be employed. The progress reports provided the following information: (1) total dose of hormone, (2) duration of therapy, (3) reason for interruption or discontinuance of therapy, (4) general condition of patient, (5) objective changes observed in each lesion, (6) side-effects and other observations relevant to hormone therapy, and (7) date of death.

TABLE 2.—*Androgen Series**

Patients, No.	Substance		Schedule of Dosage: Amount, Mg.	Schedule of Dosage: Frequency	Route of Administration
415	Testosterone propionate	A	25	3 times weekly	Intramuscular
		B	50	3 times weekly	Intramuscular

88	Methyltestosterone	A	100	Daily	Oral
		B	200	Daily	Oral
580					

* Standard of reference was testosterone propionate, 100 mg., 3 times weekly. Recommended dose of other agents in terms of estimated androgenic equivalents, as determined by an advisory panel.

Despite the attempt to centralize pathological and roentgenographic interpretations, it was impractical to interpret these data. Therefore, the interpretation of the investigator and his own radiologist or pathologist was accepted as evidence for or against tumor regression.

In the evaluation of effectiveness of hormone treatment, only evidence of objective improvement was accepted as constituting reasonably satisfactory proof of a tumor-suppressive action. The definition of objective regression, which was rigidly adhered to in the following analysis, was stated as follows: a distinct, measurable decrease in one or more dominant metastatic areas by clinical or radiographic examination, without progression of any other metastatic lesions and with no new foci of disease having appeared. Indications of subjective improvement were ignored in this study of objective data; gain in weight, relief of pain, increase in feeling of well-being, improved blood chemistries, and improvement of hematopoiesis were not regarded as objective criteria. Patients classified as exhibiting "progression" included not only those with evidence of an increased extent in any lesion or lesions while under treatment but also those in whom the disease apparently remained stationary under therapy. The static cases numbered only 29.

The primary data concerning response and survival are based on the initial treatment of 944 patients. Calculations on survival were limited to patients treated by a single sex hormone, excluding those patients who subsequently received other steroid substances or who were subjected to endocrine ablative procedures. Two hundred eight patients subsequently received one or more courses of the same or another hormone. The response to these treatments is considered separately.

Androgen Series.—A total of 580 patients received androgen therapy as outlined in table 2. Although the majority of patients were treated in accordance with the dosage schedules outlined in this table, necessary variations in the individual management of patients not infrequently required changes from one schedule to another or, less often, some departure from the recommended protocol. For this reason, the criterion of adequate dosage is based in terms of total dosage. All patients in this group were treated for a minimum period of one month, according to one of the dosage schedules shown in table 2.

Estrogen Series.—A total of 364 patients were treated with estrogenic steroids as shown in table 3, for a minimum period of one month.

Follow-up: The clinical course of 844 patients (89.4%) was followed from the beginning of steroid treatment until time of death or the time of analysis. Of the 580 androgen-treated patients, 516 (89.0%) were followed to time of death or were still alive at the time of analysis; of the 364 estrogen-treated patients, 328 (90.1%) were followed to time of death or were still alive at the time of analysis.

Results

Androgen Series.—The frequency of tumor regression among the 580 androgen-treated patients was 21.4%. The distribution of these patients by age at the time of starting hormone therapy is shown in figure 1. Due to the recommendation of the subcommittee that estrogens be avoided in the treatment of premenopausal women, the prevalence of younger women among those receiving androgen treatment is conspicuous. There were 160 premenopausal patients in this group, of whom 32 (20.0%) manifested objective regression. Objective regression was recorded for 92 (21.9%) of the 420 postmenopausal, androgen-treated patients. Within

the postclimacteric group, menopause occurred naturally in 277, was induced in 104, and was of undetermined nature in 39 patients. (All reference to patients being premenopausal or postmenopausal indicates their status at the start of hormonal therapy. The term "induced menopause" refers to patients who had oophorectomy or castration by irradiation prior to the beginning of hormone therapy, whether related or unrelated to treatment of the primary carcinoma.)

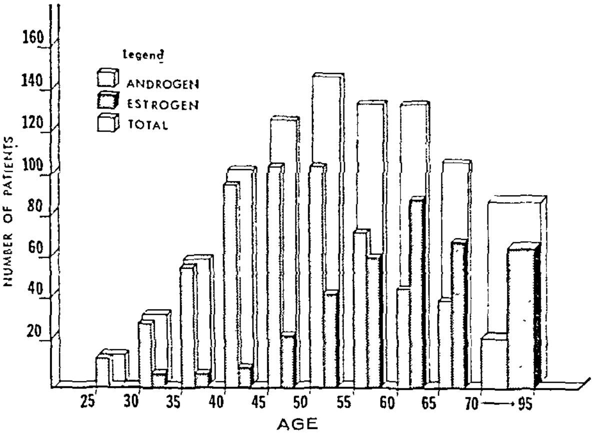

Fig. 1.—Distribution of patients by age at treatment of metastases.

The incidence of tumor regression was correlated with *treatment beginning during successive 4-year* intervals after the menopause through 16 years, and for those 17 or more years postmenopausal (table 4, fig. 2). The numerically largest group treated by androgens was in the immediate postmenopausal period of zero through four years. It is evident that nine or more years after the menopause there is an increased probability of obtaining an improvement with androgenic therapy ($\chi^2=6.65$, $p<0.01$).

Table 4.—*Incidence of Regressions Correlated with Interval Between Menopause and Beginning Hormone Therapy*

Total	944	580	124	...	364	134	...	...	...

* As applied here, "p" means the probability that differences between percentage regression with androgens and estrogens are due to coincidence.
† Each time interval is inclusive, e. g., from 0 through the entire 4th year = 0-4 yr.

This correlation of regression frequency with increasing postmenopausal interval is confirmed by a significant ($p<0.01$) "r_pb." (Whenever applicable, statistical methods have been used as an aid in the interpretation of results. Statistical significance is expressed in terms of probabilities that observed differences are due to chance. The smaller the "p" values, the less likely that observed differences may be attributed to coincidence. Thus, $p<0.05$ means that less than 5 times in 100 would a difference be attributed to chance; $p<0.01$ is less than 1 in 100. Conventionally, the rigid minimum requirement for significance is $p<0.01$, though a less critical but acceptable level of confidence is $p<0.05$. For those interested, statistical procedures [and their symbols] which have been applied to the data in this study are: "r," correlation of quantitative data; "r_pb" (point biserial), correlation of dichotomous values with quantitative values; "t" ratios, comparison of quantitative values; chi square, comparison of qualitative values. In every instance of chi square application, the correction for continuity has been included.)

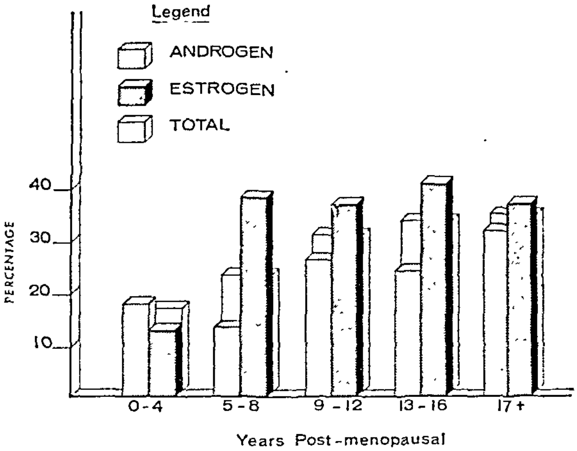

Fig. 2.—Frequency of regression by interval from menopause to treatment of metastases, shown as percentage within each 4-year group.

An evaluation of frequency of regression according to anatomic sites was attempted. Comparison of the effectiveness of androgens on metastatic involvement in peripheral soft tissue, viscera, and bone for all cases showed no significant differences (table 5). An evaluation of effectiveness on involvement of multiple system (e. g., viscera and bone, soft tissue and bone) was not practicable.

The average duration of life for all 427 patients receiving androgens as the only form of steroid therapy, and followed to time of death, was 11.4±9.9 months from institution of treatment. This period of average longevity was 19.1±12.2 months for those patients who demonstrated regressions and only 9.7±8.4 months in the nonresponsive patients ($t=8.14$, $p<0.01$). The average duration of survival of groups divided by menopausal status, primary treatment status, and responsiveness are presented in table 6. Longer survival associated with regressions is again demonstrated.

TABLE 5.—*Correlation of Incidence of Regression and Location of Metastases*

		Androgen			Estrogen		
		Patients,	Regression		Patients,	Regression	
Menopause Status	Site*	No.	No.	%	No.	No.	%
All cases	Soft tissue	69	16	23.2	98	37	37.8
	Viscera	35	10	28.6	35	14	40.0
	Bone	162	34	21.1	33	9	27.3
Postmenopausal (natural)	Soft tissue	33	6	18.2	81	33	40.7
	Viscera	10	3	30.0	25	8	32.0
	Bone	80	25	31.3	23	7	30.4
Premenopausal	Soft tissue	21	4	10.0	...	...	...
	Viscera	17	5	29.4	...	...	...
	Bone	39	7	17.9	...	...	...

* Dissemination limited to these sites; cases with involvement of multiple systems excluded.

When the androgen-treated, naturally postmenopausal patients were grouped into responsive and nonresponsive groups, and the percentage of the sample still alive at selected intervals after beginning hormone therapy was graphed (fig. 3), a significantly greater ($p<0.001$) proportion of responders was found to be alive for periods up to 48 months.

TABLE 6.—*Comparison of Average Duration of Survival of Responders and Nonresponders*

			Regression		Nonregression

		Av.	...	27	...	11	...

* After start of hormone therapy.

Estrogen Series.—The frequency of regressions among 364 patients treated by various estrogens was 36.8%. This calculation included seven premenopausal patients, in all of whom progression of the neoplastic lesion was noted. Figure 1 demonstrates that the group treated with estrogens was comprised of chronologically older women (average age, 63 years) than the androgen-treated group (average age, 51 years).

Menopause occurred naturally in 294 cases, was induced in 16, and of undetermined type in 47. The menopause of 236 of 310 patients (table 7) occurred nine or more years before institution of estrogen therapy for metastatic disease. The regression rate of this group (37.7%) was not significantly higher than that of the group with recurrence at an earlier postmenopausal phase (27.0%). However, when the group was made more homogeneous by excluding patients whose primary lesions were untreated, or had occurred premenopausally, the r_pb is significant ($p<0.05$), indicating an increase in rate of regression as the time between institution of hormonal treatment and the menopause became longer.

The average duration of life for all 243 cases receiving estrogens as the initial and only form of steroid therapy was 16.5±16.1 months from institution of therapy (table 8). This period of average longevity was 27.3±18.2 months for those who manifested regressions and only 10.4±10.8 months for the unresponsive patients ($t=9.08$, $p<0.001$). Table 6 presents, for those women who had a natural menopause, the average months of survival after beginning hormone therapy, according to their response to treatment. Again it is obvious that patients in whom the disease regressed had a significantly longer period of survival than did those who failed to improve. In a survival curve (fig. 3), the proportion of patients alive in each period through 48 months after beginning hormone therapy was very significantly greater ($p<0.001$) for responders than for nonresponders.

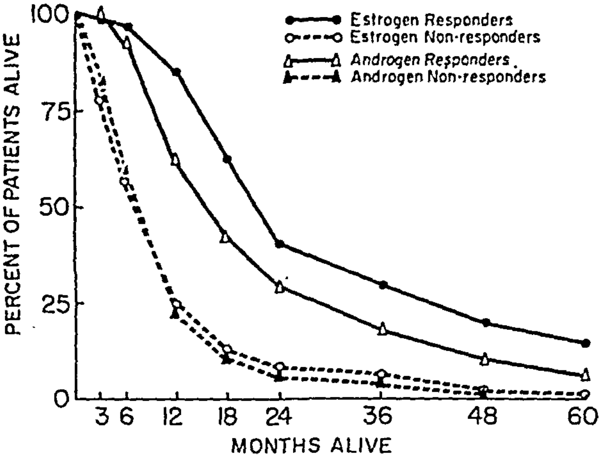

Fig. 3.—Comparative survival curves of natural postmenopausal patients from initial treatment of metastases.

Comparison of Androgen and Estrogen Series

The number of patients involved in this investigation would seem to provide an opportunity for comparing the efficacy of estrogenic and androgenic hormones in groups homogeneous with respect to the incidence of regression, response of specific disease sites, physiological and chronological age, and duration of survival. However, such effort was unrewarding in many applications of this technique because samples became too small.

TABLE 7.—*Comparison of Incidence of Regression in Terms of Ovarian Status*

		Androgen			Estrogen

Unknown interval	86	39	11	28.2	47	25	53.2	...	...

* Since last menses.

Because there is a significantly different distribution of ages in the androgen-treated and estrogen-treated groups (fig. 1), comparison of therapeutic effectiveness between the entire groups might be misleading. Nevertheless, when the frequency of regression after administration of androgen and after administration of estrogen was compared in groups of the same age (fig. 4), there was a higher frequency of response to estrogens in every decade. Statistically, the differences were significant only among patients who were over 70 years of age when hormone therapy was begun.

The older the patient was at the time steroid treatment was started the more likely was a regression to occur. In the androgen-treated cases, r_{pb} revealed a correlation with less than a 5% chance of being coincidental, whereas, within the estrogen-treated group, this correlation was much stronger, $p<0.0005$. Taken collectively, $p<0.005$ indicates that age of the patient at the beginning of treatment is an important factor in responsiveness.

As indicated in figure 2 and table 4, regressions occurred more often after estrogen therapy than after androgen therapy in groups which were comparably postmenopausal. When the postmenopausal interval was arbitrarily divided into less than nine years and nine or more years, the advantage of estrogens over androgens was of modest statistical significance (table 7). Vertical comparisons in table 7 are not without some interest. However, the only such comparison which is statistically significant is in the androgen series among those patients less than nine years postmenopausal and those more than nine years postmenopausal (x^2=6.65, $p<0.01$) The point biserial correlation of regression to post menopausal interval was calculated within the mor homogeneous population, achieved by using onl patients whose menopause had occurred spontaneously and whose primary lesions had been treate postmenopausally. This correlation was statisticall significant among the estrogen-treated ($p<0.05$ not significant among the androgen-treated, an significant when androgen-treated and estroge treated patients were pooled ($p<0.01$).

TABLE 8.—*Average Survival of Patients According to Treatment*

	Androgen		Estrogen			
Status of Patients	Patients, No.	Av., Mo.	Patients, No.	Av., Mo.	t	p
All patients	423	11.4	243	16.5	5.054	<0.001
No regression	345	9.7	156	10.4	0.784	...
Regression	78	19.1	87	27.3	3.345	<0.005

So few premenopausal patients (seven) we treated with estrogens that comparisons with andr gens within this limitation were not feasible.

The incidence of regression by androgen an estrogen treatment and by site of metastases compared in table 5. In comparing the largest, mo homogeneous sample available (natural postmen pausal), it is apparent that there was no differen in the incidence of regressions in patients wit visceral or osseous lesions. In patients with so tissue lesions (lymph nodes, skin nodules, an breast), regressions occurred significantly ($p<0.0$ more often after estrogen treatment (40.7%) tha after androgen therapy (18.2%).

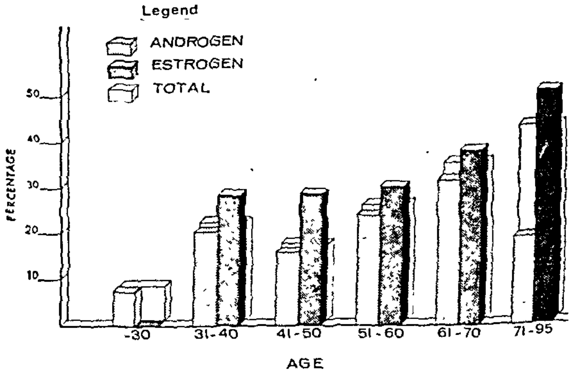

Fig. 4.—Frequency of regression by age of patient a treatment of metastases, shown as percentage within eac 10-year interval.

The excellent follow-up to time of death of thi large series provided an opportunity to compar the effect of androgen and estrogen therapy o duration of survival. The most physiologicall homogeneous sample available for this purpose wa composed of those whose menopause had occurred spontaneously (table 6, fig. 3). Fortunately, the samples were almost equal in size, 194 having been treated by androgens and 198 by estrogens. Of the combined total of 392, 111 (28.2%) were responders, and 281 (71.8%) were unresponsive to hormonal treatment. Despite the type of hormone employed, longevity in the nonresponders was virtually identical, or an average of 10 and 11 months (after beginning hormonal therapy) for patients receiving androgens and estrogens respectively. Such uniformity in lethal end-point, unrelated to treatment, is evidence of a comparable tumor-host relationship at the beginning of treatment and a further indication of the homogeneity of the sample under analysis. In table 6 it may be seen further that, among patients enjoying regression, the estrogen-treated patients survived significantly longer, on the average, than did the androgen-treated patients, or 27 and 20 months respectively ($p<0.05$).

The advantage of estrogen treatment on survival may be seen also in figure 3. Statistically, more estrogen-treated patients are still alive 6 months ($\chi^2=7.49$, $p<0.01$) and 12 months ($\chi^2=4.40$, $p<0.05$) after beginning treatment.

Repeated Courses of Hormone Therapy

One or more courses of the same, or another, hormone were used for 208 patients not included in the calculations of survival just described. Evaluation became more difficult as multiple courses of treatment constituted added variables and made comparisons more complex; a much larger sample than was available would be required for comparisons of any significance. It was apparent that, after an initial regression and subsequent reactivation, a second interval of objective regression might be obtained with hormones of the same or the opposite type. In fact, repeated regressions were obtained in some patients. Also worthy of mention was the observation of renewed remission, in occasional patients, after withdrawal of the hormonal substance which had induced the initial period of regression. Such examples of a "therapeutic" effect by omission of therapy are unusual, and the duration of the favorable response ordinarily is brief.

Comment

Validity of Study.—Certain aspects of this retrospective, co-operative study and the methods used in analyzing the available data deserve some comment. It is unfortunate that over one-half of the case records submitted were unacceptable. Contributing factors included too many investigators submitting too few cases, inadequate resources for ideal liaison with contributors and for prompt correction of deficiencies and collection of follow-up information, and failure to achieve a more effective experimental design during the planning stage over 10 years ago. Of practical importance are those exclusions suspect of producing a selective effect or making the sample for analysis biased. The exclusion of 101 cases because of inadequate dosage is justified by three items of evidence: 1. The frequency with which androgens and estrogens were used in the rejected cases was about the same as in the accepted cases. 2. Previous reports of the subcommittee have provided evidence indicating that the potential effectiveness of the sex steroids on the neoplasm is related directly to their virilizing or feminizing titer, and that regression of disease does not occur to any significant degree until clinical evidence of the physiological effect of androgens or estrogens is apparent. The minimal requirements of dose and of duration of treatment for this study are both well below the levels required for virilizing or feminizing effects and must be regarded as almost equally inadequate in antitumoral effect. 3. Another objection might be that the rejection process resulted in the acceptance of cases treated by androgens and estrogens which are not as representative as an unselected group would be, resulting in a comparison of atypical groups. The present report demonstrates conclusively that the patients treated by androgens and estrogens were comparable groups; among those who were unresponsive to treatment, average survival time was virtually identical in each series (table 6, fig. 3).

TABLE 9.—*Regression Rates According to Total Dose*

	Testosterone Propionate	
Ovarian Status	<3 Gm.	>3 Gm.
Premenopausal, %	8.8	21.5
Postmenopausal (natural), %	12.5	30.1

The criterion of a minimum period of one month of treatment was exceedingly lenient. For androgens, one month of schedule C, testosterone propionate, most commonly used, produced a dose of 1.3 Gm.; schedule A, least often used, was at the rate of only 325 mg. per month. The relative inadequacy of these dosage levels was obvious when regression rates were calculated with reference to a total dose of known effectiveness, or 3.0 Gm. in two major groups (table 9). With estrogens, a total dose of 1.0 Gm. of diethylstilbestrol is an effective level, as the following rates of regression, in naturally postmenopausal patients, will demonstrate: <1.0 Gm., 26.3%; >1.0 Gm., 47.3%. The minimum criterion of one month of treatment, at the recommended rate of 15 mg. of the substance daily, amounts to less than 500 mg., but even this is frequently an overestimate because of the number of patients with an initial intolerance and the necessity of graduated dosage at the beginning of treatment.

The duration of treatment is as important as, or perhaps of greater significance than, the total dosage. The situation just indicated for the orally administered estrogens is pertinent; some of the accepted cases were women who did not reach the minimum total dose until two or even three months had elapsed, because of difficulty in developing tolerance. A few never reached the recommended daily dose. Yet the length of treatment was an important consideration. If a total of 3 Gm. was ingested, a three-month period was required before full effectiveness of estrogens was approached, though not entirely realized for soft tissue metastasis, whereas skeletal deposits frequently required even longer intervals before objective changes of regression were demonstrable. With androgens, it seems probable that remissions were about twice as frequent in those treated for more than three months than in patients whose therapy was of briefer duration.

With such minimum criteria of dosage and duration of treatment established, it is obvious that the lenient requirements for admission to this study had a dual effect: (1) inclusion of patients in whom a favorable response may have been triggered by hormonal influences of minute dimensions, and (2) admission of potential responders in whom more prolonged treatment at recommended dosage would have achieved measurable palliation. As the latter group exceeded the former by a large margin, the process of selection was such as to diminish, rather than enhance, the true dimensions of the usefulness of hormonal therapy.

TABLE 10.—*Averages of Free Interval for Three Groups*

Patients, No.	Group	Mean, Mo.	Standard Deviation, Mo
124	B1	31.36	33.77
48	B2	87.10	57.25
377	B3	39.19	36.60

Evidence of progressive disease before starting treatment was not required. This was compensated for by designating as nonresponders those 29 patients whose disease remained static during treatment and follow-up, thus lumping them with the failures in this evaluation of the effectiveness of hormonal therapy. To do otherwise would require a largely artificial grouping of patients with static or "arrested" disease, contributed to in some part by the phenomenon of spontaneous arrest. The experience of the subcommittee, which led to the most elementary classification of "responders" and "nonresponders" as employed here, by rigid criteria of objective improvement, also suggests that more divisive groupings with such terms as "arrested," "remission," and "equivocal" are of dubious value.

In the analysis of responsiveness of postmenopausal patients to treatment, the samples were limited, in most instances, to those women who had experienced a natural climacteric. The intent was to obtain groups as homogeneous as possible for such comparisons, and, in a significant number of those whose "menopause" had been induced, the cessation of the menses was attended by uncertainty of the artifactive process used. Most frequently a pelvic operative procedure followed by amenorrhea was not accurately recorded as including ovarian ablation. In other instances, pelvic irradiation apparently had resulted in amenorrhea, but, without details of tissue (midpelvic) dose, no impression of the physiological effectiveness of this measure was possible. Actually, when the induced-menopause group was combined with the natural postmenopausal patients, and the aforementioned calculations repeated, there was no significant variation between the total postmenopausal "population" and the more physiologically homogeneous fraction.

Indications of Variations in Natural History of Mammary Carcinoma

Several trends which emerged during this review are reflections of the variable natural history of mammary carcinoma, apart from their correlation with the results of hormonal treatment.

Free Interval.—A phenomenon of intriguing interest to any observer of the clinical course of cancer of the breast is the activation of metastatic disease after many years of good health following eradication of the primary growth in the breast. Late manifestations of metastasis are so common that the traditional yardstick of survival for five years is of little value; it is not uncommon for the initial evidence of distant spread to appear 15 to 20 years after definitive, primary treatment, and in one carefully studied and verified instance the first local (axillary) recurrence was noted after 37 postoperative years. The lapse of time between primary, definitive treatment (usually mastectomy) and, in this view, the initial use of hormonal therapy is an approximate index of the latent period of foci of metastasis and necessarily must be an expression of the biological balance between host and neoplasm. The time during which metastasis remains occult, or subclinical, is referred to hereafter as the free interval.

A number of analytical procedures have been applied to available free-interval data, one of which indicated a natural division of the sample at hand into three groups. In the first group, both primary treatment and metastatic growth occurred prior to the menopause (designated B1); the second group had mastectomy prior to the menopause and recurrence after a natural climacteric (B2); the third group was comprised of those in whom a natural menopause preceded both primary disease and appearance of metastasis (B3). The free-interval averages for these three groups are shown in table 10. Each of these average values is statistically different from each of the other two: $p<0.05$, comparing group B1 with group B3, and $p<0.001$ for the other two comparisons. (These statistical statements are made on data from which "untreated primaries" and "induced-menopause" groups were excluded. Cases treated with androgen or estrogen, responders or nonresponders were pooled.)

The identification of the B2 group, characterized by an inordinately long free interval averaging 87 months (7¼ years) and by the interposition of the menopause between primary treatment and metastatic activity, represents a unique and hitherto unrecognized, though minor, fraction of patients in whom the natural history is so disparate as to require its separation from the major groups of cases.

Table 11.—*Comparison of Relative Frequency of Regression by Free Intervals and Hormone Treatments*

		Free Interval, 0-36 Mo.			Free Interval, 37+ Mo.				
		Patients,	Regressions		Patients,	Regressions			
Group*	Treatment	No.	No.	%	No.	No.	%	χ^2	p
A. All cases	Androgen	132	24	18.2	98	35	35.7	8.168	<0.005
	Estrogen	106	31	29.2	90	33	36.7	0.901	...
B. Only B2	Androgen	43	10	23.2	28	15	53.6	5.584	<0.025

	Estrogen	75	24	32.0	61	24	39.3	0.505	...

* Natural menopause cases only.

All prior studies with which the subcommittee is familiar have indicated comparably longer free intervals in patients who were older by either chronological or endocrinologic landmarks. This concept may be derived also from the study at hand, in which the average free interval of 124 premenopausal women was 31.4 months, whereas it was 44.6 months for 425 patients whose menopause had occurred spontaneously. Recalculation of free interval for the postmenopausal group after removing the influence of the B2 patients (i. e., all postmenopausal patients minus the B2 group, leaving residual B3 group), demonstrates a diminished free interval for these 377 women of 39.2 months, which is more comparable to the figure for premenopausal patients.

To explore the possibility that the effectiveness of hormone therapy might be related to duration of the free interval, it was tested for correlation, with two indexes of response. The correlation of the incidence of regression with increasing length of free interval was found to be significant ($r_{pb}=0.081$, $p<0.05$). Correlation of the length of free interval with duration of survival after beginning hormone therapy was also very significant ($r=0.138$, $p<0.01$) for the 518 cases with the necessary information. This correlation was significant, even when the test was applied separately to responders and nonresponders.

Because the free interval appeared to have some prognostic value, its association with the age of the patient at definitive treatment of the primary lesion was tested. Significant inverse correlations were found between these two values for 123 patients in whom primary treatment and metastasis preceded the menopause ($r=-0.248$, $p<0.01$), and for 375 patients whose primary and palliative therapy both followed a natural menopause ($r=-0.142$, $p<0.01$). This is to say that the younger the patient is at the time of recognition and treatment of her primary disease the longer the evidence of metastasis is likely to be postponed.

That the average free interval for the B1 group was 31.4 months and for the B3 group was 39.2 months does not contradict the surprising inverse relationship described. Although the average age and average free interval were both smaller in the B1 group, the statistical examinations produced significant inverse correlations, whether performed on data within each of the two groups or on the two groups pooled.

The unusually long free interval seen in the small B2 group suggests that in these patients there was some unusual biological or metabolic feature which favored a very long occult phase of metastatic disease. Nonetheless, the inverse correlation between primary age and free interval in this group was also significant ($r=-0.439$, $p<0.01$).

In analyzing the inverse relationship between the free interval and age, it became desirable to determine the influence of this interval on rates of regression in the B2 group, in view of postprimary free periods of such remarkable length, and to discover what differences might exist between the B2 cases and all other naturally postmenopausal women. Analyses of the entire series of naturally postmenopausal patients (at the time of beginning hormonal therapy), by division of androgen-treated and estrogen-treated groups into subgroups of free intervals through 36 months in duration and 37 or more months, appear in table 11. By this arbitrary subgrouping, the association of the longer free interval with a greater percentage of regressions was highly significant for those treated by androgens but was not statistically significant in those given estrogens.

The same analyses for the B2 group and for the remaining patients (131 and 295 cases respectively) of the naturally menopausal series are presented separately in B and C of table 11. Again, the longer free interval was unassociated with any significant increase in the occurrence of regression with treatment by estrogens. In both larger and smaller groups, the influence of the longer postprimary free interval was significant with androgenic therapy, although not as striking by statistical standards.

Table 12.—*Vertical Comparisons of Table 11*

	Free Interval,	Regressions			
Group	Mo.	Androgen, %	Estrogen, %	χ^2	p
A. All cases	0-36	18.2	29.2	3.451	<0.06
	37+	35.7	36.7	...	...
B. Only B2	0-36	23.2	22.6	...	...
	37+	53.6	31.0	2.129	<0.250
C. Without B2 ..	0-36	15.7	32.0	5.172	<0.025
	37+	28.5	39.3	1.250	...

It is revealing to examine the same data from another perspective, as shown in table 12. In the group from which the B2 cases were excluded, t frequency of regressions was significantly greater ($\chi^2=5.172$, $p<0.025$) among the estrogen-treated women than among the androgen-treated women whose free intervals were less than 37 months. If the values comparing androgen and estrogen effect are compared when the free interval exceeds 37 months, statistics indicate they are not different.

Within the B 2 group, androgen and estrogen were found to elicit equal frequencies of regression when the free interval was less than 37 months. After 37 months, a greater frequency of regression occurred after androgen treatment than after estrogen therapy (though it is statistically insignificant).

Comparing the frequency of regression under different treatments and by the arbitrary free-interval separation at 36 months, androgen was superior, though not statistically, to estrogen only when 53.6% is compared to 31.0%. Within the androgen-treated group the regression group is greater among the B2 group (53.6%) than in the B3 group (28.5%) when the free interval is more than 37 months ($\chi^2=4.41$, $p<0.05$). Thus, it is possible to suggest that, in a B2 patient who had a free interval longer than 3 years, androgen is more likely to be of benefit than if she were not in the B2 group. These data do not show that androgen will be any more favorable to this B2 patient than will estrogen.

An even more valid endorsement of the prognostic value of the free interval was its significant correlation ($r_pb=2.25$, $p<0.025$) with the incidence of regression.

Survival.—The most significant and most consistent phenomenon in the behavior of the disease under hormonal treatment, both by androgen and estrogens, was the increased survival time of patients in whom objective regression of disease occurred (tables 6 and 8, fig. 3). It should be noted that the nonresponsive groups, whether premenopausal or postmenopausal, whether treated by androgens or estrogens, and whether postoperative or with primary neoplasm *in situ*, had average survival periods in a narrow range of 8 to 11 months after starting treatment. When the status of the primary site was disregarded, the over-all mean survival time for the premenopausal and androgen-treated or estrogen-treated postmenopausal groups was 11 months, 10 months, and 11 months respectively. These short, statistically equivalent periods of survival in nonresponders provided highly dependable base lines, consistent with the natural history of untreated disease in these groups (see below), against which the responders survived for average intervals of 18, 20, and 27 months respectively. Statistical significance of the disparity in survival of responders and nonresponders was at the critical level of $p<0.001$ in comparing four of the six subgroup pairs shown in table 6 and was within the area of confidence for data of this type in the other comparisons, considering the over-all trend.

The capacity for objective regression of neoplasm and the associated increase in survival which differentiated responders from nonresponders were important indications of fundamental biological differences between the two groups. The evidence of basic disparity was not so much in the presence or absence of tumor-suppressive effect as in the fact that regression was followed by a significant alteration in the course of the disease and in survival, whereas, without regression, the pattern of disease and survival remained unaltered. The significance of the data supporting this basic separation of patients provides both incentive and promise to efforts in research aimed at the elucidation of hostal or tumoral factors responsible for these reactions.

Results of Treatment

Distribution of Patients.—There were only 167 premenopausal women, compared to 777 postmenopausal patients, making up the total of 944 available for analysis. Of these, 580 were treated by androgens and 364 by estrogens, a resounding vote for androgenic substances, justification for which is lacking in the data presented herein. If a conclusion stated earlier had been followed in this series, namely, that estrogens are more effective than androgens after the fourth postmenopausal year, the ratio of their use would have been reversed, and 588 would have been treated with estrogens (table 4).

Although those treated by androgen were of an average age (51 years), 12 years less than the estrogen series (63 years), the difference was more chronologic than endocrinologic, and there was obviously a lesser disparity (6 years) in age by years in the only patients for whom such comparison was proper—those who were postmenopausal.

Of the 716 postmenopausal women for whom the elapsed years of diminished ovarian activity were recorded, there were 167 in whom the menopause had been induced prior to the activation of metastasis. Of these, 115 were treated by androgens and accounted for 21.3% of all patients so treated; 52 of the estrogen series, or 15.9%, were treated after an induced menopause. This distribution is reasonably analogous to the over-all androgen-estrogen ratio; e. g., 38.5% (364) of the total of 944 patients and 31.1% (52/167) of the induced menopausal group were treated by estrogens.

Chronological Age: As seen in figure 4, too few patients were treated with estrogens before age 40 to allow any comparison. It is no surprise that in women past 70 years of age estrogens were of significant superiority ($p<0.02$). In the decades from 40 to 50, 50 to 60, and 60 to 70, estrogenic therapy produced greater percentage rates of regression; although these were not statistically valid, the approximate number of regressions per 100 patients, estrogens over androgens, was 29 and 16, 30 and 24, and 37 and 31 respectively. This consistent superiority of estrogen through all ages past 40 gives no indication that the performance of androgenic therapy was at a disadvantage due to factor of age.

Endocrinologic Age: In table 4 a review of percentage rates of regression, noted in successive periods beyond the menopause, shows that the estrogens reach a plateau of performance after the fourth postmenopausal year, with about 38 of every 100 patients obtaining regression. The androgen series records a similar plateau, but at a later phase, or after the eighth postclimacteric year, and at a less effective level than with estrogens, with regression occurring at a rate of nearly 27 of each 100 patients. On cross comparisons of differences within each of the two treatment series, significant values were found only between the intervals zero through four years and five through eight years among the estrogens ($\chi^2=4.804$). The possibility that the androgens are at a disadvantage due to their use in women who are younger than those in the estrogen series becomes less credible when the effectiveness of androgens at the two extremes of age is examined. In premenopausal patients in the decade from 31 to 40 years, androgens induced regression in 21.4% of 84 patients. In a group of patients aged 71 to 95 years, 21 were subjected to androgenic therapy and only 4, or 19.0%, experienced any regression. The corresponding regression rates for estrogens were 28.6% for those aged 31 to 40 years (postmenopausal women) and 51.5% for the oldest grouping.

Although the differences in these rates of regression are of statistical significance only in the postmenopausal interval of five through eight years (table 4), the consistent disparity is not without practical clinical overtones, which are amplified to a degree of real significance by considering larger samples, as in table 7. Here it is shown that, in the period ending with the eighth postmenopausal year, estrogens produced a 27.0% regression rate to 16.3% for androgens ($p<0.06$); during the years thereafter, the comparative rates were 37.7% and 27.7%, a significant difference of $p<0.05$. Inasmuch as an equally significant difference was demonstrated in the smaller samples (table 4) for the fifth through the eighth year after the menopause, it is reasonable to conclude that, in all women more than four years postmenopausal, the performance of estrogens is distinctly superior.

A recommendation that estrogens be used prior to five or more years after the menopause will seem hazardous to many clinicians, for some authors continue to sound warnings against their use for a full decade beyond the climacteric. The persistent apprehension which attends the therapeutic use of estrogens is accounted for by a number of factors: the emphasis on androgens only in the early years of treatment by hormones (1940-1945), uncertain knowledge of the role of endogenous estrogens in the genesis of breast carcinoma in human and animal varieties, and the popularization of the concept of "estrogen-dependency" in recent years. This is, however, an appropriate reminder of an obligation to emphasize again that "therapeutic" amounts of any estrogenic substance in the menstruating woman may be followed by augmentation of breast carcinoma. Several of the investigators associated with this study in its early years had the misfortune of observing acceleration of the growth and spread of the neoplasm concurrently with estrogenic therapy. Of the seven premenopausal patients of this series given estrogen, all exhibited progression, but this is not to say that all, or even any of them, were in a true phase of augmentation as distinct from the behavior of the disease in an unfavorable, rapid pattern of growth of natural origin.

Sites.—In the consideration of effectiveness by location of metastasis in patients with dominant involvement in single systems, there were no statistical differences of really critical degree in either the androgen or the estrogen series (table 5). In terms of practical probability, androgens were of lesser efficacy before a natural menopause than afterwards in metastasis to bone. For all cases, there was a striking similarity in the androgen-associated regressions in the three systems.

For estrogens, the greatest percentage of regression for the natural postmenopausal women occurred in soft tissue deposits. Regression of 40.7% of soft tissue lesions in elderly women seems more notable than the 31% control of visceral and osseous spread.

When a comparison of androgens and estrogens was limited to their effectiveness in the homogeneous group of natural postmenopausal women, regression in practically identical proportions was noted for both visceral and skeletal locations with the use of each type of hormone, or in 31 of each 100 patients. The greater control of metastasis in soft tissue by estrogens is again apparent, or in 41 of each 100 patients, compared to 18 of each 100 with use of androgens ($\chi^2=4.347$, $p<0.05$). The observation of greatest practical importance is an equally effective control of skeletal metastasis by androgens and estrogens. The notion that the andogens are of greater value at all ages for bony involvement is still widely entertained. For postmenopausal patients, many clinicians cling to a routine of using estrogens for soft tissue and visceral spread and androgens when skeletal involvement is demonstrable; the fallacy of this approach is indicated in the inconsequential difference of 0.9%.

Survival.—In responsive patients, average survival time of the estrogen-treated (table 8) is significantly longer than that of the androgen-treated. This demonstrates a more effective antitumoral function for estrogens in their contribution to greater longevity, of very significant degree in estrogen responders ($p<0.005$). Although the disease becomes less lethal with increasing time beyond the menopause, the criterion of the free interval is less favorable than in premenopausal women, as outlined earlier. The older woman therefore realizes longer survival than the younger, on the average, but she also tolerates the presence of clinically detectable cancer for a greater fraction of that increased life span. This is a denial of the usual concept that both types of hormones became more effective by reason of a predominant trend of aging women to develop neoplasms of a less aggressive pattern generally. Such a concept is now inadequate, to the extent of our recognition of earlier metastatic activity and a longer time of active growth (shorter free interval) than in the younger woman, and to a similar extent that estrogens and androgens must both be credited with a greater degree of carcinostatic potency. Further, the estrogens now must be recognized as inherently superior to androgens in a qualitative fashion and by a significant degree.

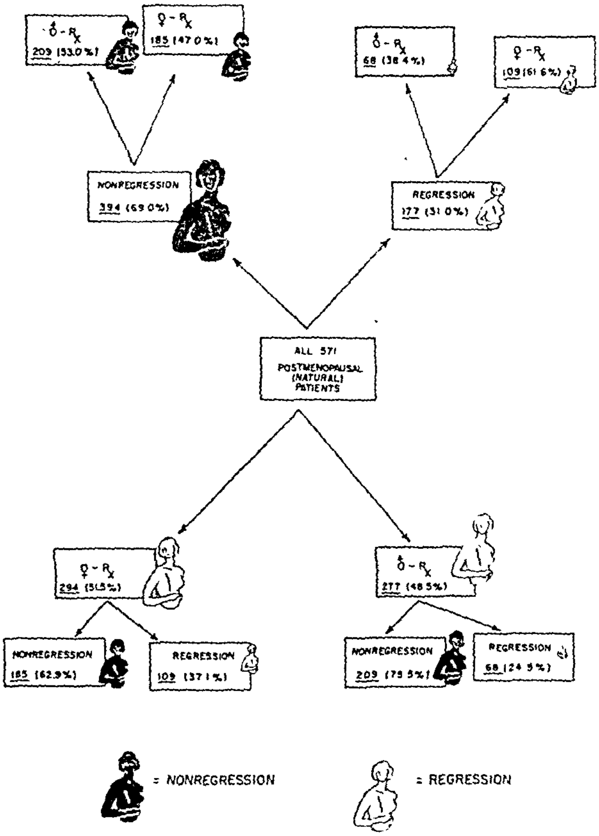

Fig. 5.—Incidence of response to treatment of natural postmenopausal patients.

Summary of Comparative Effect—Androgens and Estrogens.—There can be no reasonable doubt concerning the advantage of estrogens in the initiation of regression in postmenopausal women. For a final look at comparative performance, there are striking features in the data in table 6 and figure 5. Of the 571 natural postmenopausal women there are less than 5 chances in 1,000 that estrogen superiority in either grouping is coincidental.

In brief, at all ages past 30 (if the patients were postmenopausal, either induced or natural), at all phases of postmenopausal life, in each anatomic spread to single systems, and by average duration of life in responsive women, estrogens were equal to androgens, and more often of some advantage, in the frequency with which their use was associated with objective regression. The instances in which calculations indicated roughly equal rates of regression for both groups of hormone-treated patients were as follows: during the period of zero through four years after the menopause, in most of skeletal spread, and in visceral foci in (natural) postmenopausal women. At all other chronological and endocrinologic intervals (except, of course, the premenopausal) and in other situations of unisystemic metastases, the results were at least presumptive of a greater effectiveness for estrogens. Although the differences were of statistical significance less often than of an apparent, percentile order, there were instances in which consolidation to produce a larger sample or a more homogeneous group provided statistical validation at critical levels.

Side-effects.—A final consideration of considerable importance to the physician in his selection of hormonal agents, and of still greater moment to the woman with disseminated carcinoma of the breast, is a comparison of the extreme physiological effects on various target tissues, or side-effects, of the two groups of substances. In the physiologist's orientation, the tumor-suppressive action is the "side-effect," but the most favorable endocrinologic milieu for maximum rates of regression requires doses of a magnitude commonly producing the clinician's "side-effects." In clinical thinking this term does not include such favorable phenomena as the anabolic or hematopoietic effects but indicates rather the distressing manifestations, which, in general, are due to either virilization or feminization, the anorexia, nausea, and vomiting much more common with estrogens, the hazard of hypercalcemia, which is likely to be more frequent with androgens, and many others.

Although a review of side-effects has not been a part of the current study, progress reports of the subcommittee, based largely on the same series of patients reported here, have detailed their incidence and significance.[2] A comprehensive review of the subject was published in 1953 by Kennedy and Nathanson,[3] as an informative document ancillary to the published data from this subcommittee.

With this evidence of prior interest in the problems of side-effects and the study and publication of data pertaining to the series reported here, it is the consensus of the subcommittee that the distressing physical, psychic, and emotional side-effects of the androgens were of greater magnitude than were those of the estrogenic substances, in the doses required for the therapy of cancer. The dilemma may be epitomized by stating that a biological system conditioned for a dominant response to feminization will tolerate more kindly the insults of its untimely resurgence than it will the physiological travesty of a reversal in sexual polarity.

If this philosophy born of clinical experience is valid, a preference for estrogenic therapy is obvious whenever the probability of regression is equal, or superior, to that which may be secured by the use of androgens. Specifically, the results of this study indicate that all patients beyond the fourth postmenopausal year (or, perhaps, even earlier after the climacteric) should have initial hormone treatment by estrogens.

Summary

Reports on a series of 944 women with disseminated mammary carcinoma treated by androgenic hormones (580 women) and estrogenic hormones (364 women), from 1947 through 1956, by 60 participating investigators, have been subjected to reanalysis and an evaluation of the results. The follow-up, until time of death or the date of the analysis, was successful in 89.4% (844 women). Androgens produced objective regression in 20% of premenopausal patients and in 21% of postmenopausal women. Estrogens, limited properly to postmenopausal patients, induced regression in 36% of patients. Both types of hormones were more effective after the eighth postmenopausal year, at which time both reached a plateau of performance, but with the estrogens inducing a higher relative frequency of regressions (38%) than did the androgens (27%).

In cases with unisystemic dissemination, estrogens produced a greater degree of control in soft tissues at all post*menopausal* ages and were equal, or superior, to androgens for skeletal and visceral metastasis.

Responsive patients had significantly longer survival rates with androgenic or estrogenic therapy, whereas the unresponsive women with either mode of therapy had almost identical average periods of survival comparable to untreated patients. Steroid sex hormones are sufficiently effective in naturally postmenopausal women to deserve a primary trial in the treatment of disseminated *mammary carcinoma*. After the fourth postmenopausal year, estrogenic substances are the agents of choice.

The hormonal substances used in this study were supplied by Abbott Laboratories, North Chicago, Ill.; Ayerst Laboratories, Inc., Division of American Home Products Corporation, New York; Ciba Pharmaceutical Products Inc., Summit, N. J.; Charles E. Frosst & Co., Montreal; Lakeside Laboratories, Inc., Milwaukee; The Wm. S. Merrell Company, Cincinnati; Organon, Inc., Orange, N. J.; Pfizer Laboratories, Division of Chas. Pfizer & Co., Inc., Brooklyn, N. Y.; Rare Chemicals, Inc., Harrison, N. J.; Schering Corporation, Bloomfield, N. J.; E. R. Squibb & Sons, Division of Olin Mathieson Chemical Corporation, New York; The Upjohn Company, Kalamazoo, Mich.; Maltbie Laboratories Division, Wallace & Tiernan Inc., Belleville, N. J.; White Laboratories, Inc., Kenilworth, N. J.; Winthrop Laboratories, New York.

The work of Dr. Edwards was supported, in part, by a grant from the U. S. Public Health Service to Columbia University.

HOW THE KIDNEYS GOVERN THE DISTRIBUTION OF WATER.—In the intact animal with metabolism proceeding steadily, extracellular osmolarity controls the water balance of the cells. Hence thirst and water diuresis, which rather precisely guard against excessive or deficient levels of extracellular osmolarity, may be regarded as mechanisms controlling the volume of intracellular fluid. Since they do this by stabilizing an extracellular osmolarity which is mostly due to sodium salts, they also set the stage for the regulation of extracellular fluid volume by adjustments of the renal excretion of sodium. For so long as its osmolarity is held constant, the volume of extracellular fluid must be proportional to the amount of sodium which it contains, and this depends upon how much of the daily intake the kidneys retain. Hence the kidneys, directed in ways which largely remain to be elucidated . . . are able to regulate the volume of water inside the cells by controlling the excretion of water, and the volume outside the cells by controlling the excretion of sodium. . . . Thus the organization of intracellular as well as of extracellular fluids, together with the exchanges both between compartments within the body and between the body and the external environment, may be described to a remarkable extent, in Gamble's . . . happy phrase, as a "Companionship of water and electrolytes."—J. PRELIMINARY COMMUNICATIONS

MANAGEMENT OF DELIRIUM TREMENS

PRELIMINARY OBSERVATIONS WITH TRIFLUOPERAZINE

Naseeb B. Baroody Jr., M.D., Waddy G. Baroody Jr., M.D., Adrian Reed, M.D.
and
Walter R. Mead, M.D., Florence, S. C.

One of the commonest problems confronting the practicing physician today is alcoholism. Treatment of the patient with alcoholism encompasses not only the acute phase but also the chronic cases, which may include patients with the difficult problems of hallucinosis and delirium tremens. Alcoholic withdrawal, when complicated by acute hallucinations, disorientation, excitement, and hyperkinesia, is a difficult condition to manage in the average general hospital, unless the hospital is equipped with specific facilities for handling confused, disoriented, and perhaps belligerent patients. For this reason, or excuse, many general hospitals refuse admission to alcoholic patients; often physicians too may be guilty of shunning the alcoholic patient and refusing to accept him psychologically or realistically as a sick person in need of hospital care. For the alcoholic, withdrawal is a serious metabolic disorder involving basic abnormalities in glucose and vitamin metabolism, nutritional disturbances, and less understood enzymatic and biochemical alterations.

Perhaps if we were better equipped therapeutically to detoxify alcohol rapidly, prevention or control of the withdrawal syndrome (hallucinations and delirium tremens) might be possible, and we might be less reluctant to accept and to treat this disease. It is toward this end, therefore, that we have directed our efforts in this study.

The "habit patterns" of alcoholics are important in withdrawal. Alcoholics who hallucinate or develop delirium tremens are usually chronic or recurrent drinkers of at least five years' duration. After years of nonhallucinatory withdrawals they suddenly develop a new postalcoholic or withdrawal pattern. Hallucinations or delirium tremens dominate and complicate this postalcoholic period, and, once manifest, their recurrence can be accurately predicted and anticipated after future alcoholic debaucheries. Unfortunately, the habit pattern will usually persist regardless of the duration of intervening sobriety. Awareness of this pattern is of great value in knowing what to expect during the withdrawal period, and, when armed with this information, one is equipped to direct the therapeutic regimen more effectively.

Syndrome of Delirium Tremens

Delirium tremens is a fairly common syndrome, a result of prolonged drinking and of alcoholic withdrawal which usually comes on after the patient is detoxified. It may be preceded by a period of lucidity and apparent although agitated normalcy lasting from 48 to 72 hours. It may be precipitated by a variety of factors which include high fever, infections, injuries, exposure, anesthesia, and vigorous exercise. Delirium tremens is characterized by disorientation, confusion, hallucination, coarse tremor, hyperkinesia, and intense excitement. Actually, it is a hallucinatory delirium with marked general tremor and toxic symptoms. The hallucinations are vivid and frequently predominate at night or when the eyes are closed. They often assume the form of bizarre, usually large and fast-moving, animals, or animal-human combinations, similar to those seen in today's currently popular horror movies. Auditory delusions or hallucinations are less common and are usually in the form of human voices, with threatening conversations. In addition to these symptoms patients exhibit a coarse, arrhythmic tremor of the tongue, face, fingers, legs, and occasionally trunk, and generalized epileptiform seizures may occur. These patients occasionally exhibit marked disturbances of equilibrium and bodily orientation. Disturbances of the autonomic nervous system are common.

The differentiation of delirium tremens from alcoholic hallucinosis is frequently difficult (fig. 1). Block [1] defined alcoholic hallucinosis as a syndrome of alcoholic withdrawal characterized by visual or auditory, or both, hallucinations. With the addition of mental confusion and disorientation, according to Block, the diagnosis becomes delirium tremens. In our experience, there is considerable overlapping of symptoms, many of which are fleeting and transitory. For example, confusion and disorientation in hallucinosis may become most prominent at night,

---

From the Department of Medicine, the McLeod Infirmary.

with considerable clearing and reorientation during the day. We have found the most reliable differentiation between hallucinosis and delirium tremens to be the presence or absence of hyperkinesia and excitability. With delirium tremens, patients are not only confused and hallucinating but they also exhibit extreme motor irritability, agitation, and excitement. They are frequently frightened, may become belligerent and difficult to manage, and may require restraints and constant nursing care. Convulsions are not uncommon and may result in tongue chewing or other bodily injury due to falls.

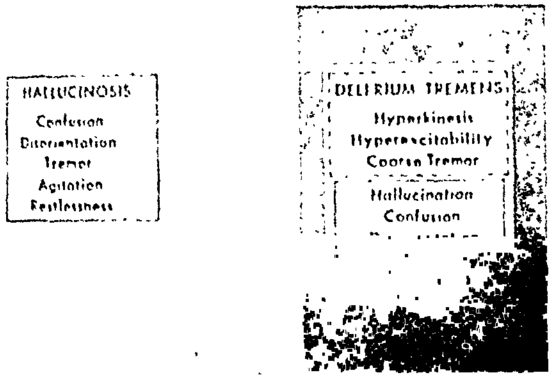

Fig. 1.—Symptoms of alcoholic hallucinosis and of delirium tremens, showing overlapping of symptoms.

The frequency with which delirium tremens occurs is extremely difficult to determine; however, the magnitude of the alcoholic problem leads to the inevitable conclusion that it represents a serious challenge to all who recognize and treat alcoholics. Further evidence of the seriousness of delirium tremens is supported by reported mortality statistics of from 5 to 15%.[2] Only subsequent to the availability of newer therapeutic agents and a better understanding of the altered pharmacodynamics of the disease has the mortality been reduced.

Until recently, the morbidity varied from one week to three weeks, with the acute brain syndrome lasting, on the average, for five to seven days. Newer therapeutic agents have reduced the period of active delirium tremens to an average of three to five days, with total period of hospitalization lasting proportionately less.

Present Study

Material and Method.—Trifluoperazine (Stelazine) is a phenothiazine derivative. Because it has been reported to have antihallucinatory effects in psychotic patients,[3] we conducted a preliminary trial with the drug in 23 alcoholics. In all of these 23 patients the problem of hallucinosis or delirium tremens was either present during hospitalization or indicated by their history. Immediately after their admission to the hospital all patients routinely received parenterally administered chlorpromazine or promazine along with intravenously given fluids, electrolytes (including magnesium), glucose, and vitamins. If there was a history of delirium tremens, trifluoperazine administration was begun on admission. If not, it was withheld until the first sign of actual or impending mental aberration was observed, at which time these patients were given trifluoperazine intramuscularly in doses of 2 mg. every six hours. This dose was reduced to 2 mg. every eight hours when symptoms were better controlled. Later, on cessation of delirium tremens, the dosage of trifluoperazine was changed to 10 mg. given orally three to four times a day. Orally given medicaments were of no value in the acute hallucinatory stage.

Results.—Our past experience indicated that in patients receiving routine therapy with fluids, electrolytes, promazine or chlorpromazine, and vitamins, delirium tremens usually lasted from three to five days. Although symptoms were markedly decreased, the natural course of this illness seemed altered little by these medications. In contrast to this, however, this study (fig. 2) revealed that of the 10 patients who hallucinated, none was disturbed for more than three days and 7 were reoriented in less than three days. In this group the average duration of delirium tremens was only one and four-fifths days. Thirteen had no hallucinations at all, although they gave a history of them with previous alcoholic bouts.

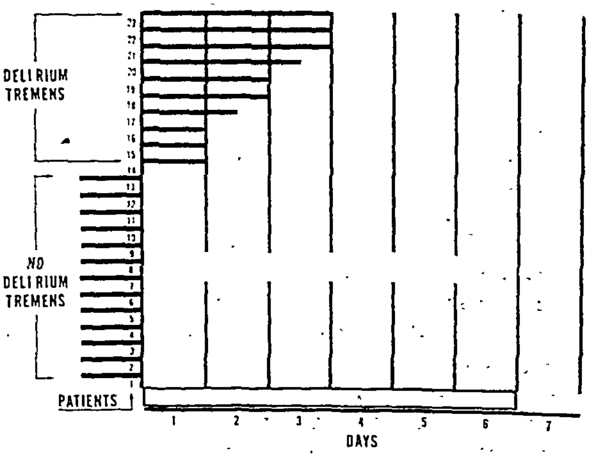

Fig. 2.—Duration of delirium tremens: summary of results obtained in 23 alcoholic patients receiving trifluoperazine. All patients had either history of delirium tremens or symptoms on admission. Axis of abscissas represents average duration of delirium tremens as reported in literature.

Report of a Case.—A dramatic instance of the effects of trifluoperazine is presented by the case report (fig. 3) of a 63-year-old man, an alcoholic of many years' standing. Previous admissions had been characterized by marked disorientation, confusion, hallucinosis, and hyperkinesia. On the first admission of this study the patient had been drinking heavily for about one week and was extremely restless and agitated. He was treated on admission with glucose, vitamins, fluids, electrolytes, promazine, and chlorpromazine. Hallucinations began 48 hours after admission and were quickly followed by marked disorientation, hyperkinesia, excitability, and tremor. Restraints were required. Once he began to hallucinate, azacyclonol hydrochloride (Frenquel) was given intravenously. Delirium tremens continued, however, and restraints were necessary for about six days before spontaneous improvement occurred.

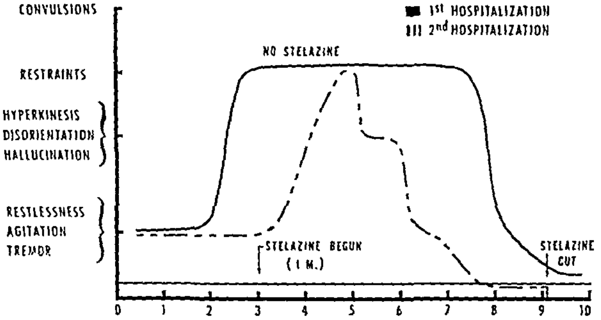

Fig. 3.—Case summary of 63-year-old alcoholic man with recurrent history of delirium tremens after each withdrawal. Axis of abscissas represents days of hospitalization.

On the patient's second admission a similar history of prolonged alcoholism was obtained. He was admitted in a state of restlessness, agitation, and tremor. He remained oriented until the third hospital day when be began to hallucinate and became disoriented and markedly hyperkinetic. At this point, trifluoperazine was given, 2 mg. intramuscularly every four hours. He became difficult to manage and restraints were required, for one night only. Despite continued hallucinations, he was much more manageable and would sit quietly in bed or in his room. Hyperkinesia was minimal. Within 72 hours he was once again oriented and exhibited only some restlessness and slight tremor.

Comment

The basic cause of delirium tremens is not known. Many factors (fig. 4) related to alcoholic intake and metabolism have been identified and investigated. Perhaps the most popular and best studied aspect is vitamin deficiency combined with altered carbohydrate metabolism.

In patients with alcoholism there is impairment of intake and absorption of carbohydrates and vitamins. Thus, the carbohydrate respiration of brain tissue, in which vitamins are essential, is put under stress. The oxidation of alcohol requires thiamine. This vitamin is in priority demand and may result in quick depletion of the body's available thiamine chloride so necessary for glucose metabolism by the Krebs cycle.[4]

Mineral deficiencies, particularly of magnesium, occur in patients with chronic alcoholism. Recent studies[4,5] have shown that magnesium deficiency may cause gross muscle tremor, choreiform movements, and occasionally delirium and convulsion. Magnesium is necessary for the action of a number of enzymes, particularly adenosine triphosphate (ATP).

"Hyper-hydremia," with resultant cerebral edema, is a recognized pathological finding in patients in an acute alcoholic state. This results in a high concentration of alcohol in the cerebral cortex, with subsequent interference of enzyme systems, particularly hydrogenase, similar to the action of narcotics and anesthetics.[6] All of these pathogenic factors become greatly exaggerated and magnified in the presence of altered liver function, whether it is due to simple fatty infiltration or to the more serious advanced alcoholic cirrhosis.

Current experimentation indicates that the basic defect in patients with delirium tremens occurs at a cellular level. Grenell has shown that in the alcoholic brain there is alteration in the structure, biosynthetic mechanism, and membranes of brain cells. This results in changes in cell membranes followed by cellular volume changes, inhibition of electron transfer, alterations of structure, greatly decreased esterification of inorganic phosphates, and inadequate synthesis and utilization of the external adenylic system to maintain normal structure.[6]

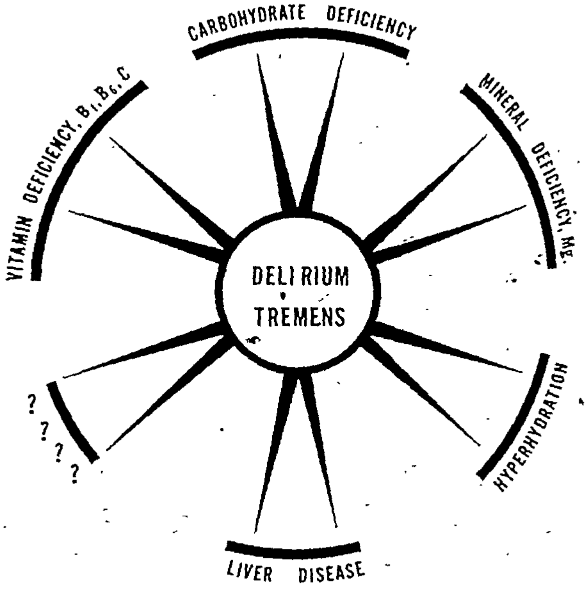

Fig. 4.—Factors related to pathogenesis of delirium tremens.

Treatment.—The essential management of patients with delirium tremens is directed toward correction of the above described pathophysiological factors (fig. 5). The administration of an electrolyte solution containing glucose maintains nourishment and proper fluid balance. Flink [5] has reported magnesium therapy to be of significant value in the treatment of delirium tremens. An electrolyte solution containing magnesium may be used. Vitamins are administered in large doses, with particular emphasis on replacement of the B complex group, especially thiamine. Insulin, once given as a part of accepted therapy, for the quicker detoxification of alcohol, is now considered of little physiological use. Insulin is not required by brain cells and, indeed, the beneficial hyperglycemia may be annulled by it.[4] Steroids have been reported of benefit in the management of acute delirium tremens.[7] Their use is directed at supporting the extreme physiological stress encountered. Diuretics have been administered, in an effort to diminish the hyper-hydremic state and, particularly, cerebral edema.

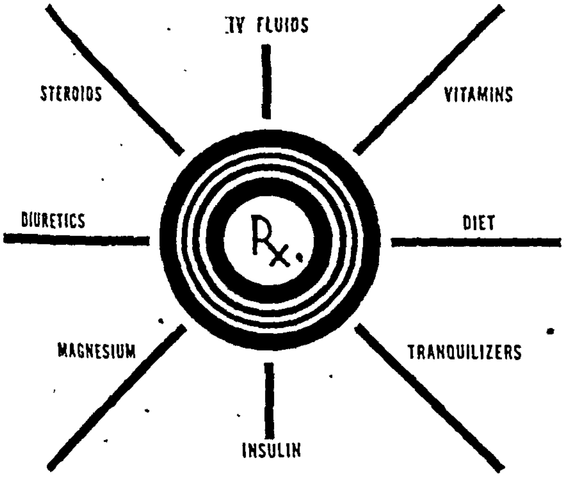

Fig. 5.—Basic principles in therapeutic management of patients with delirium tremens.

Tranquilizers have revolutionized the treatment of alcoholism.[8] Most benefits have been derived from the use of phenothiazine derivatives. Although these are useless in the initial phase of alcoholic depression, they are extremely valuable assets in the management of the agitation and restlessness of withdrawal. They produce relaxation and reduce tension, allowing the patient to resume a state of normalcy more quickly. Despite their beneficial effects, however, we have not found the incidence of hallucinosis to be significantly diminished by their use. In large and frequent doses, phenothiazine derivatives may be valuable in controlling the extreme hyperactivity of delirium tremens; however, in our experience they do not shorten the duration of this serious complication.

Summary

Delirium tremens is a serious complication of withdrawal of alcohol, in alcoholic patients, which carries a reported mortality of from 5 to 15%. The differentiation of hallucinosis from delirium tremens is not always clear-cut. Although all of the causative factors are not known, they include vitamin deficiency (especially of thiamine), carbohydrate deficiency, magnesium deficiency, liver disease, "hyper-hydration," and alterations in the cell membranes of the brain. Therapeutic principles include the administration of glucose, vitamins, magnesium, diuretics, tranquilizers, and steroids.

We have found trifluoperazine, administered intramuscularly in doses of 2 mg. four times a day, to be an effective therapeutic measure when added to the accepted treatment for delirium tremens. Orally given trifluoperazine was found to be of no value in the acute hallucinatory stage. No toxic reactions or side-effects due to trifluoperazine were observed in the patients studied. Further investigation is required to better establish the optimal dosage of trifluoperazine in patients with delirium tremens.

376 W. Palmetto (Dr. N. B. Baroody).

The trifluoperazine used in this study was supplied as Stelazine by Smith Kline & French Laboratories, Philadelphia.

SEX STEROIDS FOR PALLIATION OF DISSEMINATED MAMMARY CARCINOMA

GUEST EDITORIAL

Ian Macdonald, M.D.

ELSEWHERE in these pages is the final report of a pioneer effort in the pooling of clinical data from a cross-section of investigators in the United States and Canada, the intent of which was to replace confusion with some degree of clarity in a "new" area of cancer therapeusis. Although the use of estrogenic and androgenic hormones for palliation of mammary carcinoma is no longer new, as it was when the Committee on Research initiated this study in 1946, some of the prejudices and mistaken practices current then seem to be almost as prevalent now. The primary benefit of a cooperative study should be an accumulation of comparable data, on samples of significant size, long before the individual investigator or institution can acquire the experience necessary for valid reporting. The Subcommittee on Breast and Genital Cancer, which is responsible for this study, has published various reports; however, the final evaluation has been long delayed because of early failures in planning common to initial ventures of this sort.

More than two years ago it was finally realized that a reanalysis and recoding of reports on over 1,900 patients was required, that the interpretation of the reports required the contribution of a clinician conversant with the natural history of carcinoma of the breast, that additional follow-up of many patients was essential for maximum salvage, and, finally, that a sophisticated treatment of the data demanded discriminating biostatistical consultation rather than an undirected use of statistics. All of these requirements have been fulfilled. The criteria necessary for evaluation of effectiveness of hormonal therapy were met by 944 cases, and the immaculateness of the data is such as to command the confidence of the subcommittee in the accuracy of its conclusions.

The primary purpose of this final report is to provide for the clinician a reliable orientation for his use of androgens and estrogens in the treatment of disseminated mammary carcinoma. The relative effectiveness of these two classes of sex steroids has been determined in physiologically homogeneous groups of such size as to permit statistically valid conclusions for the first time.

A concept of both basic and practical significance seems inescapable; i. e., the effectiveness of hormonal therapy is determined by some unknown biological attribute of the relationship between host and neoplasm in each patient. The nonresponsive patient, regardless of age, type of treatment or degree or sites of dissemination, had an average survival period in the narrow range of 9 to 11 months after initiation of hormonal treatment and a median survival (or 50% point) of only 7 months. Responsive patients, after beginning treatment with androgens, had an average survival of 1 months and a survival of 26 months after therapy with estrogens. In short, the demonstration of objective regression was an almost invariable signal of a less ominous course and one of greater longevity than that of the nonresponder.

Two other factors were shown to influence materially the frequency of regression, i. e., age and choice of hormone. In general, the probability of objective regression increased in rough proportion to the passage of years, both chronological and endocrinologic (postmenopausal), with two exceptions. In the fifth decade, and after the age of 80 years, the effectiveness of the androgens decreased from the level of the previous decade. In terms of endocrinologic age, the estrogens reached a plateau of effectiveness after the fourth postmenopausal year and the androgens at the eighth year after the climacteric. These disparities by age were variable in degree; the most impressive spread was noted for estrogens before and after the fourth postmenopausal year, or in the order of 15 and 38% respectively. It is notable that estrogens continued to produce objective regressions in 4 of every 10 patients throughout the remaining postmenopausal years.

Most persistent of the myths surrounding hormonal therapy is the supposed superiority of androgens for skeletal metastasis. The best that one can say for this whimsy is that only in bony deposits did the androgens approach the effectiveness of estrogens in producing healing and recalcification. In soft tissue metastasis, the use of estrogenic substances for patients more than four years beyond the climacteric was associated with rates of regression in excess of 40%, whereas androgens in a com-

---

Chairman, Subcommittee on Breast and Genital Cancer, Committee on Research, Los Angeles.

able group were effective in only 18% of pa- ts. In fact, at any postmenopausal time, in any metastatic complex, estrogens invariably were equal to or, more often, exceeded androgens in effectiveness. Even in patients zero to four years postmenopausal, estrogens were not significantly inferior to androgens, with regression rates of 15 and 18%, respectively, in cases refractory to any other plan of therapy. The preferential use of estrogenic agents should increase rates of regression, over those induced by androgens, as much as twofold in postmenopausal women.

Therapeutic neglect of estrogens may, in part, be traced to the concept of "estrogen dependence" made popular by some authors. Their lack of logic is obvious in the fact that therapy with androgens is least successful in premenopausal women, when the principle of a hormonal "antagonist" should produce maximum effectiveness. The best performance of androgens in tumor suppression, on the contrary, occurs at the opposite end of the physiological scale, or at a time the patient is more than 7 years postmenopausal, when its use is accompanied by objective regression in almost 30% of patients.

Such considerations lend some support to the current preference for oophorectomy as a primary measure for palliation in genuinely disseminated disease prior to the menopause and also in the first three postmenopausal years. Although not a part of this study, this ablative approach earns approval by default over androgens, with their high rate of failures, the indignities of the induced state of virilism, and even by the occasional hazard of interconvertibility to estrogen.

Another contribution of this study to our knowledge of the natural history of mammary carcinoma concerns a relatively small fraction of the total sample, which may have a disproportionate impact on statistics of survival through an odd facet of biological behavior. This group is made up of women who had definitive treatment of their primary disease prior to the menopause and in whom a natural menopause intervened before metastatic disease became evident. For convenience, this group is referred to in these paragraphs as B7 patients. This sequence of events was attended by an inordinately long free interval, i. e., the lapse of time from primary treatment to recognition of metastatic disease. Excluding B7 cases, the average free interval for all other cases was 40.9 months, whereas for all B7 patients it was 139.7 months. Expressed in years, these values become, respectively, 3.40 years compared to 11.58 years.

There is also a tendency toward a negative correlation between the length of the free interval and the frequency of tumor regression. For example, the longest free period by far was recorded for naturally menopausal, estrogen-treated B7 patients, who enjoyed a phenomenal average of 16.6 postoperative years of freedom from disease but who were the nonresponders of this group; the responsive counterpart of such patients had an average free interval of only 6.6 years. Whatever the biological factors may be which contrive to produce so remarkable a free interval, they are without importance after metastasis is evident; the interval from initiation of hormonal therapy to death is comparable to the interval in all other postmenopausal cases.

The identification of the B7 group is of more than academic interest. In fact, it was an apparent inconsistency in certain data that led our biometric consultant to the discovery of the B7 group. The presence of relatively few B7 cases has a distortional effect on survival figures, requiring their identification and separation from even large series of cases, in the interest of more accurate data.

So complex is the biological constellation of mammary carcinoma that still other "mavericks" of peculiar natural history may yet remain for discovery by future investigators. Indeed, it is possible that the data developed in this study retain other biological oddities, requiring for their discovery only fresh minds and new approaches.

LUCANUS–APOSTLE AND PHYSICIAN

The narrative by Taylor Caldwell,[1] published last summer, "Dear and Glorious Physician," is the second historical novel about St. Luke that has appeared in recent years. Early in the preceding decade, after an intensive historical study of ancient medicine and ancient history, Frank Slaughter,[2] a physician turned novelist, presented a delightful portrayal of medical practice by St. Luke at the time of Christ. After I had read Slaughter's tale of St. Luke, I queried the author as to the source of information that might have been helpful in interpreting the reference to the treatment of gout 2,000 years ago. His reply was forthright, with the frank admission that a considerable quantity of speculation entered into the construction of this and other portions of his novel. ". . . and when Luke told him of the need of Ambassador Gallio for the powdered crocus leaves (Colchicum) which had so effectively relieved the gout for Sergius Paulus, he immediately procured a supply and took it to Gallio himself. Relief was immediate. . . ."

The recent recounting by Caldwell presents a different version of St. Luke's story that is equally interesting and not because of any particular reference to a disease entity. The volume is dedicated to her physician, Dr. Samuel A. Vogel, and his late wife, Frances Vogel, of Buffalo. There is also a credit in the preface to Dr. George E. Slotkin of Eggertsville, N. Y., for his help in interpreting ancient and modern medicine to the author.

[1] Caldwell, T.: Dear and Glorious Physician, Doubleday & Company, Inc., New York, 1959.

[2] Slaughter, F. G.: Road to Bythinia, Doubleday & Company, New York, 1951.

The title of Caldwell's book is taken from the gospel according to St. Paul: "Our most dear Physician." The only gentile among the apostles, Lucanus did not communicate directly with Christ but prepared his account for the New Testament from hearsay, from conversation with patients and friends in Asia Minor who knew Christ, and from his contacts with several of the other apostles, especially Paul. St. Luke was the most literary among the writers of the New Testament and is credited with the third gospel and the Book of Acts composed in the years 78-93 A.D. The father of St. Luke was born a Greek slave who became free some time after his son's birth. The early years of Luke's life were spent near Antioch. After his medical training, which was pursued in Alexandria, he conducted a practice that extended from Rome to Athens and into the biblical land. The custom of holding consultations, prescribing treatment, and practicing surgery over a wide geographical area was characteristic of physicians as successful and as popular as Lucanus and Hippocrates. Each one was a Greek by birth but a physician of the world by demand and desire, who made indelible imprints on ancient civilization. Luke's friendship with Paul is believed to have begun in Antioch and continued throughout the Eastern Mediterranean lands, at times as his medical attendant, at other times as a missionary with a common purpose. "Dear and Glorious Physician" is recommended reading. Since it was published several months ago, it should not be difficult to obtain a copy from your lending library. There is yet another reference to St. Luke that should be mentioned for physicians who may be in Toledo, Spain, and have an opportunity to visit the Toledo cathedral. An El Greco of St. Luke, which hangs in the Cathedral, shows him to be a slight, wistful man with a facial expression of deep dedication.

J. H. T.

INFLUENZA VACCINES

Epidemics of influenza and other viral diseases such as Eastern equine encephalomyelitis now receive great attention in mass news mediums and fire the imagination of the lay press and its readers. As more and more of the common infectious diseases come under control we learn of the fear of an unknown virus "X" which, in some minds, threatens to decimate the population in the fashion of plague. News stories and dramas describing man subjected to the whims and vagaries of nature will always sell. Since epidemics of influenza can be controlled by immunization with currently available and properly constituted influenza vaccine, it is important to prevent public hysteria by providi information about the causation and prophylaxis influenza.

In our time the medical profession has come f circle in attitudes toward influenza. The spec of the 1918 pandemic still hovers for older gene tions of practitioners who remember its terr The younger group of physicians for 40 years h experienced only the annual epidemics of a d ease often so mild that influenza was confused w severe colds or even a gastrointestinal upset. Ma authorities did not regard the illness as a gene public health hazard or even a reportable comm nicable disease. The reawakening has come duri the past three years as we learned once again t this formidable virus can rapidly spread from far corners of the earth, cause large numbers cases, occasionally produce severe pneumo markedly affect death rates, and result in the ruption of community activities. Many clinical a epidemiologic lessons were relearned during 1957-58 pandemic.

During the intervening period between the gr pandemics it had been clearly demonstrated t influenza could be prevented by immunization w specific formalin inactivated virus vaccine. It also found that classic influenza was caused by t distinctly different antigenic types, A and B, a that variants of each type successively replace p viously prevalent strains. These changes were f recognized as immunologically important w vaccines did not protect against the 1947-1948 e demics. The composition of vaccines was theref varied periodically to encompass these antige changes in viruses. Results of laboratory analy of virus isolates from the Far East early in 1 made it quite clear that another marked s among type A viruses had occurred and that a p demic of influenza probably would develop out the rapidly moving epidemics in Asia. Vacci containing the new variant were prepared a tested as soon as possible because it was kno that the older vaccines would not be effecti against the new antigenic form.

In spite of heroic effort, the goal of 60 milli doses of vaccine was not met until after the gr wave of the 1957 epidemic had passed. Nevert less, this unusual opportunity for field trials w the new vaccine was seized by many investigato The results from these several trials indicated th depending on dosage injected, the degree of p tection conferred varied from a 42 to 75% redu tion in the incidence of influenza. When small amounts of vaccine were injected intradermally subcutaneously, less protection was obtained th when a full dose (1 cc.) was administered. Of gre importance was the finding that the development serum antibody closely paralleled the degree of r sistance afforded by vaccination. A report in th issue, page 1223, by Dull and his associates de cribes such protection during the epidemic in the fall of 1957 and also notes the marked decrease in antibody levels six months after vaccination. However, when the epidemic wave of the winter of 1958 swept through the test population, vaccinated persons experienced much less influenza than did nonvaccinated subjects. Perhaps the earlier vaccination provided a degree of immunity which was rapidly boosted or enhanced during the second epidemic and thus provided resistance to overt disease.

Since vaccination is at present the only effective means known to cope with influenza epidemics, ontinuing efforts must be directed at increasing he potency of vaccine. One approach to preparedness for the advent of the next strain is to ompound a vaccine containing the widest possible ange of known influenza variants. This has been done, and the results of tests by Jensen and his olleagues with vaccines containing four or six different strains are reported on page 1230 in this ssue of THE JOURNAL. The role of dosage schedules and the incidence of prevaccination antibody n different age groups two years after the first sian epidemics have also been examined.

A tremendous body of knowledge has accumulated about Asian influenza, as shown by a recent ist containing 421 papers, reviews, and communications since 1957. What is needed now is a synthesis of wisdom from these experiences which will ead to a rational program for prevention of influenza. The United States Public Health Service and he World Health Organization are aware of their esponsibilities in this area. Several different research programs have been sponsored by the Public Health Service, and recently an opportunity for the evelopment of new viewpoints and discussion of roblems was provided at the International Conference on Asian Influenza held in Washington at the National Institutes of Health, February 17-19, 1960. The consensus is that influenza will continue to cause epidemics and that new variants will arise periodically through a mechanism which is as yet not understood. An elaborate system of laboratories and epidemic surveillance has been arranged to provide intelligence as soon as possible for each epidemic. The Asian variant can be expected to prevail for several more years before being replaced by a different type A virus.

The United States Public Health Service has recommended influenza vaccine for the following groups: (1) persons for whom the onset of influenza might represent an added health risk, such as those with cardiovascular or pulmonary conditions, those over 55 years of age with chronic illness of any type, and pregnant women; (2) persons responsible for the care of the sick; (3) persons responsible for providing such essential public services as law enforcement, fire protection, transportation, and communication; and (4) industries and other commercial enterprises that wish to keep the employee absenteeism rate from rising. Many authorities point out that the homemaker must be protected also in order to preserve the well-being of the family unit.

Because the attack rate is highest in children and young adults, use of vaccine in these age groups will be most efficacious. Since severity and extent of an epidemic cannot be predicted accurately, annual vaccination is recommended for all age groups.

GROWING NEED FOR TEEN-AGE CLINICS

Since the first teen-age clinic was established in Boston in 1952 there has been an increasing awareness of the special health and psychological problems of teen-agers. Dr. Arthur Roth,[1] a pioneer in this poorly understood field, has written a medical guide for young people and their parents that should help clarify many of the problems of teen-agers which although common are perplexing to those who experience them. The most baffling paradox to the growing child is normal variation. Marked differences in height, weight, age of onset of puberty, and development of secondary sex characteristics can appear as frightening abnormalities to young persons and are not always understood by their parents. These and other considerations are dealt with in the teen-age clinics and are described in the guide. The manner in which these problems are handled can be an important factor in determining the attitude taken toward the medical profession in subsequent years by today's teen-agers.

The busy practitioner who sees patients of all ages would do well to take stock of his usual approach to teen-agers. They are no longer children and not yet adults. The mere fact of being a teen-ager is not, as some persons seem to believe, an illness, and the term teen-ager is not synonymous with juvenile delinquent or "crazy mixed-up kid." No one, least of all Dr. Roth, believes that all teen-agers could or should be treated in a special clinic, although this may be desirable in some cases. On the contrary he believes that these patients must be treated with a heartfelt sympathy and kindly understanding that they sometimes are unable to find either at home or in the general medical clinic. There is probably no more rewarding experience in medicine than that of helping these youngsters to a better understanding of themselves. Dr. Roth concludes his guide on a note of optimism. Underneath the faltering and stumbling of the teen-ager he recognizes a hard core of human value that augurs well for the future of the nation and of the world.

ORGANIZATION SECTION

DR. NORWOOD TO DIRECT SPECIAL STUDY COMMITTEE

The American Medical Association has established a scholarship program for medical students. A special study committee was appointed to direct the program. William F. Norwood, Ph.D., chairman of the division of legal and cultural medicine, College of Medical Evangelists, Los Angeles, was named staff director of the committee. From 1950 to 1951 he served as a staff associate in a survey of medical education sponsored by the A. M. A. and the Association of American Medical Colleges.

Last December the House of Delegates of the A. M. A. adopted a resolution that a scholarship fund be established to aid deserving students to enter the field of medicine and that the fund be backed by the A. M. A. as a primary sponsor. Dr. L. S. McKittrick, Brookline, Mass., who is chairman of the Council on Medical Education and Hospitals, will serve as chairman of the committee.

DR. SCHOENFELD JOINS COUNCIL STAFF

The Council on Medical Education and Hospitals has added a new member to its field representatives who review intern and residency programs. He is Dr. Herbert H. Schoenfeld of Washington, D. C. Dr. Schoenfeld has served the Council as a regional evaluator for graduate programs in surgery. A graduate of George Washington University School of Medicine, he is retiring as assistant clinical professor of surgery at his alma mater. Formerly he was on the consulting staff of the Washington Medical Center and the senior advisory staff of the Children's Hospital in Washington.

GOVERNMENT SERVICES

NAVY

Recognition and Treatment of Diving Casualties.—A two-week active duty training course in recognition and treatment of diving casualties will convene at the U. S. Naval School of Deep-Sea Divers, U. S. Naval Weapons Plant, Washington, D. C., on July 18. This course offers didactic training in underwater physiology and in the recognition and treatment of casualties associated with any kind of diving. Although this course is given for active duty personnel en route to stations where there is some diving activity, vacancies in the course may be filled by reservists on active duty for training. Inactive Naval Reserve medical officers are eligible to attend. All continental naval districts have been allocated quotas.

Change of Duties.—Capt. Henry C. Hunley Jr., M. C., was made deputy director of the aviation medicine operations division of the bureau of medicine and surgery in February. He was formerly on duty at the Marine Corps Air Station, Quantico, Va.—Capt. Robert E. Walsh, M. C., reported to the bureau of medicine and surgery in February for duty as head of the procurement branch of the physical qualifications and medical records division. He was formerly assigned to the staff of the Naval Hospital, Camp Pendleton, Calif—Capt. Sidney D. Bond Jr., M. C., recently reported to the bureau of medicine and surgery for duty as head of the Medical Corps training section. His former duty assignment was on the staff of the U. S. Naval Hospital, Camp Lejeune, N. C.

PUBLIC HEALTH SERVICE

Russian Visitors.—In February, four Soviet biochemists began a month's survey of United States research developments in metabolic diseases. They spent three days at the National Institutes of Health before visiting research centers throughout the country. Dr. G. Gilbert Ashwell, of the National Institute of Arthritis and Metabolic Diseases, served as the group's director on the entire trip. Members of the Russian group are Drs. Grachiya K. Bunyatyan, of the Armenian Academy of Sciences; Mikhail P. Chernikov, of the Institute of Biology and Medical Chemistry, U. S. S. R. Academy of Sciences, Moscow; Nikolai N. Demin, of the U. S. S. R. Academy of Sciences, Moscow; and Ilya I. Ivanov, of the Leningrad Pediatrics Medical Institute. The Soviet scientists came here under provisions of a 1958 agreement between the United States and the Union of Soviet Socialist Republics to exchange missions in various fields. A return mission of U. S. scientists, headed by Dr. Floyd S. Daft, director of the National Institute of Arthritis and Metabolic Diseases, will go to the U. S. S. R. in September.

MEDICAL NEWS

ALASKA

Human Brucellosis Cases.—The Alaska Division of Health announced that two cases of human brucellosis were reported to the division during the past year. In both cases raw caribou meat or bone marrow were believed the source of infection. One case was a 13-year-old Eskimo girl from Wainwright and the other an 18-year-old girl from Barrow. Investigations of the cases were carried out by the U. S. Public Health Service personnel. Since 1939 only 51 cases of human brucellosis have been reported in Alaska, 25 of which occurred in 1942 in a community in the interior and were attributed to consumption of improperly pasteurized milk.

ARIZONA

Hospital Lecture.—"Day and Night Hospital—An Advance in the Management of Psychiatric Patients" was the topic of a talk given at Camelback Hospital, Phoenix, Feb. 23 by Dr. John Gussen, Los Angeles. Dr. Gussen spoke to the members of the Maricopa County Medical Society who were invited to attend the regular Tuesday morning staff breakfast by Dr. Otto L. Bendheim, medical director of the hospital. Dr. Gussen served as chief of the Day-Night Hospital, Langley Porter Neuropsychiatric Institute, San Francisco, and was assistant professor of psychiatry at the University of California School of Medicine, San Francisco, before his appointment as director of psychiatry at Cedars of Lebanon Hospital in Los Angeles.

COLORADO

Institute on Alcoholism in Boulder.—The University of Colorado campus will be the setting for the first Colorado Institute on Alcoholism, sponsored by the Colorado Commission on Alcoholism, the CU Extension Division, and the CU School of Nursing, June 26-29. Programs of general interest will be arranged for educators, clergymen, probation, parole, and correctional officers, personnel directors, police officers, and community leaders. There will be professional workshops for nurses, social workers, and rehabilitation personnel. Among the specialists who will lecture will be Dr. Marvin A. Block, of Buffalo, N. Y., chairman of the Committee on Alcoholism, American Medical Association, and Mrs. Marty Mann, of New York City, executive director, National Council on Alcoholism.

DISTRICT OF COLUMBIA

Freedmen Alumni Establish Two Awards.—Awards honoring the memory of two pioneer Freedmen's Hospital physicians—Dr. Daniel Hale Williams and Dr. William Alonza Warfield—were established by the Association of Former Internes and Residents of Freedmen's Hospital. First award will be presented at the 38th annual meeting of the association at the Howard University College of Medicine, Jan. 7-9. The Daniel Hale Williams Award will be given annually to an intern or resident of the hospital for "outstanding achievement" during the current year. The William Alonza Warfield Award will be given annually to a former intern or resident of the hospital for "distinguished achievement in the field of medicine and surgery and allied specialties, or for distinguished achievement in the national, civic, or community, or patriotic welfare." Dr. Williams was a charter member of the American College of Surgeons and a founder of Providence Hospital, Chicago (1891). Dr. Warfield served as surgeon-in-chief of Freedmen's Hospital for 35 years (1901-1936). The present hospital structure was erected during his administration, in 1908. A founder and first president of the association, organized in Newark, N. J., in 1919, Dr. Warfield later served as honorary president and honorary president emeritus on retirement from the hospital. Dr. Williams died in 1931, Dr. Warfield in 1951.

ILLINOIS

Dr. Fatherree to Head State Health Department.—Dr. Leroy L. Fatherree, director of the Champaign-Urbana District Health Department, was appointed director of the Illinois Department of Public Health by Governor William G. Stratton, effective Feb. 1. Dr. Roger F. Sondag, of Murphysboro, was appointed assistant director. In 1939 Dr. Fatherree organized the Little Rock, Ark., public health department and served there until 1945. In 1947 he reorganized the Omaha public health department to combine it with the department of Douglas County, Neb. Before coming to Champaign-Urbana, Dr. Fatherree headed the Will County Public Health Department. He is president of the Ameri-

---

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education, and public health. Programs should be received at least three weeks before the date of meeting.

can Association of Public Health Physicians and is a member of the governing board of the American Public Health Association.

Chicago

Hospital Plans Expansion.—Rest Haven Rehabilitation Hospital has launched a campaign for funds to build a new wing for patient services. The estimated cost of the new construction is one million dollars. Founded in 1912, Rest Haven Rehabilitation Hospital is a specialized institution which treats patients with such conditions as strokes, amputations, arthritis, paralysis, and cardiac disease. Building funds are being provided by the federal government under the Hill-Burton Act, the Ford Foundation, and the Jewish Federation of Metropolitan Chicago, of which Rest Haven Rehabilitation Hospital is an affiliate.

Society News.—At the annual meeting of the Chicago Dermatological Society Jan. 20 the following officers were elected: president, Dr. I. Myron Felsher; vice-president, Dr. Allan L. Lorincz; and secretary-treasurer, Dr. Frederick J. Szymanski.—— At the annual meeting of the Chicago Diabetes Association Feb. 5, the following officers were reelected for terms expiring in February, 1961: Drs. James B. Hurd, president; M. David Allweiss, first vice-president; R. Lincoln Kesler, second vice-president; Ralph E. Dolkart, secretary; and Mr. Melvin C. Holmes, treasurer.

KENTUCKY

Heart Operation Recorded on Video Tape.—On Jan. 29, an open heart operation was performed at the Louisville Children's Hospital on a 5-year-old boy for the correction of a large interatrial septal defect by a team from the faculty of the University of Louisville Medical School. The entire operation was recorded on video tape by WHAS-TV. On the evening of Feb. 24, WHAS-TV devoted an hour and a half to a broadcast of the operation as taped. The close-up details of the procedure were photographed through a mirror over the operating table. The result was technically excellent. During the showing on television the two operating surgeons *(in the studio)* made appropriate commentaries. The actual broadcast was preceded by a 15-minute program in which the operating room and its equipment, including the heart-lung apparatus and pump, were demonstrated. It was followed by a regularly scheduled half-hour program entitled "What's Your Question?" in which the two doctors answered questions which were telephoned in by viewers. The surgeons were Dr. J. Alex Haller and Dr. William F. Rubel, of Louisville. The broadcast was sponsored jointly by the Medical School and the Kentucky and Jefferson County Heart Associations.

MARYLAND

Annual Meeting in Baltimore.—The Medical an Chirurgical Faculty of the State of Maryland wi hold its annual meeting April 20-22 at the Alcaza Baltimore. Dr. Willis J. Potts, of Chicago, wi present "Congenital Anomalies of the Esophagu as the I. Ridgeway Trimble Lecture, the afternoo of April 20. The program includes the followin papers:

Biological Effects and Hazards of Ionizing Radiation, D Russell H. Morgan, Baltimore, Dr. Donald R. Chadwic Washington, D. C., Richard H. Chamberlain, Philade phia, and Dr. William B. Looney, Baltimore.

Chemosurgery of the Basal Ganglia in Parkinsonism, Dy tonia Musculorum Deformans and Multiple Sclerosis, D Irving S. Cooper, New York City.

Atypical Variants of Viral Hepatitis, Dr. Gerald Klatski New Haven, Conn.

Histaminic Cephalgia; Differential Diagnosis and Treatmen Dr. Bayard T. Horton, Rochester, N. Y.

Stein-Leventhal Syndrome (Polycystic Ovary Syndrome Dr. Robert B. Greenblatt, Augusta, Ga.

Immunization for Young and Old, Dr. Joseph E. Smad Washington, D. C.

The J. M. T. Finney Fund Lecture will be give the morning of April 21 by Lt. General Leona D. Heaton, Surgeon General, U. S. Army. Ps chiatric and hypertension panel discussions a planned, and a clinical pathological conference scheduled. The presidential dinner will be hel April 21. For information, write Dr. William (Ebeling III, 1211 Cathedral St., Baltimore 1.

MASSACHUSETTS

Fellowship in Cancer Chemotherapy.—A cance chemotherapy fellowship has been established i the medical services of the Lemuel Shattuck Hospital in cooperation with the Warren Laboratorie of the Collis P. Huntington Memorial Hospital c Harvard University at Massachusetts General Hospital, Boston. The program will consist of trainin in the use and critical evaluation of new chemotherapeutic agents in man and animals, with opportunities for individual research. Fellows should hav prior training in internal medicine. Informatio may be obtained from the Oncology Division, Medical Services, Lemuel Shattuck Hospital, Boston 30

MICHIGAN

Institute on Chronic Disease Control.—An Institut on Chronic Disease Control will be held June 13-2 at the University of Michigan School of Publi Health, Ann Arbor. Co-sponsors with the school ar the Directors of Chronic Disease Teaching Programs of Schools of Public Health, the Associatio of State and Territorial Chronic Disease Program Directors, the Michigan Department of Health, and the U. S. Public Health Service. The program will include lectures, seminars, and discussions in the following areas: health promotion, prevention, early detection, multiple screening, home care, institutional care, and rehabilitation, in relation to such chronic diseases as heart disease, cancer, diabetes, glaucoma, and cerebral vascular disease. The institute is designed primarily for public health physicians concerned with chronic disease control programs, but selected public health nurse consultants, nutritionists, and health educators concerned with the planning and administration of chronic disease programs at state and local levels will be eligible to attend. Application for participation must be received not later than May 15. Information may be obtained by writing the Director of Continued Education, School of Public Health, University of Michigan, Ann Arbor, Mich.

NEW HAMPSHIRE

Research Conferences.—The Gordon Research Conferences for 1960 will be held from June 13 to Sept. 2 at Colby Junior College, New London, New Hampton School, New Hampton, and Kimball Union Academy, Meriden. The conferences were established to stimulate research in universities, research foundations, and industrial laboratories by an informal type of meeting consisting of scheduled lectures and discussion groups. Time is available for informal discussions. Meetings are held in the morning and evening, Monday through Friday (except Friday evening). Afternoons are available for recreation, reading, or participation in discussion groups. The purpose of the program is to bring experts up to date on the latest developments, to analyze the significance of these developments, to provoke suggestions concerning the underlying theories and profitable methods of approach for making progress. Attendance is by application, which must be submitted on the standard application form obtainable from W. George Parks, Department of Chemistry, University of Rhode Island, Kingston, R. I. Attendance at each conference is limited to about 100 conferees.

NEW YORK

British Surgeon Named Department Chairman.—Dr. Charles G. Rob, professor of surgery at the University of London since 1950, will become chairman of the University of Rochester department of surgery in July. He will succeed Dr. W. J. Merle Scott, who has held that position since 1953. Dr. Scott is retiring June 30. Dr. Rob has been visiting surgeon-in-chief at Peter Bent Brigham Hospital in Boston and Presbyterian Hospital in New York City, and last fall was visiting professor of surgery at the University of California at Los Angeles. He also received some of his medical training at McGill University Medical School in Montreal, serving a residency at the Royal Victoria Hospital in that city. In 1954, he reportedly was the first surgeon to successfully reconstruct the carotid artery. Dr. Rob was elected last summer as president of the International Society for Cardiovascular Surgery.

New York City

Unit for Cardiac Diagnosis.—Children with heart disease will be studied from infancy through adolescence at New York University–Bellevue Medical Center in a new cardiac diagnostic unit for which plans have been completed. This unit is being created as a memorial, by colleagues and friends, to the late Dr. Janet S. Baldwin, associate professor of pediatrics at the medical center and a pioneer in the diagnosis of congenital cardiac anomalies in children. Dr. Eugenie A. F. Doyle, director of the Children's and Adolescent Cardiac Service, announced that the new unit will include facilities for cardiac catheterization and cine angiocardiography and will be under the direction of Dr. Edmund H. Reppert Jr., assistant professor of clinical medicine at the medical school. The new unit will start functioning about May 1.

Dr. Lanman Named Department Chairman.—Dr. Jonathan T. Lanman, associate professor of pediatrics, New York University College of Medicine, was appointed professor and chairman of the department of pediatrics at the State University of New York Downstate Medical Center and chief of pediatrics at the Kings County Hospital Center, Brooklyn. Dr. Lanman will take over his new duties April 1, succeeding Dr. Richard L. Day, who resigned the two positions to become medical director of Children's Hospital of Pittsburgh and chairman, department of pediatrics, University of Pittsburgh School of Medicine. Dr. Lanman served as a United States Public Health Service Fellow at the University of California from 1946 to 1949, when he became instructor in pediatrics at New York University College of Medicine.

Hospital News.—The Swedish Hospital, Bedford Ave. and Dean St., announced the opening of a department of angiology. The inpatient service is in charge of Dr. Saul S. Samuels and is prepared to admit cases of peripheral gangrene and chronic leg ulcers. The outpatient clinic is under the direction of Dr. Herbert E. Shaftel and Dr. Samuels, and will admit ambulatory cases of peripheral arterial disease on Tuesdays at 10 a. m.——Dr. Donald V. Cooney, Garden City, L. I., recently director of professional services at Pittsburgh Veterans Administration Hospital, has been named director of the new prehospitalization home care program at the Jewish Chronic Disease Hospital, Brooklyn. The program is a five-year study made possible by the National Institutes of Health to determine the feasibility of treatment of victims of stroke at home.

NORTH CAROLINA

Plan Reopening of Children's Center.—Dean C. C. Carpenter, Bowman Gray School of Medicine, Winston-Salem, announced long-range plans for the reopening of the Graylyn Estate as a center for exceptional children. Graylyn, which until one year ago was the adult psychiatry unit of Bowman Gray School of Medicine of Wake Forest College, will offer its facilities in the field of emotional and neurological problems confronting children. The program is under the direction of Mr. Joseph R. Grassi, assistant professor of psychology at Bowman Gray and director of the Medical School's Psychology, Reading and Speech Center at Reynolda. The program will be coordinated with the teaching program of the city and county schools, and Western Carolina College, and will provide classes for trainable retarded children, sheltered workshop training for educable retarded children on a part-time basis, a summer program for gifted children, training classes for teachers of emotionally disturbed children, and a psychological clinic.

The Graylyn Estate.

OHIO

Drs. Warren and Hackett Named Surgeons Emeriti.—The honorary title of surgeon emeritus was conferred on Dr. George S. Hackett and Dr. Archie W. Warren recently by representatives of Mercy and Timken Mercy hospitals, Canton. Both physicians, who retired recently from active practice, received plaques from the two hospitals "commending them for their decades of outstanding hospital and medical services."

Dr. Sabin Honored by Alma Mater.—Dr. Albert B. Sabin received the 1960 Medical Alumni Award from New York University "for his outstanding medical statesmanship." He is a 1931 graduate of NYU College of Medicine. The honor was conferred Feb. 22 in New York City. Dr. Sabin, developer of a live-virus poliomyelitis vaccine, recently announced he will turn to cancer research in 1961. He is professor of research pediatrics at the University of Cincinnati College of Medicine and fellow in Cincinnati Children's Hospital Research Foundation. Dr. Sabin's "distinction as a scientist" prompted his selection, the NYU administration said. Dr Sabin received an honorary doctor of science degree from NYU in June, 1959.

OKLAHOMA

Break Ground for Research Building.—Groundbreaking ceremonies for the University of Oklahoma Medical Research Building were held Jan. under joint sponsorship of the center and th Oklahoma City Chamber of Commerce. Paul A Weiss, Ph.D., head of the Laboratory of Developmental Biology at the Rockefeller Institute fo Medical Research, New York City, was principa speaker. The building, to cost about $800,000, i being constructed on the south side of NE 13 Stree in front of University Hospital and to the west o the hospital's outpatient clinics wing. The fou story structure will house some 50 laboratories an related facilities. Construction of the laborator space for faculty members was made possible by $400,000 federal health research facilities gran awarded in 1957 and matched by a $400,000 appropriation of the 1959 state legislature.

GENERAL

1960 Census.—The 1960 Population Census will b conducted April 1. Every fourth household will b asked to answer the question, "What kind of wor was he doing?" for each person 14 years of age o older. In order that the occupation statistics on th medical profession be developed as accurately a possible, the Census Bureau has asked that we pas along to our readers a reminder that this questio on occupation should be answered completely an precisely. In many cases the entry should consist o at least two words. Some examples of acceptabl entries are: clinical pathologist, gynecologist, medical doctor, ophthalmologist, orthopedic surgeon pediatrician. Please note that the word "doctor" b itself is not an adequate entry.

Plastic Surgeons Meeting.—The spring meeting o the American Society of Facial Plastic Surgery wil be held Wednesday, April 6, at the Hotel Elysee 60 E. 54th St., New York City. A business meeting is planned for 5:30 p. m. at which the election o officers will take place. The scientific program wil consider "Methods of Otoplasty" and the following persons will participate: Drs. Oscar J. Becker Chicago; Richard T. Farrior, Tampa, Fla.; William Schwartz, Passaic, N. J.; Herbert Friedman, Brooklyn; Samuel M. Bloom, New York City; and Sidney S. Feuerstein, New York City. Dr. Feuerstein will present a motion picture. For information, write the American Society of Facial Plastic Surgery 123 E. 83rd St., New York 28.

Survey of Snake-Bite Incidence.—The New York Herpetological Society is conducting a survey on the incidence, causes, and treatment of snake-bite in the continental United States. The society asks that hospitals and physicians responding to the treatment of snake-bite victims volunteer the following information: victim's initials, sex, age, height, weight, type and/or species of snake, preliminary treatment and antivenin treatment (dosage and frequency of doses), complications, and result of treatment. The exact length of convalescence, if known, would be appreciated. The data will be recorded and tabulated by John Hauser of Philadelphia and then evaluated. Free copies of the report will be sent to all hospitals and physicians taking part in the survey. The survey will cover the period Dec. 31, 1957, through Dec. 31, 1959. All reports should be sent to the Director of Research, New York Herpetological Society, Box 71, Brooklyn 9, N. Y.

Meeting on History of Medicine.—The 33rd annual meeting of the American Association for the History of Medicine will be held March 24-26 in Charleston, S. C., with headquarters at the Francis Marion Hotel. Ludwig Edelstein, Ph.D., of Baltimore, will present the Garrison Lecture, "The Distinctive Hellenism of Greek Medicine," the evening of March 24. A symposium on primitive medicine will include the following papers:

Foundations of Ancient Mesopotamian Medicine, Martin Levey, Ph.D., Princeton, N. J.
Origin of Death, Warner Muensterberger, Ph.D., Brooklyn.
Relationship Between Folk and Scientific Medical Practice in a Peasant Community, Michael Horowitz, Ph.D., Kent, Ohio.

Speaker at the annual dinner March 25, 7:30 p. m., will be Mr. Samuel Gaillard Stoney, of Charleston, S. C. For information, write John B. Blake, Ph.D., Secretary-Treasurer, American Association for the History of Medicine, Smithsonian Institution, Washington 25, D. C.

New Journal of Psychiatry.—Founded as a forum for American and international psychiatry, *Comprehensive Psychaitry* will be published bimonthly, the first issue being January-February, 1960. The journal will be devoted to the publication of articles concerning clinical psychiatry, research, therapeutic practice and psychiatric training. The first issue will feature papers on pharmacotherapies, existential analysis, direct analysis, research, psychiatric training, clinical psychiatry, and therapeutic practice. It is planned that at least once a year an entire issue will be reserved for exploration and discussion of one specific theme of universal interest. The journal is edited by Dr. Fritz A. Freyhan, clinical director and director of research, Delaware State Hospital. Chairman of the editorial board is Dr. Paul H. Hoch, New York City. The international advisory board has 12 members. The price for six issues is $8 per calendar year. Single issues are $2. For information, write Comprehensive Psychiatry, Grune & Stratton, Inc., 381 Park Avenue South, New York 16.

Meeting of Obstetricians and Gynecologists.—The American College of Obstetricians and Gynecologists will hold its eighth annual meeting at the Netherland Hilton Hotel, Cincinnati, April 3-6. The scientific program on Monday, Tuesday, and Wednesday, will consist of the presentation of papers, correlated seminars, clinical and breakfast conferences, and motion pictures. More than 240 participants are included in the program. Each seminar will consist of four sessions spread over three days, all devoted to the same subject under the same leader. A "doctor's luncheon" will be given on Monday. On Tuesday morning, a panel discussion on medical service plans, with representatives of industry, labor, insurance, and medicine speaking on third-party plans and their impact on obstetrics and gynecology, will be moderated by Dr. Donald C. Harrington, Stockton, Calif. For information, write Mr. Donald F. Richardson, Executive Secretary, The American College of Obstetricians and Gynecologists, 79 W. Monroe St., Chicago 3.

Orthopedic Meeting in Wichita.—The 1960 meeting of the Mid-Central States Orthopaedic Society will be held April 8-9 at the Lassen Hotel and the Kansas Gas & Electric Company Building, Wichita, Kan. Six papers include case presentations. Other papers scheduled on the program are as follows:

End-Result Studies of Forearm Fractures Reduced with Mal-Alignment in Children, Dr. Ward A. McClanahan, Wichita.
Multiple Pin Fixation of Femoral Neck Fractures, Dr. Spencer C. McCrae, Salina, Kan.
Traumatic Subtalar Dislocation, Dr. John F. Thurlow, Hays, Kans.
Bone Stimulation Procedures in Children, Dr. Harry G. Kroll, Topeka, Kan.
Heyman Procedure for Adducted Forefeet, Dr. Henry O. Marsh, Wichita.
The Use of Plaster of Paris to Fill Defects in Bone, Dr. Leonard F. Peltier, Kansas City.
Fractures About the Knee Treated with Internal Fixation with Immediate Mobilization, Dr. Charles R. Rombold, Wichita.
End-Result of Mitchell Procedure for Bunions, Dr. Harry O. Anderson, Wichita.

A panel discussion with case presentations will precede the business meeting April 9. For information, write the Mid-Central States Orthopaedic Society, 3244 E. Douglas, Wichita 8, Kan.

Annual Gastroscopic Meeting.—The 19th annual meeting of the American Gastroscopic Society will be held Wednesday, March 30, at the Auditorium of the Louisiana State University Medical School, New Orleans. A scientific program is arranged in three symposiums with the following titles and moderators: Nonsurgical Management of Esophageal Disease, Dr. John T. Howard, Baltimore; Endoscopic Biopsy and Exfoliative Cytology in the Diagnosis of Gastrointestinal Disorders: Techniques and Evaluation, Dr. J. Edward Berk, Detroit; Gastric Color Photography, Dr. Harry L. Segal, Rochester, N. Y. A total of eight papers will be presented at the three symposiums as follows:

The Medical Treatment of Hiatal Hernia, Esophagitis, Esophageal Ulcer and Diffuse Spasm of the Esophagus, Drs. Asher Winkelstein, New York City, and John Tilden Howard, Baltimore.
Treatment of Benign Stenoses of the Esophagus, Dr. Edward B. Benedict, Boston.
The Treatment of Cardiospasm, Dr. Regis A. Wolff, Pittsburg.
Biopsy of the Esophagus and Stomach, Dr. Eddy D. Palmer, Houston, Texas.
Biopsy of the Small Intestine, Dr. Cyrus E. Rubin, Seattle.
The Application of Exfoliative Cytology to Benign and Malignant Diseases of the Gastrointestinal Tract, Dr. Howard F. Raskin, Chicago.
A Comparison of Electronic Flash and Tungsten Light Gastroscopic Color Photography, Dr. Robert S. Nelson, Houston.
Further Experience with Gastric Color Photography, Dr. Ivan C. Keever, Chicago.

A business meeting will conclude the program. For information, write Dr. Arthur M. Olsen, 200 First St. S. W., Rochester, Minn.

Regional Meeting of Physicians in Salt Lake City.—The American College of Physicians will hold a regional meeting for Utah and Idaho Saturday, March 19, in the Little Theatre Union Building, University of Utah, Salt Lake City. Dr. Fuller B. Bailey, regent of the college, will open the meeting with an address. Thomas F. Dougherty, Ph.D., head, department of anatomy, University of Utah College of Medicine, will present "The Control of the Inflammatory Response" at the luncheon meeting. The following papers include invited authors:

Sub-Acute Thyroiditis, Dr. Lynn H. Anderson, Blackfoot, Idaho.
Recent Developments in Bilirubin Metabolism, Dr. Edwin Englert Jr., Salt Lake City.
I^{131} In the Diagnosis and Treatment of Disease, Dr. Philip R. Frederick, Salt Lake City.
The Digital Computer—A Potential Aid to Medical Diagnosis, Dr. Alan F. Toronto, Salt Lake City.
The Amino Oxidase Inhibitors and Their Role in Geriatric Medicine (Report on a 50 Patient Study), Dr. Everett J. Carmody, San Diego, Calif.
Demonstration of Cancer Cells in Peripheral Venous Blood, Samples and Significance, Dr. Cyril D. Fullmer, Salt Lake City.
Laboratory Aspects of Auto-Immune Disease, Dr. Crichton McNeil, Salt Lake City.
The Intracavitary Use of Radio Isotopes in the Medical Management of Cancer, Dr. Richard Y. Card, Salt Lake City.
Recent Clinical and Experimental Observations Concerning Diabetes Insipidus, Dr. J. Floyd Cannon, and Dr. Roy O. Schaub, Salt Lake City.

Dr. Thomas A. Findley, regent of the college, will present "The Kidney as a Metabolic Organ" at the afternoon session and will give "The Importance of Unlearning" at the banquet, 7:30 p. m., at which Dr. Theodore C. Bauerlein, governor for Utah, will serve as toastmaster.

1960 Pharmacopeial Convention.—The decennial meeting of the United States Pharmacopeial Convention will be conducted by the officers elected in 1950 who have held office during the decade when the meeting convenes in Washington, D. C., on March 29. At "full strength," the convention will consist of about 300 persons, the majority of whom will be delegates from organizations entitled to representation, including accredited colleges of medicine and pharmacy, state and national medical and pharmaceutical societies, several units of the federal government, and a limited number of organizations closely related to pharmacy and medicine. The first business of the convention will be consideration of an important revision of the present Constitution which will make it possible to seat a delegate from the newly formed Pharmaceutical Manufacturers Association. The convention will be asked to consider problems that have arisen during the past decade in the course of revising two editions of the Pharmacopeia. A function of the convention is to elect officers, a board of trustees, and a committee of revision of 60 experts to serve during the next decade. On the evening of March 28, an informal meeting is planned which will be addressed by Linwood F. Tice, Ds.C., Philadelphia, and Dr. Windsor C. Cutting, Stanford, Calif., of the present Committee of Revision, and George P. Larrick, Commissioner of Food and Drugs, Washington, D. C. During the convention, Arthur S. Flemming, Secretary of Health, Education, and Welfare, will deliver an address, as will Howard C. Newton, Ph.B., Boston, president, American Pharmaceutical Association. The present officers of the convention include Drs. Allen H. Bunce, Atlanta, Ga., president; Theodore G. Klumpp, New York City, vice-president; W. Paul Briggs, Sc.D., Washington, D. C., treasurer; and Adley B. Nichols, Ds.C., New York City, secretary. George D. Beal, Ph.D., Pittsburgh, is chairman of the board of trustees.

LATIN AMERICA

International Gastroenterology Meeting.—The second biennial scientific meeting of the Bockus Alumni International Society of Gastroenterology will be held during the week before the seventh Pan American Congress of Gastroenterology. The meeting will take place in Rio de Janeiro, Brazil, Oct. 17-21. The Brazilian host alumni will present a program, "Gastroenterology in Tropical Medicine." Alumni members are invited to present papers on

"Diseases of the Pancreas." A panel discussion will be moderated by Dr. Henry L. Bockus, Philadelphia, for whom the society is named. Free papers will be limited to 10 minutes and will be accepted until Aug. 1 on notification of the secretary general. For information, write Dr. Figueiredo Mendes, Av. Rio Branco, 257-18, Rio de Janeiro, Brazil, or Dr. James L. D. Roth, Graduate Hospital, Rm. 520, Philadelphia 46.

FOREIGN

Congress of Endocrinology in Copenhagen.—The first International Congress of Endocrinology will be held at the Technical University of Denmark, Copenhagen, July 18-23, under the presidency of Prof. Bernardo A. Houssay, Argentina. Ten symposiums at which invited speakers will participate are listed as follows:

Central Nervous System Regulation of Anterior Pituitary Secretion.
Polypeptide Anterior Pituitary Hormones.
Posterior Lobe Pituitary Hormones.
Parathyroid Hormone and Calcium Metabolism.
Aspects of Reproduction.
Adrenocortical Syndromes.
Aldosterone.
Steroid Pharmacology.
Hormone Action at the Cellular Level.
Topics in Comparative Endocrinology.

A round-table discussion on hormone assays of clinical value is scheduled. Scientific and technical exhibits and a program of social activities are arranged. For information, write the General Secretary, Prof. F. T. C. Prunty, Department of Chemical Pathology, St. Thomas's Hospital, Medical School, London S. E. 1.

Tour to Europe and Israel.—A special chartered jet-flight tour to Europe and Israel, highlighted by the dedication of the new medical school building of the Hebrew University of Jerusalem Aug. 3, was announced by the American Jewish Physicians' Committee, the medical section of the American Friends of the Hebrew University. Featuring a 12-day visit to Paris, Florence, and Rome and a two-week stay in Israel, the tour will include a seminar on Israel medicine and progress of medical research Aug. 4 at the Hebrew University's medical school. Participating physicians will be invited to attend lectures. The new medical school building of the Hebrew University, which replaces the old school premises on Mount Scopus, is the result of a five-year program and an expenditure of 5 million dollars. Funds for its construction have been raised by the 20 chapters of the American Jewish Physicians' Committee. Reservations and information for the tour may be obtained from the mid-west office of the American Jewish Physicians' Committee, 188 W. Randolph St., Chicago (FRanklin 2-5496).

Pediatric Congress in Czechoslovakia.—Dr. V. Kafka, president of the Congress Committee of the Medical Society of Czechoslovakia, Section of Pediatric Surgery, announced that the sixth annual meeting of Czechoslovak surgeons will be held in Prague, May 23-25. The program will include two main topics: Surgery of the Intrathoracic Organs and Internal Injuries, with the following subjects listed:

Open Heart Surgery.
Problems of Diagnosis and Results of Treatment in Atresia of Esophagus.
Mediastinal Tumors.
Urgent Thoracic Surgery in the Newborn and Infants.
The Importance and Value of Prevention in Traumatology.
Discussion on Injuries of CNS.
Rupture of the Heart.
Traumatic Rupture of the Tracheobronchial Tree and Lungs.
Posttraumatic Hydrocephalus.
Total Abruption of the Renal Hilus.

The official languages of the congress will be Russian, English, Czechoslovakian, and Slovak, with the lectures preferably given in English or Russian. A social program is planned, including the International Music Festival. For information, write Dr. Emil Frynta, Department of Pediatric Surgery, Charles University, Prague 2, Ke Karlovu 2, Czechoslovakia.

CORRECTION

Dr. Rosenman Is Not Dead.—In the Feb. 13 issue of The Journal, page 724, under Deaths, an obituary appeared on Dr. Jacob Daniel Rosenman. Dr. Rosenman, who resides in Venice, Calif., is not dead.

EXAMINATIONS AND LICENSURE

EDUCATIONAL COUNCIL FOR FOREIGN MEDICAL GRADUATES, INC.

Educational Council for Foreign Medical Graduates: Stations around the world. Sept. 21, 1960. Exec. Director, Dr. Dean F. Smiley, 1710 Orrington Ave., Evanston, Ill.

NATIONAL BOARD OF MEDICAL EXAMINERS

National Board of Medical Examiners: Part I, Various Cities, June 21-22 and Sept. 7-8. Part II, Various Cities, April 26-27. Applications must be received at least six weeks before the date of the examination. Exec. Sec., Dr. John P. Hubbard, 133 South 36th St., Philadelphia.

BOARDS OF MEDICAL EXAMINERS

ALABAMA: *Examination.* Montgomery, June 21-23. Sec., Dr. D. G. Gill, State Office Bldg., Montgomery.

ALASKA:* On application in Anchorage or Fairbanks. Sec., Dr. W. M. Whitehead, 172 South Franklin St., Juneau.

ARKANSAS:* *Examination and Reciprocity.* Little Rock, June 9-10 Sec., Dr. Joe Verser, Harrisburg.

California: *Written.* San Francisco, June 20-23; Los Angeles, Aug. 22-25 and Sacramento, Oct. 17-20. *Oral and Clinical.* Los Angeles, San Francisco, June 19; Los Angeles, Aug. 21, and Los Angeles, Nov. 29. *Oral for Reciprocity Applicants.* San Francisco, June 18; Los Angeles, Aug. 20 and Nov. 19. Sec., Dr. Louis E. Jones, Room 536, 1020 N Street, Sacramento.

Canal Zone: On Application. Acting Sec., Dr. B. K. Levin, Health Bureau, Balboa Heights.

Colorado:* *Reciprocity.* Denver, April 12. *Examination.* Denver, June 14-15. Sec., Dr. John B. Farley, 1612 Tremont Place, Denver 2.

Delaware: *Examination and Endorsement.* Dover, June 12-14 and July 21. Sec., Dr. Joseph S. McDaniel, Professional Bldg., Dover.

District of Columbia:* *Examination.* Washington, June 13-14. Deputy Director, Mr. Paul Foley, Department of Occupations and Professions, 1740 Massachusetts Ave., N.W., Washington 6.

Florida:* *Examination.* Miami Beach, June 19-21. Sec., Dr. Homer L. Pearson, 901 N.W. 17th St., Miami 36.

Georgia: *Examination and Reciprocity.* Atlanta, June. Sec., Mr. Cecil L. Clifton, 224 State Capitol, Atlanta 3.

Guam: *Subject to Call.* Act Sec., Dr. F. L. Conklin, Agana.

Idaho: *Examination and Endorsement.* Boise, July 11-13. Exec. Sec., Mr. Armand L. Bird, 304 Sonna Bldg., Boise.

Indiana: *Examination.* Indianapolis, June 22-24. *Reciprocity.* Indianapolis, fourth Wednesday of each month. Ex. Sec., Miss Ruth V. Kirk, 538 K. of P. Bldg., Indianapolis.

Kentucky: *Examination.* Louisville, June 6-7. Sec., Dr. Russell E. Teague, 620 South Third St., Louisville 2.

Louisiana: *Examination and Reciprocity.* New Orleans, June 9-11. Sec., Dr. Edwin H. Lawson, 930 Hibernia Bank Bldg., New Orleans 12.

Maryland: *Examination.* Baltimore, June 15-18. Sec., Dr. Frank K. Morris, 1215 Cathedral St., Baltimore 1.

Michigan:* *Examination.* Ann Arbor and Detroit, June 6-8. Sec., Dr. E. C. Swanson, 118 Stevens T Mason Bldg., Lansing.

Mississippi: *Examination.* Jackson, June. Sec., Dr. A. L. Gray, Old Capitol, Jackson 13.

Montana: *Examination and Reciprocity.* Helena, April 5. Sec., Dr. Thomas L. Hawkins, 555 Fuller Ave., Helena.

Nebraska:* *Examination.* Omaha, June 13-15, 1960. Dir., Bureau of Examining Boards, Room 1009, State Capitol Bldg., Lincoln 9.

Nevada:* *Examination and Reciprocity and Endorsement.* Reno, March 8. Sec., Dr. G. H. Ross, 112 No. Curry St., Carson City.

New Hampshire: *Examination.* Concord. March 9-12. Sec., Dr. Edward W. Colby, 61 South Spring St., Concord.

New Mexico:* *Examination and Reciprocity.* Santa Fe, May 16-17. Sec., Dr. R. C. Derbyshire, 227 East Palace Ave., Santa Fe.

New York: *Examination.* Albany, Buffalo, New York City, Rochester and Syracuse, June 28-July 1. Sec., Dr. Stiles D. Ezell, 23 S. Pearl Street, Albany.

North Carolina: *Endorsement.* Raleigh, May 9. *Examination and Endorsement.* Raleigh, June 20-23. Sec., Dr. Joseph J. Combs, 716 Professional Bldg., Raleigh.

North Dakota: *Examination and Reciprocity.* Grand Forks, July 6-9. Sec., Dr. C. J. Glaspel, Grafton.

Ohio: *Reciprocity.* Columbus, April 5 and June 17. *Examination.* Columbus, June 16-18. Sec., Dr. H. M. Platter, 21 West Broad St., Columbus 15.

Oklahoma:* *Examination and Endorsement.* Oklahoma City, May 31-June 1. Sec., Dr. E. F. Lester, 813 Braniff Bldg., Oklahoma City.

Oregon:* *Reciprocity and Endorsement.* Portland, April 14-16. *Examination.* Portland, July. Exec. Sec., Mr. Howard I. Bobbitt, 609 Failing Bldg., Portland.

Pennsylvania: *Examination.* Philadelphia and Pittsburgh, July 5-7. Sec., Mrs. Margaret G. Steiner, Box 911, Harrisburg.

Rhode Island:* *Endorsement.* Providence, March 24. *Examination.* Providence, April 7-8. Administrator of Professional Regulations, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

South Carolina: *Endorsement.* Myrtle Beach, May 17. *Examination.* Columbia, June 28-29. Sec., Dr. Harold E. Jervey, Jr., 1329 Blanding St., Columbia.

Tennessee:* *Examination.* Memphis, March 23-24. Sec., Dr. Alfred D. Mason, Jr., 1635 Exchange Bldg., Memphis 3.

Texas:* *Examination and Reciprocity.* Fort Worth, June 20-22. Sec., Dr. M. H. Crabb, 1714 Medical Arts Bldg., Fort Worth 2.

Utah: *Examination.* Salt Lake City, July 6-8. Director, Mr. Frank E. Lees, 324 State Office Bldg., Salt Lake City 1.

Virgin Islands: *Examination.* Charlotte Amalie, St. Thomas, June 8-9. Sec., Dr. Benjamin A. Nath, Charlotte Amalie, St. Thomas.

Virginia: *Examination and Reciprocity.* Richmond, June 13-17. Address: Board of Medical Examiners, 631 First St. S.W., Roanoke.

West Virginia: *Examination and Reciprocity.* Charleston, April 18. Sec., Dr. Newman H. Dyer, State Office Bldg. No. 3, Charleston 5.

Wyoming: *Examination and Reciprocity.* Cheyenne, June 6. Acting Sec., Dr. Carleton D. Anton, State Office Bldg., Cheyenne.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Arizona: *Examination.* Tucson, March 18. *Endorsement.* Tucson, March 15. Sec., Mr. Herman E. Bateman, University of Arizona, Tucson.

Arkansas: *Examination.* Little Rock, April 21-22. Sec., Dr. A. W. Ford, Department of Education, Education Bldg., Little Rock.

District of Columbia: *Examination.* Washington, May 23-24. Deputy Director, Mr. Paul Foley, Department of Occupations and Professions, 1740 Massachusetts Ave., Washington 6.

Florida: *Examination.* Miami, June 4. Sec., Mr. M. W. Emmel, Box 340, Gainesville.

Iowa: *Examination and Reciprocity.* Des Moines, April 12. Sec., Mr. Elmer W. Hertel, Wartburg College, Waverly.

Kansas: *Examination.* Kansas City, June 10-12. Sec., Dr. Leon C. Heckert, Kansas State College, Pittsburg.

Minnesota: *Examination.* Minneapolis, April 5-6. Sec., Dr. Raymond N. Bieter, 165 Millard Hall, University of Minnesota, Minneapolis.

Nebraska: *Examination.* Omaha, May 3-4. Sec., Mr. R. K. Kirkman, Room 1009, State Capitol Bldg., Lincoln 9.

Nevada: *Examination.* Reno, March. Sec., Dr. Kenneth C. Kemp, Box 9355, University of Nevada, Reno.

Oklahoma: *Examination.* Oklahoma City, April 15-16. Exec. Sec., Mrs. E. L. Haidek, 813 Braniff Bldg., Oklahoma City.

South Dakota: *Examination and Reciprocity.* Vermillion, June 10-11. Sec., Dr. Gregg M. Evans, 310 E. 15th St., Yankton.

Tennessee: *Examination.* Memphis and Nashville, March 23-24. Sec., Dr. O. W. Hyman, 62 S. Dunlap St., Memphis.

Texas: *Examination.* Austin, Houston and Galveston. Sec., Dr. Cornelia M. Smith, State Office Bldg., 201 East 14th St., Austin.

Washington: *Examination.* Seattle, July 13-14. Administrator, Mr. Thomas A. Carter, Department of Licenses, Capitol Bldg., Olympia.

Wisconsin: *Examination.* Madison, April 9. Milwaukee, June 4. Sec., Dr. W. H. Barber, 621 Ransom St., Ripon.

---

*Basic Science Certificate required.

DEATHS

Allen, Clarence Genon Ⓜ Commerce, Texas; Baylor University College of Medicine, Dallas, 1913; served on the medical staff of the East Texas State Teachers College; fellow of the American College of Surgeons; owner of the Allen Hospital; died Dec. 27, aged 68.

Allen, William Dean Hall Ⓜ Tallulah, La.; Tulane University School of Medicine, New Orleans, 1935; died in the Parker Hospital, Jackson, Dec. 11, of liver disease, aged 48.

Alvarez, Manuel, Bluffs, Ill.; Dearborn Medical College, Chicago, 1904; died in Jacksonville Dec. 21, aged 86.

Anderman, Sigurd Ⓜ New York City; Karl-Franzens-Universität Medizinische Fakultät, Graz, Austria, 1920; died of congestive heart failure, Dec. 17, aged 65.

Anderson, Jacob Campbell, Rockford, Tenn.; Tennessee Medical College, Knoxville, Tenn., 1891; died Dec. 23 of acute atypical pneumonia, aged 95.

Apfelberg, Isidor Ⓜ New York City; University and Bellevue Hospital Medical College, New York City, 1909; member of the American Academy of Dermatology and Syphilology; died of cerebral accident in the Columbus Hospital Oct. 22, aged 71.

Arnold, Hermann Bruno Ⓜ New Haven, Conn.; born in New Haven Oct. 27, 1902; Yale University School of Medicine, New Haven, 1926; in 1947 appointed to the State Board of Examiners for Physiotherapy Technicians; specialist certified by the American Board of Physical Medicine and Rehabilitation; certified by the National Board of Medical Examiners; member of the American Academy of Physical Medicine and Rehabilitation; veteran of World War II; served on the board of health of Woodbridge; associated with the New Haven area of the Rehabilitation Center, State of Connecticut Veterans Home and Hospital in Rocky Hill, and the Hospital of St. Raphael; died Jan. 7, aged 57.

Bailey, Archie Charles Ⓜ Nashville, Tenn.; University of Nashville Medical Department, 1899; formerly on the faculty of his alma mater; died Dec. 14, aged 92.

Baze, Perry Allen Ⓜ Mason, Texas; Memphis (Tenn.) Hospital Medical College, 1902; veteran of World War I; associated with the Mason Memorial Hospital; died of arteriosclerotic heart disease Dec. 6, aged 82.

Beck, Frank William Ⓜ Erie, Pa.; College of Physicians and Surgeons, Baltimore, 1903; died in St. Vincent Hospital Dec. 14, aged 86.

Billingsley, Paul Raymond Ⓜ Sioux Falls, S. D.; Northwestern University Medical School, Chicago, 1918; fellow of the American College of Surgeons; past-president of the staff of the McKennan Hospital, where he died of coronary occlusion Dec. 11, aged 72.

Blanton, Wyndham Bolling Ⓜ Richmond, Va.; born in Richmond June 3, 1890; Columbia University College of Physicians and Surgeons, New York City, 1916; specialist certified by the American Board of Internal Medicine; in 1937 member of the House of Delegates of the American Medical Association; past-president of the Richmond Society of Internal Medicine and Richmond Academy of Medicine; formerly vice-president of the American Academy of Allergy and the Southern Medical Association, member of the American Clinical and Climatological Association, Virginia Academy of Science, Industrial Medical Association, American Association of the History of Medicine, Pi Kappa Alpha, Phi Chi, Omicron Delta Kappa, Sigma Delta Chi, and the Phi Beta Kappa; fellow of the American College of Physicians; professor emeritus of clinical medicine and the history of medicine at the Medical College of Virginia, where he was named associate professor of medicine in 1930, professor of the history of medicine in 1933, and professor of clinical medicine in 1939; veteran of World War I; senior surgeon in the U. S. Kantor, Dominic Benjamin, Fairbury, Neb.; University of Nebraska College of Medicine, Omaha, 1923; veteran of World War I; died Dec. 28, aged 67.

Kennard, William Sorrento, Newark, N. J.; University of Pennsylvania School of Medicine, Philadelphia, 1911; died Jan. 1, aged 81.

Kneucker, Alfred Walter, Chicago; born in Vienna, Austria, June 30, 1904; Medizinische Fakultät der Universität, Vienna, 1929; assistant professor of surgery at Chicago Medical School; at various times chief of the department of urology, General Hospital of Shanghai, China, head of the department of physiology, Riverside (Calif.) College, and visiting professor of the University of California, Santa Barbara; fellow of the International College of Surgeons; discovered that the kidney gives an electric potential; published two books and many papers; on the staffs of the American, Northwest and Mount Sinai hospitals; was lecturing in Europe on his research on the problem of human deaths when he died of coronary occlusion in Vienna, Jan. 12, aged 55.

Kraemer, Samuel Harry Ⓜ Jersey City, N. J.; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1930; died of coronary occlusion Nov. 21, aged 54.

Krolicki, Thaddeus Alphonsus Ⓜ Providence, R. I.; born in Bridgeport, Conn., Dec. 19, 1904; St. Louis University School of Medicine, 1929; specialist certified by the American Board of Proctology; member of the American Proctologic Society and the American College of Gastroenterology; fellow of the American College of Surgeons and the International College of Surgeons; past-president of the Pawtucket Medical Association; for a time school physician in Pawtucket; for many years state medical examiner; served on the staffs of the Memorial Hospital in Pawtucket, State Hospital for Mental Diseases, Howard, Roger Williams General and St. Joseph's hospitals in Providence, Our Lady of Fatima Hospital in North Providence, and the Notre Dame Hospital in Central Falls; died Dec. 12, aged 54.

McGannon, Francis Lambert Ⓜ Lakewood, Ohio; Western Reserve University College of Medicine, Cleveland, 1929; specialist certified by the American Board of Otolaryngology; member of the American Academy of Ophthalmology and Otolaryngology, American Laryngological, Rhinological and Otological Society, American Society of Ophthalmologic and Otolaryngologic Allergy, of which he was past-president, and the American College of Allergists; fellow of the American College of Surgeons; associated with St. John's Hospital, where he died Dec. 26, aged 56.

Martone, Edward Jay Ⓜ Brooklyn; George Washington University School of Medicine, Washington, D. C., 1931; died in the Wyckoff Heights Hospital Dec. 5, aged 54.

Nace, Alvia George Ⓜ Tacoma, Wash.; University Medical College of Kansas City, Mo., 1909; veteran of World War I; an active and honorary member of St. Josephs, Tacoma General, and Mountain View General hospitals; died Nov. 24, aged 77.

Schwartz, Frederick Ⓜ Brooklyn; University and Bellevue Hospital Medical College, New York City, 1930; certified by the National Board of Medical Examiners; specialist certified by the American Board of Surgery; clinical instructor in surgery at the State University of New York, Downstate Medical Center and the New York Medical College; fellow of the International College of Surgeons; veteran of World War II; on the staffs of the Morrisania City Hospital in New York City, the Jewish Chronic Disease Hospital and the Maimonides Hospital; died Dec. 26, aged 53.

Shelton, Josephine Annette Ⓜ Refugio, Texas; Baylor University College of Medicine, Dallas, 1938; interned at the Hospital for Women in Baltimore; died Dec. 25, aged 47.

Stewart, Helen Montgomery, Chambersburg, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1911; died Dec. 5, aged 75.

Stewart, Milton B. Ⓜ Logansport, Ind.; Cleveland Medical College, Homeopathic, 1897; for many years county coroner; died in the Memorial Hospital Dec. 17, aged 86.

Strobach, Rolla Lenox, Kansas City, Kan.; Washington University School of Medicine, St. Louis, 1936; interned at St. John's Hospital in St. Louis; service with the U. S. Public Health Service terminated Aug. 4, 1946; associated with the Providence Hospital, St. Margaret's Hospital, and the Bethany Hospital, where he died Dec. 23, aged 49.

Sutherland, Wade Hampton Ⓜ Booneville, Miss.; Memphis (Tenn.) Hospital Medical College, 1904; member of the Southeastern Surgical Congress and the American College of Chest Physicians; fellow of the International College of Surgeons and the American College of Surgeons; on the staff of the Northeast Mississippi Hospital; died Dec. 16, aged 83.

Switzer, John Wesley Ⓜ North Palm Beach, Fla.; University of Toronto Faculty of Medicine, Toronto, Ont., Canada, 1921; fellow of the American College of Surgeons; formerly associated with the Hamot Hospital in Erie, Pa.; died in the St. Mary's Hospital, West Palm Beach, Dec. 22, aged 67.

Tannenbaum, Karl Hart Ⓜ Frederick, Md.; Johns Hopkins University School of Medicine, Baltimore, 1918; formerly practiced in Chicago, where he taught at Northwestern University Medical School and was on the staff of St. Luke's Hospital; died in the Chicago Wesley Memorial Hospital Dec. 23, aged 67.

Taylor, Duane Russell Ⓜ Portland, Ore.; Washington University School of Medicine, St. Louis, 1948; interned at St. Louis City Hospital; served a residency at the Veterans Administration Hospital in Jefferson Barracks, Mo.; veteran of World War II; formerly associated with the Veterans Administration; affiliated with the Physicians and Surgeons Hospital, Emanuel Hospital, and the Good Samaritan Hospital, where he died Dec. 6, aged 38.

Thomas, Victor F., Evans City, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1889; died in the Butler County Memorial Hospital in Butler Dec. 5, aged 96.

Tinsley, Helen M. Frost, Palo Alto, Calif.; Stanford University School of Medicine, San Francisco, 1950; interned at San Francisco Hospital; from 1954 to 1956 a member of the Atomic Bomb Casualty Commission in Japan; died in the Palo Alto–Stanford Hospital Dec. 6, aged 35.

Toth, John Joseph Ⓜ Chebanse, Ill.; Chicago Medical School, 1944; interned at St. Joseph Hospital in Elgin; veteran of World War II; member of the American Academy of General Practice; associated with St. Mary's Hospital in Kankakee; died Dec. 7, aged 50.

Towle, Murray Hanson Ⓜ Manchester, N. H.; Dartmouth Medical School, Hanover, 1909; veteran of World War I; chairman of the Manchester Board of Health; on the staff of the Sacred Heart Hospital; died Dec. 21, aged 75.

Treichler, Albert Julius Ⓜ Lieut. Col., U. S. Army, retired, Kentfield, Calif.; Universita degli Studi di Roma, Facolta di Medicina e Chirurgia, Italy, 1902; veteran of World Wars I and II; retired from the U. S. Army Feb. 29, 1940; died in the Letterman Army Hospital, San Francisco, Dec. 18, aged 83.

Vandenberg, Bernice Helen, Pittsburgh; University of Wisconsin Medical School, Madison, 1956; interned at the Presbyterian Hospital of Pittsburgh; served a residency at the Western Psychiatric Institute; died Nov. 28, aged 30.

Vincent, Charles P. Ⓜ Laurens, S. C.; Baltimore Medical College, 1907; on the staff of the Laurens County Hospital; died Dec. 5, aged 76.

Vose, Robert Henry Ⓜ Milton, Mass.; Harvard Medical School, Boston, 1896; veteran of World War I; died Dec. 18, aged 89.

Wallace, Benjamin Cicero Jr. Ⓜ Waxahachie, Texas; Tulane University School of Medicine, New Orleans, 1935; past-president and secretary of the Ellis County Medical Society; fellow of the American College of Physicians; served as vice-president of the Texas Heart Association and the Scott and White Alumni Association; veteran of World War II; associated with the Waxahachie Sanitarium; died in Dallas Dec. 7, aged 50.

Wallin, William B. Ⓜ Brooksville, Ky.; University of Louisville (Ky.) Medical Department, 1893; served on the Bracken County Board of Education; in 1954 named Kentucky Doctor of the Year by the Kentucky State Medical Association; a director of the First National Bank; past-president of the Bracken County Medical Society; served on the staff of the Hayswood Hospital in Maysville; died Dec. 16, aged 89.

Wead, John Trimmer Ⓜ Wyoming, Ill.; University of Illinois College of Medicine, Chicago, 1924; veteran of World War I; associated with the Methodist Hospital, Peoria, where he died Dec. 22, aged 63.

Weinberg, Joseph, Jackson Heights, N. Y.; Cornell University Medical College, New York City, 1900; retired chief medical examiner for the department of sanitation; died in the Bayside (N. Y.) Gardens Nursing Home Dec. 28, aged 80.

Wendel, Elmer John Ⓜ Rochester, N. Y.; University of Buffalo School of Medicine, 1907; veteran of World War I; served on the board of directors of the Park Avenue Hospital, where he was a member of the staff; died Dec. 25, aged 76.

Wilder, Russell Morse Ⓜ Rochester, Minn.; born in Cincinnati Nov. 24, 1885; Rush Medical College, Chicago, 1912; on Oct. 1, 1919, entered the Mayo Clinic as an associate in the division of medicine and assistant professor of medicine in the Mayo Foundation; in 1929 left the clinic to become professor of medicine and chairman of the department of medicine in the University of Chicago; on Oct. 1, 1931, returned to the Mayo Clinic and became professor of medicine in the Mayo Foundation and head of the department of medicine; retired from the Mayo Clinic and Mayo Foundation on Dec. 31, 1950; director of the National Institute of Arthritis and Metabolic Diseases, U. S. Public Health Service in Bethesda, Md., from 1951 to 1953; honorary member, past-president, and vice-president of the American Diabetes Association, which in 1947 conferred the Banting Medal on him; the University of Chicago gave him the Distinguished Service Medal in 1941 and the Howard Taylor Ricketts Award in 1949; the Medical Alumni Association of the University of Chicago presented him with the honorary gold key in 1955; the American Medical Association honored him with the Joseph Goldberger award in 1954 and in 1956 the American Bakers' Association gave him an award in recognition of activities in promoting enrichment with vitamins of white flour and bread; elected president of the National Vitamin Foundation in 1956; chairman, Section on Pharmacology and Therapeutics of the American Medical Association, 1930-1931 and served on its Council on Foods and Nutrition, 1931-1951; specialist certified by the American Board of Internal Medicine; member of the Association of American Physicians, Central Society for Clinical Research, American Society for Clinical Investigation, and the American Society for Experimental Pathology; fellow of the American College of Physicians; held membership in the Society of the Sigma Xi, Alpha Omega Alpha, Nu Sigma Nu, and Delta Kappa Epsilon; member of the committee on medicine of the National Research Council from 1940 to 1946, and chairman of that committee in 1940; in 1941 organized and became the chairman of the Food and Nutrition Board, serving on that board from 1941 to 1947; in 1943 was chief of the Civilian Food Requirements Branch of the War Food Administration, Washington, D. C.; veteran of World War I; from 1941 to 1946 was a member of the editorial board of the *Journal of Nutrition;* from 1932 to 1950 served on the editorial board of the *Archives of Internal Medicine;* in 1942 became a member of the editorial committee of *Nutrition Reviews* and in 1952 appointed an associate editor of *Public Health Reports;* author of "Primer for Diabetic Patients" and "Clinical Diabetes Mellitus and Hyperinsulinism; contributor to several textbooks on medicine and to the Encyclopædia Britannica; died in St. Mary's Hospital Dec. 16, aged 74.

Wilkins, George Clarence Ⓜ Manchester, N. H.; Harvard Medical School, Boston, 1899; member of the founders group of the American Board of Surgery; past-president of the Manchester Medical Association, Hillsborough County Medical Society, and New Hampshire Medical Society; member of the American Radium Society; fellow of the American College of Surgeons; veteran of World War I; served as chairman of the state cancer commission; for many years member and president of the state board of health; consultant, Veterans Administration Hospital; associated with the Elliot Hospital, where he was past-president of the medical staff, and where he died Dec. 6, aged 83.

Williams, William George, Brownwood, Texas; Memphis (Tenn.) Hospital Medical College, 1902; veteran of World War I and the Spanish-American War; died in the Medical Arts Hospital Dec. 6, aged 85.

Williamson, Ora Monroe, Sedona, Ariz.; Barnes Medical College, St. Louis, 1907; veteran of World War I; died in the Whipple (Ariz.) Veterans Administration Center Dec. 17, aged 78.

Wilson, John G. Ⓜ Keo, Ark.; Kansas City (Mo.) College of Medicine and Surgery, 1918; mayor of Keo; died in the Arkansas Baptist Hospital, Little Rock, Dec. 8, aged 92.

Wofford, William Earl, Cartersville, Ga.; Atlanta College of Physicians and Surgeons, 1913; past-president of the Bartow County Medical Society; veteran of World War I; died Dec. 14, aged 70.

Worden, John Edward, San Francisco; Northwestern University Medical School, Chicago, 1899; formerly associated with the Indian Service; served as health officer of Nevada and secretary of the state medical association; died Dec. 28, aged 84.

FOREIGN LETTERS

BRAZIL

Blood Transfusion Precaution.—Dr. R. I. Carvalho and co-workers (*Sangre* 4:26, 1959) recommended adding gentian violet to blood to be transfused. This precaution may prevent the spread of Brazilian trypanosomiasis, especially in highly endemic regions. Since there was some doubt about whether the erythrocytes which were treated with a concentration of gentian violet (1:4,000) sufficient to kill Trypanosoma cruzei would survive, the authors studied survival of red blood cells exposed to this concentration of the drug for 24 hours at 4 C, using radioactive chromium as a tracer. The mean cell life varied between 66 and 91 days. From this it was concluded that other properties of the red blood cells were not significantly changed, and the prophylactic use of gentian violet was considered practicable.

Cesarean Section.—Dr. B. Neme of the University of São Paulo stated that the obstetric future of patients subjected to cesarean section depends mainly on the uterine scar, the vitality of which depends on the type of the incision and the suture of the myometrium (*Rev. gynec. e obst.*, Nov., 1959). There is, however, no agreement as to the best kind of myometrial suture. The following elements are believed to be essential for a proper suture: perfect apposition of the edges of the uterine wound, preservation of local circulation, noninclusion of the endometrium, and nondiminution in the elasticity of the tissues.

Prophylactic Appendectomy.—Salvatore and Martins (*Rev. gynec. e obst.*, Nov., 1959) removed the appendix as a prophylactic measure in 250 gynecological laparotomies. In 58% of these there were histopathological changes typical of chronic appendicitis. They believed that this justified their procedure.

FRANCE

Blood Transfusions.—A. Suchet (Golden Book of the 1959 Congress of the Federation of Blood Donors) stated that the serologic test for syphilis and determination of the blood groups, which are usually the only examinations made, are not sufficient to protect the donor and the recipient in transfusions. Certain laboratory examinations may reveal chronic diseases in apparently healthy subjects and thus protect the recipient and the donor. Since a sedimentation rate is more significant than the number of leukocytes in the detection of latent infections, no blood should be transfused from a donor with an increased sedimentation rate, and because most such donors are unaware of their low sedimentation rate the results of a test may give them a timely warning. Alpha hemolytic streptococcus infections, such as rheumatic fever, may also be recognized in prospective donors with the aid of antistreptococcin. A test for mucoproteins which showed positive results in patients with chronic rheumatic fever or collagen diseases, which are frequently not recognized, or diseases of the reticuloendothelial system constitutes a further basis for rejecting a prospective donor and advising him to seek treatment.

The test for lipoproteins gives an accurate indication of the donor's vascular age. If an unrecognized abnormality is discovered the donor should not be bled frequently and in some cases should be rejected. This test was made in 1,000 subjects, and the findings were pathological in 21% of those aged 35 years or over, in 28% of those aged 45 years or over, in 30% of those aged 55 years or over, and in 47% of those aged 65 years or over. With the aid of a technique elaborated by the author all these indispensable examinations can be made rapidly and without great expense.

Determination of Circulatory Velocity.—J. Pieri and co-workers (*Presse méd.*, July 25, 1959) described a new technique for the direct determination of circulatory velocity. A histamine wheal is produced on the root of the thigh, the interior surface of the knee, the middle and external portion of the leg, the anterior surface of the ankle, and the root of the great toe. A needle is placed in the internal saphenous vein at the level of the malleolus. Then 10 ml. of a 5% solution of fluorescein is injected into the femoral artery at the site of the crural arch. The leg is examined in a dark room with the aid of a Wood light by estimating both the rapidity with which lighting up of the histamine wheals occurs and fluorescence appears in the venous blood. In order to obtain precise results the administration of all vasodilator drugs should be stopped at least 24 hours before the test, the systemic circulatory velocity should be determined previously, and the patient should be examined at a room temperature of 20 to 22 C.

The items in these letters are contributed by regular correspondents in the various foreign countries.

In a healthy person the appearance of fluorescence in the venous blood and the lighting up of the last wheal in the region of the great toe occurs at the same time (in less than 22 seconds). A delay in either or both indicates lesions caused by diffuse and massive overloading of the arterial tree. When the results of the classic fluoroscopy are normal and the appearance of fluorescence and the lighting up of the last wheal in the arteriovenous test do not occur within 22 seconds, the patient probably has arteritis or some deep-seated disorder of the capillary system.

Explosion of Flatus.—J. Guillotte (*Phlébologie*, no. 2, 1959) described an accident which occurred during a minor operation in which electrocoagulation was used in a 33-year-old man with hemorrhoids. The injection of a sclerosing substance into the hemorrhoidal swelling produced a significant hemorrhage. In order to stop the bleeding a glass anuscope was inserted and forceps were placed on the bleeding artery. Then an electrode was applied for coagulation. At that moment the patient passed flatus which caught fire and exploded. The patient became unconscious. Operation showed a 10-cm. (3.9-in.) laceration of the lower part of the sigmoid which was sutured. The patient sued the surgeon for malpractice, but the court ruled that the surgeon could not be blamed.

Withdrawal Therapy in Drug Addiction.—J. P. Temple and co-workers (*Thérapie*, no. 2, 1959) used dextromoramide (Pyrrolamidol or Palfium) to ameliorate withdrawal symptoms in drug addicts. Since prolonged treatment with this drug may cause a persistant psychic dependence on it, a rigidly controlled institutional environment and, in some patients, psychotherapy is required. The authors gave 650 to 700 mg. of cortisone daily. The administration of dextromoramide was discontinued after cortisone therapy had been given for 48 hours. The treatment with cortisone was continued in gradually decreasing doses for five or six more days, and then ACTH was given for a few days. This treatment brought about disappearance of the abstinence syndrome, sleep returned to normal, and a condition of euphoria ensued. The authors suggested that the drug addict should be given dextromoramide as a substitute for an equivalent dose of morphine derivatives for the period of at least one month, after which he should be given cortisone therapy.

Pentobarbital for Delirium Tremens.—J. Fours (*Anesthésie, Analgésie, Réanimation*, no. 4, 1958) gave pentobarbital intramuscularly to a series of 50 patients with delirium tremens. Given thus the drug was better tolerated than when given intravenously. With doses ranging from 2 to 2.5 Gm. every 8 hours for 24 hours a deep sleep was produced. It was necessary to watch the patient for at least 45 minutes after each injection and, by placing him in the proper position, to prevent the falling backward of the tongue. When the patient fell asleep after the injection his temperature, respiration, and blood pressure returned to normal. It took longer for the pulse to become normal. The intramuscular injection of 1 Gm. of pentobarbital combined with the vitamins B_1 and B_{12} sometimes prevented the onset of delirium. Treatment was continued for several days. Of 40 patients who received preventive treatment 6 developed a mild delirium, but all recovered. Of eight who were treated for true delirium, all recovered without sequelae.

GERMANY

Absorption from the Small Intestine.—U. Ritter of Berlin (*Medizinische*, no. 10, p. 406, 1959) stated that isotope techniques have provided reliable means for estimating absorption and transport of fat in the small intestine. Labeled linoleic, palmitic, or stearic acid and tagged muscle fats, triolein, or oleic acid were used. The studies confirmed the belief that higher fatty acids are almost completely carried away in the lymphatics. In quantitative estimations of the amount of fat in the feces, 10% of the fat ingested was considered normal. After gastric resection an increased excretion of fat, especially of bacterial fat, was regularly found. In patients with ileitis delayed and decreased absorption of fat was found in addition to an increase of oleic acid in the stool. Fat absorption was delayed and decreased also in patients with carcinoma of the head of the pancreas. Biliary acid and pancreatic juice are no longer considered so important in the absorption of fat. Fat may be absorbed in their absence. Studies with tagged yeast protein showed that protein is mainly absorbed in the jejunum.

It was found that less than 10% of the iron contained in the food is absorbed, but the absorption rate is increased in patients with anemia. Absorption of vitamin A depends on various factors. Calcium absorption in the ileum was improved by administering vitamin D. Absorption of vitamin K required the presence of bile. The importance of the vitamin B complex in the utilization of food was confirmed further. The absorption of vitamin B_{12} was reduced in general disturbances of absorption.

Changes in Tuberculosis.—F. G. Schmidt (*Beitr. Klin. Tuberk.* 121:42-48, 1959) reported that marked changes in the manifestations of tuberculosis are occurring. Tuberculous cavitation now proceeds without noticeable symptoms. Highly inflammatory, exudative-caseous tuberculosis has become rare. The decrease in laryngeal and intestinal tuberculosis is believed to have resulted from chemotherapy. Bronchial tuberculosis has been regressing. On the other hand, the number of lower lobe infections and tuberculomas is increasing. In tuberculomas isoniazid probably enters the granules but there meets a quiescent and therefore invulnerable bacterial flora. This does not follow treatment with streptomycin, thiosemicarbazone, and para-aminosalicylic acid. In patients with tuberculous cavities even if the healing process has not been changed by chemotherapy, it is accelerated and the therapeutic results probably last longer.

Extrapulmonary Tuberculosis.—J. Kastert (*Beitr. Klin. Tuberk.* 121:61-75, 1959) stated that chronic tuberculosis of the cervical lymph nodes with extensive scar formation and fistulas is more rare than in the preantibiotic era. This is not so much a result of chemotherapy as of early diagnosis. Intestinal tuberculosis is decreasing. Only intestinal obstruction has remained an indication for operation. Peritoneal tuberculosis has become rare, and the incidence of mesenteric lymph node infection is steadily decreasing. The incidence of skeletal tuberculosis has been the same for 10 years. Chemotherapy has reduced the danger of abscess and fistula formation in tuberculous spondylitis. There is a predominance of hyperplastic changes after specific joint or bone processes, while previously hypoplastic processes predominated.

Scrofula.—E. Brügger (*Beitr. Klin. Tuberk.* 121:244-245, 1959) stated that until 1949 he resected only the softened and fistulating tuberculous cervical lymph nodes, but since the end of 1949 he has resected all nodes larger than a small cherry with or without calcium deposits. Smaller nodes were excised when they showed a tendency to progress. Between 1950 and 1956, 1,016 patients with such nodes had radical resections. The duration of treatment was comparatively short (about three months) and the number of relapses was low in this series. An inquiry among 300 patients five years after operation showed 3% with relapses and 1.7% with new infections. None of the patients operated on later developed lupus. All were given chemotherapy postoperatively in addition to general treatment. Surgical treatment obviated the need for radiotherapy.

Postoperative Gangrene.—Schuermann and Hornstein of Bonn (*Chirurg* [no. 8] 30:371, 1959) said that postoperative gangrene is not frequent but is alarming because of the great pain it causes, its steady progression, its resistance to treatment, and the death rate of about 30%. The average duration is about eight months. Circumferential incision is recommended. The authors used corticosteroids instead of antibiotics for treatment. They reported excellent results with the oral use of prednisone.

Actinomycosis.—A. M. Walter (*Deutsche med. Wchnschr.* [no. 32] 84:1421, 1959) stated that when diagnosed early actinomycosis should be treated with large doses of combined chemotherapy for 6 to 12 weeks. A combination of general and local chemotherapy together with surgery should always be considered, but its use should depend on the stage of disease and location of foci. Careful follow-up examination is necessary to detect relapses and delayed metastases. The author recommended a mixture of sulfonamides; penicillin in doses of 1 to 6 million units a day; 1.5 to 2 Gm. of tetracycline daily by mouth; 2 to 2.5 Gm. of chloramphenicol daily; 1 to 2 Gm. of streptomycin a day intramuscularly; or erythromycin and oleandomycin in daily doses of 1.2 to 1.6 Gm. orally. Penicillin and sulfonamides may be used locally. For the treatment of oropharyngeal actinomycosis, benzoquinone, guanylhydrazone, thiosemicarbazone, and large doses of prednisolone were recommended.

Cause of Pneumonia.—H. Fischer of Berlin (*Ztschr. ges. inn. Med.* [no. 13] 14:648, 1959) reported that pneumococci no longer play the predominant role as the cause of pneumonia. He examined the sputum of 26 patients with lobar and 24 with lobular pneumonia before the patients had been given any treatment. Streptococcus viridans predominated followed by Escherichia coli and staphylococci. In each patient the same micro-organisms were found in the sputum and in the pleural exudate. Treatment was directed specifically against the organism identified.

Progressive Scleroderma.—E. Nägele of Giessen (*Klin. Wchnschr.* [no. 13] 37:697, 1959) stated that some conditions such as disseminated lupus erythematosus, dermatomyositis, and progressive scleroderma that were previously thought to be skin diseases are cutaneous manifestations of systemic diseases. Scleroderma occurs in a disseminated and in a harmless circumscribed form which is confined to the skin and is also referred to as sclerodactyly or acrosclerosis. In progressive scleroderma the esophagus is frequently transformed into a rigid tube without peristalsis. The patients complain of difficulty in swallowing and a feeling of pressure in the epigastrium and must wash down every mouthful of food with liquids. Esophageal ulcers may occur.

Similar changes may affect the whole gastrointestinal tract and cause pain, ileus, sprue-like diarrhea, and tarry stools. Histological examinations show that muscular tissue in the digestive tract is replaced by connective tissue, but there is probably also disturbance of the intramural nervous plexuses which decreases peristalsis. There may also be signs of progressive myocardial fibrosis, usually attended by cardiac dilatation. Nodules and cell aggregates resembling Aschoff's nodules are found on histological examination. The clinical diagnosis of sclerodermatic myocardial changes is difficult. The electrocardiogram may show arrhythmia, broadening of the QRS complex, or low voltage. Medium-sized arteries may show proliferating endarteritis, and the small arteries and arterioles may show fibrinoid intimal damage.

Pulmonary fibrosis occurs mainly in the lower lobes. Histological examination of the lungs shows an increase of interstitial tissue and cyst formation, which in some cases resembles bronchial dilatation and in some emphysematous vesicles. Endarteritic vascular changes are also found in the lungs. Renal involvement causing increased blood pressure and abnormal findings on urinalysis is always an indication of the terminal stage. The kidneys show the signs of chronic nephritis with thickening of Bowman's capsules and hyalinization of the capillary loops, as in malignant sclerosis. The endocrine glands may be involved. Joints are often stiff and contracted because of capsular shrinkage. Osteolysis in the terminal phalanges and calcification of soft tissues and internal organs are characteristic. The serum calcium level is often raised. ACTH and cortisone are the most effective therapeutic agents, although their effect may be transitory. Antibiotics are indicated, especially in patients with pulmonary fibrosis and inflammatory signs. Appropriate skin care, respiratory exercises, and massages are important. The average duration of the disease is seven years.

Prednisone and Phenylbutazone.—K. Dziuba (*Medizinische*, no. 38, p. 1768, 1959) obtained good results with a combination of 50 mg. of phenylbutazone and 1.25 mg. of prednisone in a series of 210 patients. The dosage (four to nine of the combined tablets daily) depended on the type and severity of the disease. After five days the dosage was reduced to two to six tablets daily. The duration of treatment varied. One group of patients, in particular those having rheumatoid arthritis, osteoarthritis, or spondyloarthrosis, were referred to their family physicians for further treatment with a minimal maintenance dosage. For a trial the combination was given to 27 patients with thrombophlebitis and 9 with skeletal metastases.

In the whole series 135 patients had been treated unsuccessfully with other drugs. Criteria for successful treatment were subsidence of pain, local inflammation, swelling, fever if there was any, and improved mobility. Inflammation, swelling, pain, and fever were promptly relieved. Results were excellent in those with rheumatic diseases and thrombophlebitis. Most patients with osteoarthritis, spondyloarthrosis, and affections of intervertebral disks with brachialgia, sciatic neuralgia, and lumbago responded well. Surprising results were seen in four patients with rheumatic endocarditis and one with myocarditis who had been treated with antibiotics, sulfonamides, pyrazole, and aminophenazone derivatives for prolonged periods. Three promptly became afebrile, the sedimentation rate declined, and leukocytosis and subjective symptoms improved. In the other two the effect occurred more slowly.

Interruption of the treatment resulted in spontaneous relapses in two patients, but these were controlled by renewed administration of the preparation. The results were excellent in the patients with acute thrombophlebitis, but only one patient with skeletal metastases became free of pain within 48 hours. Results were excellent in 105 patients, good in 50, and fair in 26; 29 patients were not benefited. The preparation was well tolerated, even when large initial doses were given. No major side-effects were seen. Only two patients had to discontinue treatment because of gastric intolerance. Because of these good results the preparation is recommended, in particular, for continuous treatment of chronic diseases.

Pemphigus Vulgaris.—E. Schlotter (*Hautarzt* 10:173, 1959) gave corticosteroids to 20 patients with pemphigus vulgaris. The initial dose depended on the severity of the disease and localization of the cutaneous or mucosal changes. The prognosis is most favorable when there is no mucosal involvement. Larger doses are required when the skin lesions have spread to the mucosa. In patients with pemphigus vulgaris confined to the skin, remission was achieved with total doses of 500 units of ACTH, 900 mg. of cortisone, or 860 mg. of prednisolone. In those with secondary spread to, or changes of, mucous membranes the doses were 1.80 to 4.15 Gm. of cortisone or 1.135 to 2.380 Gm. of prednisolone. Large single and total doses were required when the primary lesions were mucosal, when they remained localized, or when they secondarily affected the skin. One patient who had frequent severe exacerbations became symptom-free on maintenance doses of 150 mg. of prednisone daily.

Undesirable side-effects were nephrosis (present before treatment), increase of blood sugar level, moon face, and obesity of the trunk. These were treated appropriately, and it was not necessary to discontinue hormonal therapy. Prednisone proved generally valuable. Corticosteroids promptly achieve a remission of the acute activation, but use of hormones is not a specific treatment for pemphigus vulgaris. Four patients had relapses, but these responded to further treatment with corticosteroids. In this series 15 of the patients were alive and 12 of them were free from skin symptoms when last seen, some with and some without a maintenance dose. The duration of freedom from symptoms was two months to four years.

Asphyxia Neonatorum.—A. Braun and A. Mann (*Arch. Kinderh.* 159:130, 1959) said that cerebral, pulmonary, and cardiac forms of asphyxia neonatorum occur. Only few, and sometimes contradictory, reports are available on the pulmonary form. Hyalin-like membranes were found in 63 of 202 neonates (34 full term and 188 premature) who died within the first week of life. No hyalin-like membranes were found in a series of 37 stillborn infants. Hyalin-like membranes occurred in 56 of the premature infants and 7 of those born at full term. It is thought that the hyalin-like membrane develops from the exudation of blood components in the septums and alveolae of the lungs, as it is mainly seen in premature infants, and that it dries up and is reabsorbed. The membranes may contain cellular material and fat plugs. In the course of increasing blocking of gas exchange, latent anoxia develops and eventually causes the premature infant's death, but the prognosis is not invariably hopeless. Neonates have survived even severe symptoms and recovered within a comparatively short time. No specific treatment is known.

Multiple Sclerosis.—D. Ploog and co-workers (*Klin. Wchnschr.* 37:946, no. 18, 1959) treated a series of 30 patients who had multiple sclerosis with prednisolone. They used short-term massive courses of treatment, expecting a more distinct prednisolone effect than with the common continuous treatment and better differentiation between therapeutic results and spontaneous remissions. They gave 60 mg. for 2 days, 90 mg. on the 3rd and 4th day, then reduced the dose by 5 mg. every 2nd day and completely withdrew the drug on the 14th day. About half of the patients were given ACTH after prednisolone treatment. Neurological examination and, whenever possible, examinations of the spinal fluid were made after each phase of prednisolone treatment. The number of courses depended on the success of treatment, occurrence of complications, etc.

Response to treatment was evident in 63% of patients with acute, 56% of patients with intermittent, and 35% of patients with chronic progressive forms of the disease. Symptoms were favorably influenced in the following order of frequency: bladder and rectum disturbances, subjective symptoms, spinal fluid changes, sensory and coordinative disturbances, reflex anomalies, ocular changes, and cranial nerve deficiencies. Optic nerve atrophy was irreversible. In 15 patients the spinal fluid showed a reduction in the number of cells and total protein. There was no fixed relationship between degree of improvement and number of prednisolone courses given, but chronic forms were not essentially improved when this effect did not become apparent after the first course.

Side-effects were usually mild euphoria, restlessness, and occasionally an alteration of the sleeping-waking rhythm. More serious side-effects (appendical irritation in two and activation of previous inflammatory processes in two) occurred. One adolescent patient had a mild pituitary basophilism after the third course. Comparing the prednisolone-treated patients with a group of 30 who were given retroplacental serum, the author concluded that improvement was generally greater in the first group. It was concluded that prednisolone as used in this series was at least as effective as the usual treatments and clearly superior for treating patients with acute forms.

Erythroblastosis Fetalis.—G. Essigke of Jena (*Monatsschr. Kinderh.* 107:1-5, 1959) tested the excretory capacity of the liver for sulfobromophthalein in 29 infants who had erythroblastosis fetalis and who had been given exchange transfusions. The half life of the dye in the serum was markedly above normal. Normal liver function was not reached until the fourth week. In infants with this disease who had not been given an exchange transfusion, normal liver function was not achieved until the sixth week. The half-life values were also prolonged in healthy neonates, but in these normal values appeared within two weeks. The studies showed that in erythroblastotic infants hemolysis and hepatic insufficiency are independent of each other and are of different degrees. True liver damage occurs in erythroblastotic infants. It consists mainly in a disturbance of permeability and hypoxia, both due to an antigen-antibody reaction.

Renal Function Test.—H. Mühlan (*Ztschr. Kinderh.* 82:40-43, 1959) estimated the phenol red excretion for a renal function test, according to the method of Stave, in 57 children with healthy and 21 children with diseased kidneys. Since the values obtained at 15 and 30 minutes were scattered within a wide margin, the author recommended evaluation of the excretion at 60 minutes. In healthy children the amount of phenol red excretion averaged 60%. Values below 55% were considered pathological. These results were in fair agreement with those obtained by Zapp. In healthy infants in the second month of life excretion was markedly below later readings, but by the third month excretion approached the normal average. Excretory values were usually lowered in children with disease of the kidneys or urinary passages.

Metabolism of Vitamin D.—O. Hövels and D. Reiss (*Ergebn. inn. Med. u. Kinderh.* 11:206-263, 1959) stated that the intake of adequate amounts of protein and fat is necessary for good calcium absorption. An absorption-promoting effect of vitamin D is found in patients with rickets but not in healthy children. The vitamin has only a slight effect on constitutionally poor calcium utilization. A direct effect of the vitamin on phosphate absorption is doubted. Vitamin D increases calcium excretion even if serum calcium levels are not raised, since the inhibition of tubular reabsorption alters the calcium clearance rate. In rickets caused by vitamin D deficiency the phosphate clearance is increased but returns to normal after administration of vitamin D. Phosphate clearance is not raised in rachitogenic tetany but is increased after ingestion of vitamin D.

In vitamin D resistant rickets phosphate clearance is raised because of disturbance of tubular reabsorption and can be improved by daily doses of 100,000 to 800,000 units daily. The clearance is markedly raised and causes the characteristic hypophosphatemia in patients with hyperparathyroidism. Vitamin D lowers the increased phosphate clearance and in patients with hypoparathyroidism it causes the reduced phosphate excretion to increase. It has no effect on phosphate clearance in healthy subjects. Reduced tubular reabsorption of amino acids is a specific indication of vitamin D deficiency. Aminoaceturia subsides within three to eight weeks after administration of vitamin D. Of two groups of children with equal intestinal calcium absorption, the one receiving the larger amount of vitamin D showed the greater improvement in growth.

Dexamethasone.—Scheiffahrt and Zicha (*Medizinische*, no. 38, p. 1737, 1959) stated that the marked side-effects of cortisone and hydrocortisone prompted the search for new but related substances. Triamcinolone was developed by the introduction of a fluorine atom and hexadecardrol and dexamethasone by methylation. Since the latter proved markedly superior to other glucocorticoids in animal experiments, the authors gave it to 130 patients for whom corticoid treatment was indicated. The initial doses were 5 to 10 mg. daily by mouth; after two or three days the dosage was reduced by 0.5 mg. every other day. Patients with acute diseases were treated for two or three weeks, but in those with such chronic diseases as nephrosis, Hodgkin's disease, and hemolytic syndromes treatment was continued for up to 120 days with a total dose up to 320 mg. The maintenance dosage was 1 to 2 mg. daily.

Therapeutic successes depended on the type of disease and on the dose. In patients with rheumatic diseases, acute hepatic disorders, and hemolytic syndromes, success was apparent after 12 to 24 hours. The effect in patients with ulcerative colitis was similar to that of prednisolone. The preparation was least effective in patients with acute bronchial asthma, who responded best to derivatives for intravenous injection. In all patients with chronic nephritis and nephrosis, satisfactory diuresis set in and the subjective condition improved, but protein excretion was improved in only a few patients and only temporarily. The best effect of dexamethasone was seen in patients with active rheumatic processes. Dexamethasone and triamcinolone treatment did not effect the serum sodium level even in long-term treatment with large doses. The serum potassium level and potassium excretion at first remained unchanged, but after prolonged treatment a slight decrease of serum potassium and an increase of potassium excretion occurred.

Calcium, on the other hand, was mobilized more promptly. The excretion more than doubled, and the serum level declined below normal after four weeks at the latest. The results for organic phosphate in serum and urine were similar. Two patients being treated for a prolonged period developed osteoporosis. It was therefore recommended that in long-term treatment protein-anabolic hormones be given. The diuretic effect of dexamethasone was marked and usually set in after three to five days. While the neutral 17-ketosteroid excretion decreased after 30 days of corticoid treatment, corticoid excretion was significantly reduced after only a few days and decreased still further as treatment continued. Other hormonal effects occurred only with prolonged use of large doses. Eosinophil counts were checked in few patients and were found to return to normal in patients in whom they were previously extremely high.

Dexamethasone had less diabetogenic effect than did prednisolone and triamcinolone. Only 1 of 10 diabetic patients required an increase of the insulin dose by 8 units daily. The others, including those taking sulfonyl carbamide, showed no essential changes. Triamcinolone, on the other hand, in some patients caused a marked deterioration of glucose metabolism. Dexamethasone caused a greater catabolic effect than did prednisolone. The usual gastrointestinal side-effects were seen with dexamethasone, but only one patient who had neither an ulcer nor hyperacidity had marked gastrointestinal symptoms. Best tolerated by the stomach was 6-methylprednisolone. In one patient silicotuberculosis of long standing was activated by steroid treatment. Dexamethasone should be reserved for hospital treatment, in view of its possible side-effects. Long-term treatment with large doses may require antibiotic prophylaxis and antacids. For the termination of treatment depot-ACTH should be given for at least two days.

Cortisone and ACTH for Infections in Children.—D. Palitzsch (*München. med. Wchnschr.* **101**:241-246, 1959) treated 1,000 children who had severe infections with cortisone and ACTH. Cortisone inhibits eosinophils, lymphocytes, plasma cells, phagocytosis, toxic proteolysis, synthesis of hyaluronic acid, hyaluronidase, permeability, migration of leukocytes, antibody formation, fibroblasts, sprouting of capillaries, and scar formation. It promotes maturation of neutrophils, reticulocytes, thrombocytes, protein decomposition, thickening and polymerization of the ground substance, sealing of vessels, and vascular tone. Most diseases from infections require simultaneous antibiotic treatment. Special attention should always be paid to the disturbance of antibody formation by steroids. Short-term treatment in which large initial doses are administered before the dosage is gradually decreased is generally to be preferred. The indications now recognized include emergency treatment of Waterhouse-Friedrichsen syndrome, severe acute encephalopathy, and highly toxic conditions in infants and small children; resistant infections; hyperergic infections; and antibiotic-chemotherapeutic allergy. Cortisone is preferred in severe infections since these are associated with temporary blocking of adrenocortical function. The dosage depends less on age than on the severity of the infection. Short-term treatment is almost free of dangers even with large doses.

With long-term treatment the nitrogen losses in cortisone treatment (negative nitrogen balance and increased proteolysis) and sodium chloride water retention and potassium losses (severe potassium losses lead to energetic-dynamic heart failure) must be borne in mind. Intrathecal treatment of purulent meningitis with 5 to 10 mg. of hydrocortisone every other day counteracted the development of hydrocephalus by virtue of inhibiting mesenchymal proliferation. Steroid treatment proved valuable against staphylococcic sepsis, abscess-forming pneumonia in infants and small children, pleural empyema, bacterial enteric infections, tuberculosis including tuberculous meningitis, hemorrhagic measles, measles encephalitis, meningoencephalitis in smallpox and mumps, mumps orchitis, severe hepatitis, and infectious mononucleosis.

Tri-iodo-thyronine.—Knorr and Freislederer of Munich U. (*München. med. Wchnschr.* 101:718-723, 767-769, 1959) reported a series of 50 hypothyroidal children treated with tri-iodo-thyronine. Improvement occurred promptly. Sclerosis of the base of the skull in myxedema regressed in 17 months, cretinistic hips in 21 months. The margin between the therapeutic and toxic dose is greater than that of the dried gland. Cumulative effects were rare. Good results were achieved in some patients with obesity, nephrotic syndrome, nervous anorexia, dwarfism, and goiter of puberty.

Strophanthin and Cardiac Infarction.—Anschütz and Toker (*Ärztl. Wchnschr.* 14:609, 1959) noted that Edens highly recommended strophanthin for cardiac infarction. Other authors strongly advised against this treatment, and a third group recommended strophanthin only for patients with cardiac failure. Between 1953 and 1958 the authors gave strophanthin to every other patient with cardiac infarct. All patients also rested in bed and were given a salt-free diet, oxygen, analgesics, and sedatives. The dose of strophanthin was 0.625 mg. twice daily or 1.25 mg. once daily. Of 53 patients treated with strophanthin 20 died during their stay in hospital and 33 were discharged after six weeks of strict bed rest. Of the 53 controls 17 died and 36 were discharged. A total of 31 patients had signs of cardiac failure after the infarction, which usually occurred on the second and fourth day in the form of tachypnea and symptoms of congestion; 20 of these patients were treated with strophanthin, and 8 died in the first week. Of the eight patients three had not been given strophanthin. Although the number of patients was too small to permit valid conclusions, the results suggested that the prospects of surviving cardiac failure in infarction are not changed by strophanthin.

Long-Acting Sulfonamide for Children.—Schönfeld and Sommerfeld (*Ärztl. Wchnschr.* 14:619, 1959) reported that 2,4-dimethoxy-6-sulfanilamido-1,3 diazine is especially suited for the treatment of bacterial infections of children, since it is the only long-acting sulfonamide available in solution. Children prefer to take drops, and it is easier to add flavor to drops. Since the half-life of this drug in serum is about 40 hours, one dose a day is sufficient. The recommended dosage for infants and small children is 10 mg. per kilogram of body weight after an initial dose of twice that amount. In severe infections in children there are no disadvantages in doubling the dose. Infants and small children were always given the preparation in the form of drops, but older children may be given tablets. A series of 120 patients who had bronchopneumonia, bronchitis, tonsillitis, otitis media, lymphadenitis, gastroenteritis, dysentery, and enteritis, all associated with a high fever, were treated with the drug. In two patients with bronchopneumonia and two with otitis media the response was poor, and they were given antibiotics. None of the patients lost appetite; no blood and urine changes were observed; and no allergic skin reactions or renal impairment was noted. The preparation was highly effective and well tolerated.

Hydroxydione Anesthesia.—J. E. Rollenhagen (*Deutsches. med. J.* [no. 9] 10:310, 1959) stated that hydroxydione has proved a valuable basic anesthetic for elderly patients in whom cardiac or circulatory complications are to be expected. It has hypnotic action. The patients sleep quietly, as in normal sleep, but sleep is induced more slowly and evenly than with barbiturates. Increasing the dose prolongs but does not strengthen the effect. Combination with barbiturates is contraindicated since the combination increases the danger of respiratory depression. The substance can be used in patients with hepatic and renal disorders. Cytochrome C and cocarboxylase are antidotes.

Hydroxydione is indicated in patients with cardiac and circulatory insufficiency, diabetes, ileus, and peritonitis. Since the product is partly broken down in the liver and is excreted through the kidneys, careful dosing is necessary in patients with renal and hepatic conditions. Hydroxydione is best given in a 2% procaine solution with a 10% isotonic sodium chloride solution as a solvent. Premedication with meperidine, atropine, or promethazine and an antihistaminic is recommended. Since hydroxydione is used only as a basic anesthetic, anesthesia is continued with ether or nitrous oxide. The patients usually awaken soon after the operation and then often sleep for another two to three hours. When this drug is used requirements for analgesics in the first 12 to 24 hours are greatly reduced.

Chronic Rheumatic Disease.—W. Grab of Giessen (*Therap. Gegenw.* 98:323, 1959) stated that mesenchymal connective tissue plays an important role in rheumatic diseases. With increasing age there is a decrease of ground substance and an increase of fibers. All inflammatory reactions take place in the ground substance and are always elicited by chemical agents which activate extracellular enzymes, in particular hyaluronidase. The latter reduces or depolymerizes the large molecules of the ground substance to smaller molecules. Cortisone inhibits this process and thus exerts a nonspecific antirheumatic action. This explains the reactivation of rheumatic processes when such treatment is discontinued. Reactivation can be prevented by prolonging administration. The inflammation then has time to heal. Prednisolone, whose antiphlogistic action is 5 to 30 times greater than that of cortisone, does not have the side-effects of the latter. All adrenocortical hormones, however, increase the degradation of proteins and mineral deprivation. This leads to osteoporosis, which can be suppressed by giving sex hormones. Treatment must never be stopped abruptly, since this would cause atrophy of the adrenal cortex. Dosages should be gradually decreased and ACTH prescribed to bridge the withdrawal period.

Salicylates are more effective in the acute than in the chronic phase, and their use in rheumatic conditions is still justified. Aspirin (4 to 6 Gm. daily) is effective, and aminopyrine has proved valuable. Phenylbutazone has been widely used, but it may damage the bone marrow, affect blood coagulation, and cause allergic reactions and giddiness. Radioactive gold is comparatively harmless. Chloroquine has an indirect antirheumatic action which becomes manifest only after a comparatively long latent period.

Chlorpromazine and Shock for Chronic Psychoses.—R. Vosseler (*Med. Monatsschr.* [no. 5] 13:284, 1959) treated a series of 50 patients who had chronic schizophrenia with a combination of convulsive treatment and chlorpromazine. The patients had been treated for at least one year by the usual methods without success in a mental hospital. For eight days prior to the combined treatment the patients were given 150 to 200 mg. of chlorpromazine by mouth daily. They were then given electroshock in the evening for four days in addition to 100 mg. of chlorpromazine daily for three to four weeks. No side-effects from the chlorpromazine were observed. To obtain lasting improvement the patients were given three such courses of treatment over a period of about eight months.

The combination of additional chlorpromazine and electroshock in the evening (with the use of the natural requirement for sleep) freed the patients of shock fear. A short-acting anesthetic was not required, and instead the patients were given 50 mg. of chlorpromazine intravenously or intramuscularly in the terminal stupor. The next morning they woke up refreshed and did not remember the happenings of the previous night. After three shock treatments they could usually be admitted to occupational therapy. After conclusion of the combined treatment, 14 women were discharged improved. They were free from hallucinations and in a balanced state of mind, but four of them had to be readmitted after three months. Nevertheless, one could not consider the treatment to have failed in these or in the other 36 patients since all of them were markedly improved and some of them could be admitted to occupational therapy for the first time in several years of hospitalization.

Thrombosis from Chlorpromazine and Reserpine Treatment.—Grahmann and Suchenwirth (*Nervenarzt.* [no. 5] 30:224, 1959) stated that no references to thrombotic complications were found in the literature on the use of chlorpromazine or reserpine. Because of an impression that thrombotic processes occurred more frequently in psychiatric patients treated with the above-mentioned drugs than in those having other treatment, they studied a series of 338 courses of 100 to 500 mg. daily of chlorpromazine and 60 courses of 3 to 12 mg. daily of reserpine. In only a few patients were the drugs combined. The patients were suffering from endogenous schizophrenia and cyclothymia. The results were compared with those in 464 psychiatric patients who were treated with insulin, electroshock, nonspecific sedatives, and hypnotics.

Thrombosis developed in 11 in the group treated with chlorpromazine and in 2 of those treated with reserpine but in only 2 in the control group. This indicated a clear-cut tendency to thrombosis in patients treated with chlorpromazine and reserpine. No such tendency has been observed in patients undergoing other treatments. Thrombophlebitis occurred especially in those who were severely agitated and needed heavy sedation. Two deaths from pulmonary embolism occurred in patients who were agitated and depressed. The greater tendency to thrombosis in patients treated with chlorpromazine and reserpine might be due to damage of the vascular wall, an influence on the coagulation system, and stasis of the venous circulation, the latter being the most important factor. Countermeasures advised for endangered patients are regular massage of the legs, getting up for a brief period daily, and administration of anticoagulants.

INDIA

Conference on Leprosy.—At the Seventh All-India Leprosy Workers' Conference, held in Bombay in December, the Union Health Minister said that by the end of the third five-year plan the government hoped to cover the whole country with facilities for treatment of this disease, which at present is as widely prevalent as tuberculosis. The governor deplored the lack of sympathy from the public for those affected with leprosy. There is an urgent need for realization on the part of the public that leprosy is a curable disease. Family and social boycott of lepers does not lead to the cure or the eradication of the disease. The president of the conference said that about 1,500,000 lepers are found in India, or more than half of the world's total number of lepers. He urged that leprosy control and eradication be treated as a national problem and that control measures be supported by the people and the government.

Citicide.—Citicide, a pesticide that is much more efficient than DDT and less costly, has been developed in the regional research laboratory in Hyderabad. The raw materials used in this product are chlorine and turpentine, both of which are plentiful. Tests have shown citicide to be highly toxic to a wide variety of pests.

Medical Education.—Addressing the 52nd session of the Medical Council of India, C. S. Patel (*Antiseptic,* vol. 56, Dec., 1959) said that the shortage in the number of physicians even at the end of the second five-year plan period is estimated to be not less than 10,000. In spite of the fact that a number of medical colleges have been started in different parts of the country in recent years, it will be some time before all of them are able to take all the students they have planned for. Even then it is feared that their full number of students will not provide the number of doctors the country needs. It is expected that there will be a total pool of about 80,000 trained graduates in medicine by the school year 1960-1961, if about 2,500 doctors graduate each year. One way of overcoming the shortage would be to expand the capacity of the existing colleges by 25 to 30%, particularly in areas where there are few colleges. Most of the existing colleges are prepared to undertake such an expansion provided they receive financial assistance. It is, however, necessary to ensure that quality is not sacrificed in an attempt to secure a quantitative expansion.

Furazolidone.—A. Massa (*Antiseptic,* vol. 66, Dec., 1959) used furazolidone in the treatment of a series of 71 patients who had acute and chronic intestinal infections. The dosage for adults was 100 mg. four times a day for 6 to 12 days. The patients were considered cured when pathogenic bacilli disappeared from the stools. The pathogens isolated from different patients were Shigella in 8, Salmonella in 16, Entamoeba histolytica in 5, Proteus in 4, and Escherichia coli and Staphylococcus aureus in 12, while 26 suffered from nonspecific diarrhea. After treatment, the pathogens were eradicated and clinical cure obtained in all but two patients with shigellosis, two with salmonellosis, and one infected with Esch. coli and Staph. aureus. Some patients who had proved resistant to antibiotics such as tetracycline, chloramphenicol, and streptomycin responded to furazolidone readily and were cured.

The drug was found to be effective not only in patients infected with a single bacterial species but also in those with mixed infections. All the patients with acute amebic dystentery responded well to the new drug, and follow-up studies revealed absence of any recurrence of infection. Similarly, the group of 26 patients with nonspecific diarrhea showed good results. The attack usually lasted for 24 to 48 hours, while in untreated patients the presence of Salmonella organisms could be demonstrated for 7 to 12 days. Thus bacteriological and clinical cure was obtained in more than 85% of the treated patients. The results were consistent and much superior to those obtained with antibiotics and sulfonamides. The drug was found to be safe and effective even in infants and pregnant women. No cumulative effect was observed. The incidence of unfavorable side-reactions was negligible. A few patients complained of nausea, but the drug therapy did not have to be discontinued in any patient. The drug would be of value in intestinal infection in places where laboratory facilities are lacking or in treating patients with acute cases where delaying treatment till the laboratory reports arrive is undesirable.

NETHERLANDS

Pheochromocytoma.—M. Smits (Thesis, University of Utrecht, 1959) studied the family (39 persons) of a patient with a pheochromocytoma. In the infants and children (17 persons) his examination was limited to the history and the physical examination. The examination of the adults included in addition a glucose-tolerance test, histamine test, and determination of catacholamine excretion in the urine. Four members of this family appeared to have a pheochromocytoma, and in 10 of the deceased members such a diagnosis was likely. This is the ninth family which has been described in which inherited pheochromocytoma occurs. Of the present family, four of the deceased members had diabetes and three of these probably had a pheochromocytoma. Eight members of this family had an enlarged thyroid gland and one of these had a pheochromocytoma. In five of the deceased women of this family, pregnancy had been complicated by an eclampsia-like syndrome. All these women had a pheochromocytoma.

The relationship between pheochromocytoma and diabetes or enlargement of the thyroid gland remained obscure. The simultaneous occurrence of an eclampsia-like syndrome and pheochromocytoma suggested a definite relationship in the pathogenesis of both diseases. Some authors have observed certain differences between true eclampsia and eclampsia in patients with a pheochromocytoma. No marked difference in the excretion of catacholamines could be demonstrated between the members of the present family and a control group of equal number. The results of the present investigation and the reports of earlier observers led the author to conclude that the mode of inheritance of pleochromocytoma is monomeric, dominant, and autosomal, with variable expression in the phenotype.

NORWAY

Pleuropulmonary Manifestations in Lupus Erythematosus.—Jon R. Myhre (*Acta med. scandinav.* 165:55-60, 1959) stated that pleuropulmonary manifestations occurred in 16 of a series of 18 patients with systemic lupus erythematosus. In 10 the changes were bilateral when first demonstrated, and, with one exception, bilateral changes developed in the others. The pleuropulmonary affection often appeared months or years after the onset of the disease but could not be considered a preterminal or terminal event. It might be the first local manifestation of the malady. In the basal portion of the lung uneven and ill-defined opacities of varying size and density appeared together with a pleural effusion of small or moderate size. The diaphragm tended to rise, and the elevation was often unusually marked in proportion to the pleuropulmonary changes. Plate-shaped shadows of the type usually considered to be of an atelectatic nature tended to develop in the basal lung field.

On improvement the diaphragmatic elevation generally persisted much as before. Though the separate components of the pleuropulmonary manifestations in lupus erythematosus were nonspecific, together they constituted a clinicoroentgenologic syndrome that might be more characteristic than was generally appreciated. After later observing another patient with pleuropulmonary lupus erythematosus who was wrongly assumed to have a subdiaphragmatic abscess, the author stated that lupus erythematosus should be included in the list of possibilities to be excluded before making a diagnosis of subdiaphragmatic abscess in obscure cases.

UNITED KINGDOM

Home on the Second Day.—It is the practice at St. Luke's Maternity Hospital, Bradford, to examine weekly, from the 24th week of pregnancy onward, women who have shown abnormalities in previous pregnancies. The main object is early detection and hospitalization of those with hypertension. With a fixed number of beds, however, the hospitalization of these patients could be achieved only by reducing the number of lying-in beds. It was, therefore, decided as an experiment to send home on the second day of the puerperium 25% of the mothers who had their confinement in the hospital.

During the first year of the experiment, 741 women were sent home on the second day under the care of their family doctors and domiciliary midwives. None of the 741 babies died during the first 14 days of life, and it was necessary to hospitalize only 4 of them. Only three mothers were readmitted to hospital, two because of secondary postpartum hemorrhage and one because of pyrexia. Dr. G. Theobald, department head, stated that sending the mothers home on the second day, besides making beds available for urgent cases, prevented the babies from becoming a culture medium for antibiotic-resistant staphylococci so prevalent in hospitals.

Control of Anticoagulant Therapy.—Long-term anticoagulant therapy is being given to an increasing number of patients who have had a myocardial infarction or recurrent arterial or venous thrombosis. The methods of control vary from laboratory to laboratory. If anticoagulant therapy and prophylaxis are to become recognized practice, a standardized and easily performed procedure for determining the coagulability of the blood is essential. Matthews and Walker (*Lancet* 2:1159, 1959) tried the thrombotest introduced by Owren of Norway. This is designed to overcome the disadvantages of tests in current use, mainly the Quick prothrombin time and the prothrombin and proconvertin (P and P) method of Owren and Aas. Four clotting factors in blood are depressed by synthetic anticoagulants derived from coumarin, and only one of them is revealed by the Quick test and only two by the P and P test.

The new test reflects sensitively the reduction in all four factors, vitamin K deficiency, and liver disease. The reagent, which is now available commercially, contains a crude cephalin, which is a weak tissue thromboplastin made from horse brain, and normal plasma from which all the factors depressed by coumarin anticoagulants, but no others, have been removed. The preparation, which is stored in ampuls as a freeze-dried powder, may be stored for many months and is suitable for use with capillary or venous blood. The procedure is to add 0.1 ml. of whole blood to 0.5 ml. of reagent at 37 C and to observe the clotting time. The normal figure is 35 to 40 seconds. The result is expressed as a percentage of normal read from a correlation curve prepared from dilutions of pooled normal plasma. For any one batch of reagent such a curve is valid for any subsequent tests done with this batch. This makes it possible for the manufacturer to supply a correlation curve with each batch of material. The test is simple and reliable, giving clotting times that are reproducible within ±1 second. In routine laboratory work thrombotest is likely to become the procedure of choice in controlling anticoagulant therapy and in following the clotting defect in patients with liver diseases.

Bathing Beach Pollution.—Health officers of holiday resorts along the coasts of Britain have repeatedly reported the contamination of bathing beaches with sewage washed up by tides. An expert committee was set up by the Medical Research Council to investigate the possible hazards to the health of holiday makers from this cause. (Medical Research Council Memorandum 37, Her Majesty's Stationery Office, 1959). Thousands of samples of sea water from over 40 beaches were examined bacteriologically. The results showed that there is virtually no danger of contracting infectious diseases such as enteric fever or poliomyelitis from sea bathing. With the possible exception of a few esthetically revolting beaches, the risk to health of bathing in sewage-contaminated sea water can be ignored. Only one typhoid epidemic has been ascribed to sea bathing, and the circumstances were most unusual. No evidence could be found of an association between poliomyelitis and bathing in sewage-polluted river or sea water. An association between upper respiratory infection and diving is widely accepted, but this association is independent of the bacterial content of the water.

The report states that possibly a million or more salmonellae would have to be swallowed before clinical infection resulted. The isolation of small numbers of organisms therefore need not cause alarm, as many gallons of sea water would have to be consumed to produce an infection. The bathing histories of 150 children living by the sea who contracted poliomyelitis and the same number of controls matched for sex and age were compared. Of 94 patients with paralytic poliomyelitis, 23 bathed during the three weeks before the onset of infection. Among the controls 24 of 94 bathed in the same period. In the nonparalytic group 22 of 56 and 20 of the 56 controls, 20 had bathed. These findings suggest that surf bathing is not associated with poliomyelitis.

Ketosis and Obesity.—Kekwick and co-workers investigated the mechanisms underlying the resistance of fat people to ketosis (*Lancet* 2:1157, 1959). They found that this resistance does not depend on a higher rate of utilization or excretion of ketone bodies by the obese because, after the intravenous injection of sodium β-hydroxybutyrate, one of the ketone bodies found in urine, its rate of disappearance from the blood was the same in obese as in nonobese subjects. Both groups excreted about the same amount in the urine, which was less than 1% of the injected dose. The possibility that the rate of production of ketone bodies is less in the obese was investigated.

Attempt was made to produce ketosis in obese and nonobese subjects by giving them a diet providing 1,000 calories daily of which 90% were supplied in the form of fat. Fourteen obese subjects were able to take this diet for as long as required, whereas seven of eight nonobese subjects were compelled to abandon it by the fifth day because of symptoms referable to ketosis. The obese had a slower rise of blood ketone levels and their urinary excretion was lower than that of the nonobese. In the latter the development of ketonuria and ketosis was preceded by a fall in the fasting blood sugar level, whereas in the obese there was no such fall, or it was minimal.

The authors calculated that the diet provided insufficient carbohydrate to satisfy the needs of the nervous system. They believed that the minimum of 75 Gm. a day required by the brain alone was derived from the dietary fat of the subjects studied and that the obese may be able to turn fat into carbohydrate at a higher rate than the nonobese. This would explain their resistance to ketosis.

CORRESPONDENCE

CRANBERRIES, TURNIPS, AND GOITER

To the Editor:—The first issue of THE JOURNAL this year ushered in 1960 with a pleasantly amusing statement, on page 62, implying that a bit of thought might be helpful in the enactment of laws having to do with the addition of chemical compounds to foods or with the interpretation and enforcement of these laws. The choice of three examples was excellent: aminotriazole, an efficient weed killer and a good antithyroid compound which was detected in cranberries; charcoal, used to color candy; and diethylstilbestrol, used to make capons without a highly paid cockerel surgeon. I heartily agree that consumption of charcoal is unlikely to induce cancer and that we can all continue to eat our burned toast; I agree, too, that diethylstilbestrol, though used for one-quarter of a century and in millions of people, has given no suggestion of being carcinogenic, but I am no expert in these matters. The indictment of cranberries, however, (and perhaps other comestibles to come), because of trace contamination with the weed killer aminotriazole, which has caused such devastation in the cranberry industry, introduces a subject of great personal interest.

It is misleading to refer to an antithyroid compound such as aminotriazole as a carcinogen because this term brings to mind locally acting chronic irritants such as coal tar, which when painted on the skin of animals induces epidermoid carcinoma, and soot, which is more carcinogenic than charcoal, and induction of scrotal carcinoma in chimney sweeps—if such still abound. The so-called carcinogenic action of aminotriazole and related compounds in rats results entirely from the antithyroid effect. Synthesis of thyroid hormone is inhibited (Alexander: *J. Biol. Chem.* 234:148 [Jan.] 1959), profound hypothyroidism is induced, and thereby excessive secretion of thyrotropin from the pituitary is evoked. It is this intense thyrotropic stimulus that causes goiter and, if the stimulus is continued long enough, nodular goiter. These hyperplastic, friable, and vascular glands have sometimes been found associated with nodules of hyperplastic thyroid tissue in the lungs. The implication of metastasis is the reason for suggesting that these nodules are cancers.

Thyroid nodules of this type, usually labeled cancers by the investigators who have studied them, have been induced in rats or mice by several experimental maneuvers which lead to excessive thyrotropic stimulation: iodine-deficient diet, partial destruction of the thyroid by radioiodine, feeding with one or another antithyroid drug, and even partial thyroidectomy. These experiments clearly show that there is no unique carcinogenic action of any one antithyroid compound. It is important, too, that no known antithyroid compound has ever been implicated in the induction of cancers elsewhere in the body, even when fed to rats or mice in large doses for a long time (Morris: *Advances in Cancer Res.* 3:51, 1955, and Isler: *J. Nat. Cancer Inst.* 23:675 [Oct.] 1959).

In order to be designated as carcinoma, thyroid nodules would have to grow autonomously, but no one has yet succeeded in producing such a nodule. When the goitrogenic influence of excessive thyrotropic stimulation is relieved, the nodules regress. This result may be achieved by removing the antithyroid compound from the diet, by giving iodine to iodine-deficient animals, or by giving thyroid hormone in any of the experimental designs. One exception to this generalization is a most interesting type of benign nodule, designated as type γ and described by Isler and Leblond, which apparently is accelerated in growth when iodine is given to animals raised on a diet low in iodine. Autonomous carcinoma of the thyroid has been induced only by serial transplantation of thyroid tissue through several generations of thyroid-deficient animals. The animal experiments forming the basis of the conclusion that aminotriazole causes carcinoma of the thyroid have not been published and are not accessible for evaluation. Apparently they were not extensive and thyroid deficiency was not taken into account and corrected by supplement of thyroid hormone. No antithyroid drug yet studied leads to thyroid enlargement or nodular goiter when thyroid deficiency is prevented.

Several antithyroid drugs, thiouracil, mercaptoimidazole, and derivatives thereof, have been widely used in the treatment of hyperthyroidism in the past 17 years, and no instance of the induction of carcinoma has been encountered. The doses used for this purpose were much larger than the quantity of aminotriazole that would derive from the most highly contaminated cranberries. Still larger doses would be needed in man to reproduce thyroid changes comparable to those induced in rats, and presumably dosage would have to be continued for most of a lifetime. Meanwhile, a progressively enlarging goiter would make its appearance, the subject would lapse into profound myxedema, and the execution of the experiment would be intolerable. It seems inconceivable, therefore, that an antithyroid compound, no matter how potent and however prevalent in food, could ever lead to the development of the sort of thyroid nodules elicited in rats.

In 1949 it was shown that the edible portions of certain vegetables of the mustard family, notably the rutabaga or yellow turnip and the seeds of many others, yielded on extraction L-5-vinyl-2-thiooxazolidone, an antithyroid compound accounting for the goitrogenicity of these foods (Astwood; Greer; and Ettlinger: *J. Biol. Chem.* 181:121 [Nov.] 1949). A rough estimate, based on insufficient data, would suggest that these Swedish turnips may be 100 times as potent as cranberries "badly contaminated" with aminotriazole. The reason for studying these foodstuffs was to determine whether they played a part in the mysterious prevalence of goiter in regions where iodine deficiency was not a cause. In spite of continuing inquiry for several years, I have not been able to trace a single instance of even simple goiter to the excessive ingestion of vegetables such as the rutabaga. It is also of interest that among the first means of inducing the growth of nodules in the thyroids of rats was the feeding of a diet made up of corn meal and rolled oats supplemented with calcium chloride (Hellwig: *Am. J. Cancer* 23:550 [March] 1935) and a mixed diet containing rape seed, which was more effective (Griesbach; Kennedy; and Purves: *Brit. J. Exper. Path.* 26:18 [Feb.] 1945). The lesion has since been induced by the incorporation in the diet of thiourea, thiouracil, methylthiouracil, propylthiouracil, and now aminotriazole.

Before the cranberry episode my associates and I had been looking for an antithyroid compound that might have a longer duration of action than those currently in use for the treatment of hyperthyroidism and Dr. W. E. Mayberry had found that aminotriazole might be such a compound. A single oral dose of 100 mg. inhibited radioiodine uptake by the thyroid of normal and thyrotoxic subjects for 24 hours, which means that there is a possibility of therapy with one dose per day; 10 mg. had only a slight effect. Should experience show the compound to be well tolerated, we will be faced with the anomalous situation that an effective remedy suitable for human use is banned from use in killing weeds.

DEATH FROM USE OF THROAT LOZENGE

To the Editor:—The conclusions in the article, "Anaphylactic Death from Use of Throat Lozenge," by Hesch in The Journal, Jan. 2, page 12, are subject to question. Sudden laryngeal obstructi in the presence of sore throat and hoarseness wi out evidence of previous respiratory difficulty is well-known clinical entity. The edema is usua located in the epiglottis. I have seen two patie who had sore throats but who were not hoarse a were not given medicaments develop sudden c struction requiring emergency tracheotomy. In o of these, the patient was in the operating roo awaiting orderly tracheotomy because the ede was diagnosed when sudden obstruction occurr

The published case report indicates that the p tient had a severe respiratory infection. There w no examination of the larynx prior to administrati of the medicament. The implication that the dru in the throat lozenge were responsible for death I believe, very doubtful.

ANAPHYLACTIC REACTION TO CHYMOTRYPSIN

To the Editor:—Liebowitz and Ritter reported a case of anaphylactic reaction to chymotrypsin The Journal, Jan. 9, page 159. Anaphylac reactions were seen in 3 of 10 patients with canc in another study who received courses of chym trypsin without carrier. The study was recorded the *Proceedings of the Society of Experimen Biology and Medicine* (71:250 [June] 1949).

IDEALS IN MEDICINE

To the Editor:—Who among us cannot recall wi longing the idealisms of our student and inte days or taste with remorse the disillusionment these ideals? Is not the most bitter disillusionme of all that of strife within our own professio Physicians, being human, share with other peop the frailties of sin and failure. They also sha the common desire for acceptance, recognition, an praise. Similarly, they react to oppression, crit cism, and threats to freedom with suspicion an hate. To whom can we turn for solace and su port when we fail, if not to one another.

The fundamental purpose of the physician ha always been and shall ever be to heal the min and body of his fellow man. It would seem incor gruous that, with so powerful an adversary a death, we find energies to devote to petty bickering and puerile lust for political power. Expending energy jockeying for position is neither mature nor intelligent and causes a terrible loss of scientific productivity. Ideals which have motivated most young physicians are being weakened by sarcasms and adverse witticisms. Common codes of courtesy are being destroyed by gossip and defamation.

Are we so insecure we cannot praise our fellow physician, whether he be general practitioner or specialist? Can we not simply refrain from saying anything about him if we cannot say something good? Do we not understand that by innuendoes and faint praise we destroy ourselves? Do we increase our stature by ridiculing the advances of others? Can we not recognize that if we simply ignore those out of step in our midst they must conform or perish? Is it not time that we leave battles to the warriors and politics to the politicians and return to the pursuit of our science and the care of the sick? Our work is the best in life and our ideals should be the finest. We have nothing of which to be ashamed. Let us join hands and daily reaffirm these ideals to ourselves, profess them to all who will listen, and strive ever to live by them.

FOREIGN MEDICAL GRADUATES

To the Editor:—The editorial, entitled "America's Responsibility to the Foreign Medical Graduate," which appeared in The Journal, Nov. 14, 1959, page 1577, deserves wide reading and the approbation of all American physicians and others who are involved in the problems of meeting America's health needs. Since World War II, foreign medical graduates have been an important factor in reducing the gap between the physician population and the general population in the United States. They have also filled many thousands of internships and residencies in the hospitals in this country which would otherwise have been vacant. The National Committee for Resettlement of Foreign Physicians, since its founding in 1939, has provided evaluation and placement services for foreign physicians. These services have been provided primarily for escapees and voluntary immigrants, but help has also been given to a limited number of exchange students. The committee has worked to maintain the high standards of medical practice of the United States, and service has not been given to candidates whose training was considered substandard.

It is with pleasure, therefore, that we read this editorial which places the responsibility for initiating continuing programs that will insure proper educational opportunities for the foreign medical graduate on hospital staffs, administrators, and specialty certifying boards. It is to the interest of all, but especially of the sick in hospitals, to be attended by skillful and well-trained interns and resident physicians. The chaotic, uncontrolled situation of the last decade, in which thousands of unscreened foreign physicians, with untested language facility and unknown professional skills, were accepted for house staff positions, often sight unseen, has been tragic for all concerned. The Educational Council for Foreign Medical Graduates has been helping to solve this problem by screening these persons overseas, but the voluntary immigrant who arrives legally, under federal immigration laws, must be tested and advised in this country for hospital placement and for postgraduate education.

Our committee, with an annual intake of several hundred new foreign medical graduates each year, can provide placement services for only a fraction of the 9,000 to 10,000 foreign physicians in training in the United States. We believe it is now time for one of the national medical agencies with greater resources and staff than ours to face the problems presented by the continuing wave of medical immigrants and exchange students. It is the only way that an orderly guidance and placement program can be provided for all foreign physicians in the United States.

To the Editor:—The editors should be congratulated for suggesting, in the editorial appearing in The Journal, Nov. 14, "America's Responsibility to the Foreign Medical Graduate," a common agreement with regard to the basic eligibility of the fully qualified foreign physician for certification by American specialty boards. Being a graduate physician from India, I am personally concerned, and although it is just a suggestion it will be warmly received by foreign doctors generally.

The banning of foreign graduates from American specialty board examinations has always been the greatest single hindrance to the physicians of my own country in pursuing postgraduate experience and gaining prestige in the United States, mecca of world medicine. Foreign physicians have struggled be intolerable. It seems inconceivable, therefore, that an antithyroid compound, no matter how potent and however prevalent in food, could ever lead to the development of the sort of thyroid nodules elicited in rats.

In 1949 it was shown that the edible portions of certain vegetables of the mustard family, notably the rutabaga or yellow turnip and the seeds of many others, yielded on extraction L-5-vinyl-2-thiooxazolidone, an antithyroid compound accounting for the goitrogenicity of these foods (Astwood; Greer; and Ettlinger: *J. Biol. Chem.* 181:121 [Nov.] 1949). A rough estimate, based on insufficient data, would suggest that these Swedish turnips may be 100 times as potent as cranberries "badly contaminated" with aminotriazole. IRRADIATED BLOOD-TYPING SERUM

To the Editor:—In the first paragraph of a paper entitled "Irradiated Blood-Typing Serum" by Robert M. Jamison in The Journal, Jan. 23, page 334, it was stated that "a search of the literature does not reveal any previous studies of this problem." Dr. David Macht and others have written papers on the reactions of serums which have been radiated with roentgen rays (*Am. J. Roentgenol.* 61:534-542 [April] 1949). While these papers did not deal with blood typing of serums per se, they dealt with the changes which occur in serum when it is irradiated.

USE OF NEOMYCIN IN RETROGRADE PYELOGRAPHY

To the Editor:—In The Journal, page 236, there is a clinical note by Hoffman and Carvalho entitled "Retrograde Pyelography and Use of Contrast Mediums Containing Neomycin." There can be no quarrel with the authors' observations in two parallel series of 100 patients each with retrograde pyelography with and without the addition of 2.5% neomycin as an antimicrobial additive. In each series two patients with bacteremic episodes were observed. These required supplementary antibiotic therapy.

We take issue, however, with the authors' conclusion that "the prophylactic or therapeutic value of the addition of neomycin sulfate to opaque mediums seems insufficient to justify its use at an increased cost." Let us consider the added cost. Agreeing wholeheartedly with the authors that 3 cc. of contrast medium is adequate for visualization of the usual renal pelvis, and allowing for bilateral pyelograms in every case, plus the loading of a syringe with 5 cc. of contrast medium for good measure, we conclude that a 5-Gm. ampul. of neomycin sulfate, which costs a hospital well under $10, will serve 20 patients at an added cost of about 50 cents per patient. Cystoscopy with retrograde pyelography is a sufficiently expensive procedure so that the 50-cent addition is scarcely a major consideration.

More important is the suspicion that the authors have overlooked the virtue of the additive that they used, which is surely not for the purpose of permitting overdistension of the pelvis or of covering up any damage resulting from improper technique. In the years previous to our use of an additive we collectively have seen about four patients with fulminating parenchymal renal infections that seemed possibly to be due to the retrograde introduction of pathogens. A few other patients have been seen in whom a previously uninfected hydronephrotic kidney or a kidney containing calculi presumably became first infected after retrograde procedures. Such a condition, leading to a nephrectomy that would otherwise not have been deemed necessary, kindled our enthusiasm for a study of additives six years ago. Up to the present, several thousand pyelograms later, we have found no cause to regret the use of neomycin and we have, which is more important, felt that the applicability of retrograde pyelography has been extended.

Prior to use of neomycin we were reluctant to use retrograde injection techniques to study a kidney which did not excrete the contrast medium given intravenously if this required an approach through an infected bladder. This is still not done with gay abandon or as a matter of routine, but it has now been done many times without mishap. Hoffman and Carvalho provided no information in respect to presence or absence of infection in their patients, and no special significance can be attached to a series of retrograde pyelograms with reactions in 2% of patients since a complete absence of significant reactions in 100 patients might be accepted with equanimity. Perhaps, if the present Senate investigation persists, the cost of the additive may become even less of a consideration, in which case to ignore the added protection of neomycin in retrograde mediums will be even more penny-wise than it seems now to be. May we respectfully commend its use to all who undertake retrograde pyelography.

to climb the ever narrowing pyramid of residency training for five or six golden years of their lives in the United States, only to find at the end that they are discriminated against. They return home discouraged, disgusted, and without any concrete evidence of their proficiency. This is indeed a sad and traumatic experience. As a result, at least 90% of Indian doctors who plan to further their studies abroad are only too glad to proceed to England where they are accepted with open arms and fair treatment. A small percentage of the rest, to which I belong, prefer to obtain the teaching on this side of the Atlantic, in spite of the obstacles, and come to Canada instead so that they may be exposed to whatever American influences may have permeated here.

It is understandable, and desirable, that the American specialty boards maintain a high professional standard, but banning a foreign doctor, who comes from a fully approved medical school in his own country and has completed the required course of approved graduate residency training on American soil, from the examinations is a bitter instance of discrimination. Foreign students of today will be their countries' mainstay tomorrow. They could return home pro-American, bringing the American culture and way of life. No one can deny that, in these days of international conflict, mutual understanding and cooperation among various peoples of the world *is the only means* for the promotion of world peace.

May I venture to say that if the United States, the mecca of medicine, is to compete successfully with the United Kingdom, Canada, Germany, and even Russia, all of which allow foreign graduates to take their specialty board examinations, it is time that an effort be made to facilitate rather than to hinder the pursuit of undergraduate and graduate training of students from foreign lands.

Montreal, Quebec.

SMOG IN LOS ANGELES

To the Editor:—The article on smog by Motley and co-workers in THE JOURNAL, Nov. 14, 1959, page 1469, contains a common misstatement which should be corrected. The major source of smog in Los Angeles is industry, not automobiles as stated. Proof of this statement follows. I might add that the automobile is used as a convenient red herring to shield industry.

The figures are in tons per day. Automobile figures include trucks and buses. In the San Francisco bay area figures are from the Air Pollution Control District; Jan. 16, 1959. These figures are more reliable than those for Los Angeles, since the county is more compact.

Even though these figures show automobile to constitute less than half of the contributions they are completely unreliable for the followin reasons: 1. Automobile statistics are based on gasoline consumption for the entire county. Obviousl many automobiles are in nonsmoggy areas. The Ai Pollution Control District estimates that th automobile's contribution for the center of th county is only one-fifth of the total. 2. While automobile gas consumption remains fairly constant fiv days a week, on Saturday and Sunday the smo pattern should be markedly different. This is not s Even on these days smog clouds originate from th same industrial refinery area. 3. The figures fo industry are inaccurate for several reasons: (a while a chimney is being monitored the owners ca control its emanations; (b) the figures are based o a yearly average, but industrial contaminatio comes in peaks. For instance, power plants burn o only when gas is not available. This is brought o by the Air Pollution Control District news release of April 30, 1959, in which it was stated tha enforcement of rule 62 would prevent as much a 800 tons of sulfur dioxide on a day of peak use. Th figure previously given for total sulfur from a sources was only 550 tons per day; (c) proof i available that refineries contaminate the air primarily at night (one observer took photograph around the clock to demonstrate this).

Component Parts of Smog

	Petro-chemical Industry	Combustion and Fuel Oil	Metal-lurgical Industry	Automotiv
Hydrocarbons	572	1	17	579
Sulfur	234	177	104	30
Nitrogen oxides ..	55	86	00	237
Total	861	264	121	846
Grand total ..	1,246 vs. 846			

The figures for the Los Angeles area are as follows:

	Industry and Fuel Combustion	Petroleum Refining, Storing, and Marketing	Automotive
Hydrocarbons	186[*]	250[*]	550-1,100[§]
Sulfur oxides	400[*]	150[‡]	34-48[§]
Nitrogen oxides	260[†]	56[‡]	137-412[§]
Organic gases	176[*]	2[*]	27[*]
Total of averages	1,022	458	1,119
Grand total	1,480 vs. 1,119		

Circumstantial evidence includes the followin facts: 1. Smog originated in 1942, during gasolin rationing but concurrently with the introductio of a new cracking process at the refineries. 2. Vernon, an industrial district, has more smog alerts tha downtown Los Angeles. 3. There are no "halo" patterns over freeways and automobile raceways. 4. Aerial views show smog originating at industrial sources. 5. If the automobile contribution were as important as supposed, why would smog not form over large accumulations of cars, such as at the Rose Bowl parade and at Santa Anita race track? 6. Why does smog always originate in the same industrial refinery areas?

This is still not done with gay abandon or as a matter of routine, but it has now been done many times without mishap. Hoffman and Carvalho provided no information in respect to presence or absence of infection in their patients, and no special significance can be attached to a series of retrograde pyelograms with reactions in 2% of patients since a complete absence of significant reactions in 100 patients might be accepted with equanimity. Perhaps, if the present Senate investigation persists, the cost of the additive may become even less of a consideration, in which case to ignore the added protection of neomycin in retrograde mediums will be even more penny-wise than it seems now to be. May we respectfully commend its use to all who undertake retrograde pyelography.

MEDICAL LITERATURE ABSTRACTS

INTERNAL MEDICINE

Metalloenzymes and Myocardial Infarction: III. Lactic Dehydrogenase Activity of Serum—A Determinate Diagnostic Measure. P. J. Snodgrass, W. E. C. Wacker, E. C. Eppinger and B. L. Vallee. New England J. Med. 261:1259-1266 (Dec. 17) 1959 [Boston].

Interest in the diagnostic value of the metalloenzymes in myocardial infarction began when a marked increase in serum copper value after in*farction was observed in 1952. Later the serum* concentration of another metal, zinc, was investigated. Since zinc is a component of lactic acid dehydrogenase (LDH), the activity of this enzyme was studied in the serum of patients with acute myocardial infarction, and a marked increase in activity was found. Assay of the serum LDH proved to be a simple, precise, and accurate method for the diagnosis of acute myocardial infarction. The authors investigated the serum LDH activity in 1,250 tests on 500 patients hospitalized in the Peter Bent Brigham Hospital, Boston. There was no selection of cases other than that conditioned by the judgment of the physicians in charge, who requested determinations whenever the information was deemed potentially useful in differential diagnosis. In 308 of the 500 patients the measurements were requested primarily as diagnostic aids in various cardiovascular diseases. The remaining 192 cases represented a wide spectrum of other medical diseases seen at a general hospital.

All LDH measurements were performed with a Beckman DU spectrophotometer at 23 C and later with a simple, portable, monochromatic, ultraviolet photometer. In every patient in whom acute myocardial infarction was proved, and in whom measurements were made between the 2nd and the 10th day after onset, the serum LDH activity was elevated significantly. False-negative results did not occur in any of the 28 cases proved by autopsy or in 66 patients with electrocardiograms considered diagnostic by established, classic criteria. Moreover, 4 patients with LDH activity in the normal range, who were thought to have sustained an acute myocardial infarction by other criteria, were proved at autopsy not to have the disease. An elevated serum LDH activity is, therefore, a necessary confirmatory criterion for the diagnosis of acute myocardial infarction. The addition of this method to those currently employed in the diagnosis of acute myocardial infarction should permit the diagnostic accuracy to approach 100%. The *existence of increased LDH activity always denotes* serious disease, and should lead to further diagnostic search for the underlying cause.

Glycogen Liver in Diabetes Mellitus: An Iatrogenic Acute Abdominal Condition. A. Schotte, H. K. Lankamp and M. Frenkel. Nederl. tijdschr. geneesk. 103:2258-2262 (Nov. 7) 1959 (In Dutch) [Amsterdam].

The authors present the history of a 40-year-old woman who had diabetes mellitus that was difficult to control. She had been receiving antidiabetic treatment for 7 years, and at the time she was hospitalized, in a precomatose condition, she had been maintained on dietetic treatment and on 40 units of a delayed-action insulin daily. Two days previously she had awakened with an abdominal pain, so severe that morphine had to be administered. The following day she began to vomit and reduced her insulin dose to 10 units. She was brought to the hospital when she became increasingly comatose. Examination revealed hyperglycemia and diabetic acidosis, with sugar, acetone, and diacetic acid in the urine. With the administration of 180 units of insulin (in the first 24 hours) and of isotonic sodium chloride solution, the diabetic *acidosis improved rapidly*, but the appetite remained poor and the abdominal pain persisted. Subsequently, the patient had several recurrences of the attacks of abdominal symptoms, and painful hepatomegaly became increasingly evident. When among other diagnoses a rapidly growing metastasis from a sarcoma was suspected, laparotomy was performed. It was found that the liver contained excessive deposits of glycogen and some fat, and these changes were believed to be the cause of the symptoms.

The patient was freed from her attacks when she was given an additional dose of insulin at midnight. It is believed that the attacks were probably of iatrogenic origin, in that they were probably

The place of publication of the periodical appears in brackets preceding each abstract.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by persons in continental United States or Canada who subscribe to its scientific periodicals. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover 1956 to date for English language and 1958 to date for foreign language journals. No photoduplication services are available. No charge is made to members, but the fee for others is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

brought on by an overdosage of invert sugar and of insulin, resulting in a temporary exhaustion of the glycogenolytic enzyme system of the liver. Injection of either epinephrine or glucagon during the recovery phase did not reveal any permanent abnormality of the glycogenolytic system. Knowledge of this syndrome will prevent unnecessary laparotomy.

Long-Term Results in Corrected Fibrillation. P. Broustet, H. Bricaud, P. H. Blanchot and J. C. Chignon. Semaine hôp. Paris 35:3085-3089 (Nov. 18) 1959 (In French) [Paris].

The authors report the long-term results in 186 patients in whom conversion of chronic atrial fibrillation was obtained with quinidine treatment. The duration of fibrillation prior to treatment varied from several weeks to several months. It was possible to sustain normal sinus rhythm in 163 of the patients for periods ranging from 3 months to 6 years with small maintenance doses of quinidine, regardless of the origin of fibrillation. There was an evident clinical improvement in all these patients. The degree of improvement was more marked in patients with less severe cardiac involvement. In 41 of the 186 patients the discontinuation of quinidine treatment after restoration of normal sinus rhythm was followed by a recurrence of fibrillation, which was associated, particularly in those with mitral stenosis, with exacerbation of cardiac insufficiency or with the appearance—or reappearance—of arterial embolism. Normal sinus rhythm was again restored in some of these patients with the reinstatement of larger doses of quinidine. The comparison between 2 identical groups of patients with atrial fibrillation, one of which was given quinidine treatment, while in the other this therapy had not been tried or had not been successful, showed that the probability of survival and of the return to normal function was far better in the treated group.

Studies in Man on Hyper- and Hypoaldosteronism. S. R. Hill Jr., J. F. Nickerson, S. B. Chenault and others. A. M. A. Arch. Int. Med. 104:982-994 (Dec.) 1959 [Chicago].

The authors determined the aldosterone, 17-ketosteroid, and 17-hydroxycorticosteroid levels in the urine and the sodium and potassium levels in the serum and urine during control periods, during periods of inhibition of adrenal cortical secretory activity by Amphenone B [3,3-bis (*p*-aminophenyl)-2-butanone], and during periods of stimulation by sodium withdrawal and potassium administration in 5 patients with secondary hyperaldosteronism, 1 patient with primary hyperaldosteronism, and 1 patient with primary hypoaldosteronism. Similar studies were made in normal persons for comparison. Of the 5 patients with secondary hyperaldosteronism, this condition resulted from intercapillary glomerulosclerosis (Kimmelstiel-Wilson syndrome) in 1, from congestive heart failure in 2, and from cirrhosis of the liver in 2. The results of the studies in these 5 patients showed that Amphenone (1 Gm. dissolved in 1,000 cc. of 5% dextrose in water) may be administered intravenously for at least 23 days without toxic effects, except when severe disease of the liver is present. In the patient with the Kimmelstiel-Wilson syndrome, Amphenone, administered in this manner, induced a twofold increase in sodium excretion, a marked water diuresis, and a clinical remission beginning 10 days after the institution of the therapy. Glucocorticoid suppression also began about 5 days after the administration of Amphenone was started. In the 2 patients with congestive heart failure, sodium and water diuresis failed to occur even though elevated urinary aldosterone levels were reduced to normal by the administration of Amphenone. This implies that other abnormalities, presumably hemodynamic, are more important than elevated aldosterone levels in causing and maintaining edema in these patients with congestive heart failure.

The patient with primary hyperaldosteronism, a 54-year-old man, was completely asymptomatic except for severe hypertension of 12 years' duration; the hypertension was completely ameliorated by the subtotal removal of the bilaterally hyperplastic adrenals, which emphasizes the necessity of correct diagnosis and definite surgery. A decreased serum potassium level assumes major diagnostic importance in patients with hyperaldosteronism, as symptoms suggesting hypopotassemia may be absent, and urinary aldosterone levels may either not be consistently elevated or be elevated secondarily. The use of antihypertensive drugs which cause potassium diuresis and consequent hypopotassemia makes this diagnostic index also open to question. However, in most patients treated with these compounds, the serum sodium concentration is low, rather than normal or high as seen in patients with hyperaldosteronism. If, at the time of adrenal exploration, an adrenal adenoma is found, the surgeon's course of action is clear. If, however, the adrenals appear normal, the diagnosis should have been well enough established beforehand to be able to advise subtotal adrenalectomy despite this. Repeated determination of serum sodium and potassium levels still remains the most satisfactory method now readily available for making such a diagnosis.

The patient with primary hypoaldosteronism, a 62-year-old man, showed abnormalities in potassium metabolism in addition to relative primary deficiency of aldosterone. Patients with total bilateral adrenalectomy, who are being maintained on glucocorticoids alone, do not always manifest abnormalities in potassium metabolism. It is possible, however, that the follow-up has not been long enough or that the dietary conditions have not been provocative enough for these patients to show this syndrome. The production of a hypothetical antialdosterone substance could theoretically produce electrolyte abnormalities identical to those reported This patient could not tolerate either severe sodium restriction or potassium loading, unless desoxycorticosterone was simultaneously administered. His condition, however, was fairly well maintained on a moderately high sodium and moderately low potassium intake, without added steroids. The urinary 17-hydroxycorticosteroid excretion of the patient did not increase on prolonged sodium restriction. The question as to how much of the patients' clinical picture of shortness of breath and musculoskeletal pains can be attributed to the inadequate aldosterone response and how much to renal disease cannot be completely answered, although the results of the studies favor the former as the dominant cause of the findings.

Diabetic Nephropathy: A Clinical and Pathologic Study Based on Renal Biopsies. D. D. Gellman, C. L. Pirani, J. F. Soothill and others. Medicine 38:321-367 (Dec.) 1959 [Baltimore].

In 1936 Kimmelstiel and Wilson described peculiar hyaline masses in the centers of the glomerular lobules in 8 elderly patients, 7 of whom had diabetes. They called the process "intercapillary glomerulosclerosis," but since their illustrations emphasized the circular cross sections of the masses, the term "nodular" was used by some investigators to distinguish the lesion from other varieties of glomerulosclerosis. In addition to the nodular lesion, the term "intercapillary glomerulosclerosis" has been applied to a diffuse process which frequently involves the glomerulus in diabetics, for the so-called exudative lesion, and even for a clinical syndrome.

Three main points have been at issue: (1) whether the lesion is specific for diabetes; (2) whether it is really the cause of the clinical syndrome which Kimmelstiel and Wilson found in their patients; and (3) whether the lesion is intercapillary or not. The authors describe clinical and pathological studies on 53 patients with diabetes mellitus. Each patient had at least one renal biopsy; some had more than one. At the time of each biopsy clinical and laboratory investigations were made, and the results correlated with the severity of the histological lesions. Nine patients subsequently came to autopsy. All the histological features which have been described in the kidney in diabetes mellitus were seen in this series.

Diffuse diabetic glomerulosclerosis was present in 75% of the biopsies and all the autopsies. The lesion consisted of a uniform deposition of abnormal hyaline material, rich in mucopolysaccharides, in and around the capillary walls, with early narrowing and eventual obliteration of the capillary lumens. Nodular diabetic glomerulosclerosis was the glomerular lesion next in frequency to diffuse diabetic glomerulosclerosis. It was found in 48% of the biopsies and in 8 of the 9 autopsies. Nodular glomerulosclerosis of the diabetic type was not found in more than 600 renal biopsies in nondiabetic patients.

Nodular diabetic glomerulosclerosis was always accompanied by diffuse diabetic glomerulosclerosis, but the diffuse lesion sometimes occurred alone. When the severity of nodular diabetic glomerulosclerosis was plotted against the height of the diastolic blood pressure, the amount of proteinuria, the levels of serum urea nitrogen, serum creatinine, and serum albumin, or the urea or creatinine clearance, a constant pattern of relationship was found. The presence of nodular glomerulosclerosis was associated with abnormal findings in each test, but there was no tendency for the test to become increasingly abnormal as nodular glomerulosclerosis becomes more severe. Similarly the presence of nodular glomerulosclerosis was associated with an increased incidence of episodes of ketosis, of diabetic retinopathy, and of edema and the nephrotic syndrome, but the incidence did not increase further with increasing severity of nodular glomerulosclerosis.

By contrast, increasing severity of diffuse diabetic glomerulosclerosis was closely correlated with increasing diastolic blood pressure, proteinuria, and serum urea nitrogen and creatinine levels; with decreasing serum albumin levels and urea and creatinine clearances; and with increasing incidences of ketosis, retinopathy, edema, and the nephrotic syndrome. It was suggested that the abnormalities associated with the presence of nodular glomerulosclerosis are, in fact, caused by the diffuse glomerulosclerosis which invariably accompanies the nodular lesion. It was concluded that nodular glomerulosclerosis, the "Kimmelstiel-Wilson lesion," though of great diagnostic value, is of little functional importance. The nephrotic syndrome combined with renal failure in diabetes is not caused by this lesion and, therefore, should not be called the Kimmelstiel-Wilson syndrome. These changes in renal function are caused by diffuse diabetic glomerulosclerosis and by the associated arteriolar and tubular lesions.

Parathion Intoxication with Complicating Cardiac Arrhythmia: Three Cases. T. O. Iversen. Ugesk. læger 121:1735-1736 (Nov. 5) 1959 (In Danish) [Copenhagen].

In 2 of the 3 cases reported of Parathion intoxication combined with cardiac arrhythmia, the atrial fibrillation disappeared with other symptoms of the poisoning. In the third case, however, the premature ventricular contractions and variations persisted after other symptoms of acute intoxication had disappeared, but the cardiogram became normal after digitalization. Intoxication with Parathion depends on the ability of the substance to inhibit the activity of the organism's cholinesterases. The arrhythmia is ascribed to the action of acetylcholine.

Acute Intermittent Porphyria: A Family Study. D. H. Cannow, E. H. Morgan and G. A. Sarfaty. Australasian Ann. Med. 8:267-271 (Nov.) 1959 [Sydney, Australia].

The incidence of acute or latent porphyria was studied in several interrelated family groups after the death from acute intermittent porphyria of a 27-year-old woman. Each family group was personally visited, and a medical history of each member was obtained. Evening and morning urine specimens were collected and tested for porphobilinogen. Stool specimens were obtained from 36 members of the total family. Both urine and feces were stored at −20 C. and quantitative estimations were made within 2 to 4 days by the Watson and Schwartz technique. The results were interpreted according to 3 categories, namely, acute porphyria (presence of clinical and chemical stigmata), latent porphyria (excretion of abnormal quantities of porphobilinogen and porphyrins without clinical symptoms), and normal (absence of clinical symptoms and of urinary or fecal excretion).

Acute porphyria was diagnosed in 5 members of the total family, and latent porphyria was diagnosed in 6, including the father of the original patient whose death gave way to this investigation. The incidence of porphyria in this family is compatible with inheritance by a non-sex-linked dominant gene (5 of the porphyric members were male and 6 were female). The porphyric disorder was found in 3 successive generations, with transmission from father to daughter and from mother to son. The highest incidence was in the third generation, in which 9 out of 16 members had either acute or latent porphyria. The findings in this study are clinically, genetically, and biochemically identical with those of Waldenström's familial studies in Sweden.

Occurrence of Miliary Tuberculosis as Malignant Neoplastic Disease. B. Zachau-Christiansen. Ugesk. læger 121:1721-1728 (Nov. 5) 1959 (In Danish) [Copenhagen].

The author discusses the difficulty in diagnosis of acute generalized tuberculosis, especially in older persons, in whom the clinical picture can suggest a hopeless case of cancer. French authors speak of a "forme pseudoneoplasique." The differential diagnosis between malignant neoplastic diseases and malignant tuberculous diseases will always be so difficult that all diagnostic and therapeutic attempts must be made. In uncertain cases the final diagnosis should be established by biopsy or operation. In the first of the 3 cases described, the diagnosis was based on pathologicoanatomic examination and cultivation of tubercle bacilli; in the second case, on the histological picture; and in the third case, on the microscopic cellular picture. The cases reported to date indicate that, if there is to be hope of helping this category of patients, modern antituberculous agents must be applied on clinical suspicion alone. Therapy of miliary tuberculosis should consist in treatment with PAS, streptomycin, and isoniazid in largest possible doses. Continued treatment for at least 9 months is recommended; Lesorbe and Oury advise up to 3 years.

Occlusion of the Hepatic Veins in Man. R. G. F. Parker. Medicine 38:369-402 (Dec.) 1959 [Baltimore].

Occlusion of the hepatic veins (Chiari's or Budd-Chiari's syndrome) is comparatively rare, and the literature on this condition consists mostly of individual case reports. In studies at the Bernhard Baron Institute of the London Hospital, the author was able to study a large number of cases, including 149 previously reported, in which there was evidence of hepatic vein occlusion during life and in which the diagnosis was confirmed at autopsy, as well as 15 others from the London Hospital. Hepatic vein occlusion occurs with approximately equal frequency in either sex. It may occur at any age, but is especially common in the third and fourth decades. The duration of symptoms has varied from 2 days to 23 years. In only 20% of the patients did the illness last less than 1 month; in 55% it lasted 3 months or longer, and in 25% a year or more. In cases of short duration there were often vague prodromal symptoms, and the vascular lesions were often more chronic than was anticipated from the clinical history.

Hepatic vein occlusion may present in one of 5 ways: (1) in about 76% of cases as a subacute or chronic illness dominated by severe ascites; (2) as an acute illness with more or less evidence of hepatic parenchymal failure (4%); (3) as obstruction of the inferior vena cava with symptoms referable to the liver appearing later (16%); (4) as hematemesis (3%); and (5) rarely as cachexia and pain from primary hepatic carcinoma dominating the picture (1%). Ascites appears in 93% of cases, hepatomegaly in 70%, epigastric pain in 54%, edema in 56%, and distended abdominal veins in 55%. Splenomegaly and jaundice are found in 30 and 28% respectively. The majority of cases proved fatal, and there is little evidence to suggest that recovery from occlusion of the major hepatic veins occurs, once symptoms have been produced. Hepatic parenchymal failure and surgical shock are among the immediate causes of death.

At the London Hospital the autopsy incidence of symptomatic hepatic vein occlusion was 0.061%, in that 18 cases were detected among 29,720 autopsies in which the liver was examined. The cause of the hepatic vein occlusion was established in 49 of 164 symptomatic cases (about 30%). In the remaining 115 symptomatic cases (70%), the cause was either unknown or inadequately established. The etiology of the occlusion was also known in most asymptomatic lesions. Of the known causes, polycythemia rubra vera, hypernephroma, and tumors of the inferior vena cava have been most frequently reported. In some of the cases of uncertain etiology, a general disorder of blood coagulation may have been present. In others, endogenous or exogenous toxins may have damaged the hepatic veins or led to thrombosis within them. Poisoning by pyrrolizidine (Senecio) alkaloids is discussed, but it is considered unlikely that these substances have been responsible for more than a very small proportion of cases.

Stenosis of the inferior vena cava accompanied the hepatic vein occlusion in 30% of the idiopathic cases and in many of those with known etiology. Occlusion of the ostiums of the hepatic vein existed in 44% of the idiopathic cases, but in most of these cases more distally situated lesions also existed. While in most cases the vascular lesions are explicable on the basis of thrombosis alone, an initial endophlebitis cannot be excluded on morphologic grounds.

The acute stages of hepatic vein occlusion are characterized by centrilobular congestion and either destruction or atrophy of the centrilobular parenchyma. The acuteness of the lesion, as judged histologically, often correlates poorly with the length of the clinical history, and lesions of different ages are usually found at death. With long-standing obstruction, centrilobular and later diffuse fibrosis and regeneration, at first periportal and later nodular, appear. Finally, cirrhosis may develop. Seven cases of primary hepatic carcinoma complicating hepatic vein occlusion have been reported.

The spleen is enlarged in about 25% of cases with hepatic vein occlusion. Evidence of portal hypertension has been reported. Secondary thrombosis of the portal veins occurs in about 20% of cases. After occlusion of the hepatic veins, alterations in the intrahepatic blood flow may occur, and the possibility of retrograde flow in the portal veins is discussed.

Study of Pulmonary Alterations in Patients with Leukemia. E. Tortarolo, G. Büchi and S. Chiarle. Minerva med. **50**:3507-3523 (Nov. 3) 1959 (In Italian) [Turin, Italy].

The authors report on 64 patients with leukemia, in whom there were also pulmonary manifestations of the disease. Acute leukemia was present in 28 patients, the chronic myeloid variety in 16, and the chronic lymphatic variety in 20. There were lesions in the parenchyma of the lung alone in 44 patients (70%). Nodular masses were mostly observed in lymphatic leukemia, and thickened masses in the acute variety. The involvement of the pleura was mostly found in lymphatic leukemia, and thickening of the base of the lung in the myeloid variety.

Histological examination of the material obtained from 10 patients at autopsy revealed enlargement of hilar and mediastinal lymph nodes in 5 instances, hemorrhagic areas in 3, diffuse thickening of the lung tissue in 4, edema in certain parts of the lung in 3, presence of enlarged nodules and nodes in 8, and vascular thrombosis of the medium-caliber vessels in 1. There were some indications that the pulmonary manifestation of systemic leukemic disease in a few instances set in early. However, the timing of the pulmonary manifestation in most patients could not be demonstrated.

SURGERY

Pituitary Tumors in Patients with Cushing's Syndrome. R. M. Salassa, T. P. Kearns, J. W. Kernohan and others. J. Clin. Endocrinol. **19**:1523-1539 (Dec.) 1959 [Springfield, Ill.].

Presence of pituitary tumor either before or after adrenalectomy was indicated by roentgenologic findings at the Mayo Clinic in 12 of the 122 patients who had adrenocortical hyperfunction (Cushing's syndrome) associated with adrenocortical hyperplasia. The group included 9 women and 3 men, and the ages varied from 21 to 60 years. Cushing's syndrome was severe in 8 patients, moderate in 1, and mild in 3. The duration of the illness varied from 1 to 10 years in 10 of the patients; the disease had developed in the other 2 patients within a period of 4 months before the examination. The urinary excretion of corticosteroids was above normal in each of the 12 patients, and the urinary excretion of 17-ketosteroids was increased in 5. Microscopic examination of the pituitary tumor was carried out in 7 of the 12 patients, and it demonstrated that all lesions were chromophobe adenomas. One tumor was malignant with extracranial metastatic lesions, but the other 6 showed no clear histological evidence of malignancy. Six patients had ocular disorders. Five patients had defects in the visual fields, 3 of them having involvement of motor nerves to the eye. One patient had paralysis of the 3rd, 4th, 5th, and 6th cranial nerves without involvement of the visual pathways.

The occurrence of pituitary tumor, sufficiently large to cause enlargement of the sella turcica in this group, suggests that there is likely a causal relationship of the pituitary tumor to Cushing's syndrome. Nine of the 12 patients had some clinical evidence of a pituitary tumor before adrenalectomy. The clinical course of 5 patients treated by total adrenalectomy and of 3 of 5 patients treated by subtotal adrenalectomy suggested that adrenalectomy favored the development of the pituitary tumor. Cutaneous melanosis developed in 8 of the 10 patients who survived adrenalectomy for more than 3 months. Its persistence despite adequate or excessive replacement therapy with cortisone suggests an uncontrolled excessive secretion of some type of pigmentary hormone. The usual and effective treatment of Cushing's syndrome associated with adrenocortical hyperplasia at the Mayo Clinic during the past 14 years has been total or radical subtotal adrenalectomy, despite the possibility that the remote cause of the disease may reside outside the adrenal cortex.

Hypophysectomy in the Treatment of Breast Cancer. A. G. Jessiman, D. D. Matson and F. D. Moore. New England J. Med. 261:1199-1207 (Dec. 10) 1959 [Boston].

The authors report on 52 women and 1 man, between the ages of 32 and 69 years, who underwent hypophysectomy as part of their treatment for metastatic cancer of the breast at Peter Bent Brigham Hospital in Boston. Most of the patients had been treated previously with local x-ray and hormone therapy, and each of the patients had undergone castration. Total excision of the anterior pituitary body was the aim in every patient. The pituitary stalk was cut just above the gland, but was not clipped or cauterized. After extracapsular dissection of the gland it was possible in the last half of this series to remove the gland intact. Intravenous administration of 17-hydroxycorticosterone (compound F) was started at the time of stalk section and continued, so that 50 mg. was given by the time operation was completed. Intravenous administration of 17-hydroxycorticosterone was continued in the postoperative period, so that a total dose of 200 to 250 mg. was administered by this route during the first 24-hour period. Cortisone was administered in doses of 200 mg. per 24 hours the first 2 or 3 days after the operation, and then decreased at the rate of 25 mg. every second day until a maintenance level of 50 mg. per day was reached, usually in 7 to 10 days. All patients except one required maintenance treatment with U. S. P. thyroid in doses of 0.06 to 0.12 Gm. (1 to 2 grains) daily. This need for thyroid replacement did not appear for 5 or 6 weeks.

Among the 53 patients, in only one is it believed that life was shortened by the hypophysectomy. This patient had bilateral pulmonary and pleural disease and died of aspiration pneumonitis on the 7th postoperative day. The operative mortality thus was less than 2%. Clinical results have been reported on 45 of the 53 patients. Excellent results were obtained in 10 patients (22%), with an average duration of remission of 12 months and an average survival period of 15 months. By excellent is meant a significant measurable regression in the disease with demonstrable healing of metastatic lesions. Fair results were obtained in 17 patients (38%), with an average duration of remission of 6 months and an average survival period of 11 months. By fair is meant obvious halting of the natural progress of the disease, with no detection of new lesions. Poor results, with not alteration in the progressive worsening of the patient's condition or with a temporary halt in the growth of some lesions accompanied by simultaneous appearance of new lesions, were obtained in 18 patients (40%), with an average survival period of 3½ months. The course of the disease thus was favorably altered in 27 patients (60%). Two additional women in whom the disease developed during pregnancy were treated by hypophysectomy. Both women delivered normal infants; one patient died subsequently of causes unrelated to hypophysectomy or to carcinoma of the breast; the other patient died of the disease one month after the delivery.

The results obtained suggest that prolongation of the patient's life and symptomatic relief during this period of remission will best be served when hypophysectomy is employed in treatment of early metastatic spread of cancer of the breast as opposed to diffuse or terminal disease. The most favorable patient for hypophysectomy appears to be a woman who is less than 10 years postmenopausal, with disease involving the skin, lymph nodes, skeleton, or lung, but not the brain, liver, or the viscera generally, who has good cardiac, renal, and pulmonary function, and who has responded well to castration or had some other evidence of a hormone-sensitive tumor. The endocrine changes resulting from the operation are related both to the completeness of the procedure and to the subsequent clinical course of the patient. The significance of the observed resurgence of estrogenic activity with exacerbation of the disease is discussed. Surgical hypophysectomy has become a safe procedure and a valuable addition to the methods of therapy available in the treatment of advanced cancer of the breast.

Traumatic Infarction of the Anterior Lobe of the Pituitary Gland. P. M. Daniel, M. M. L. Prichard and C. S. Treip. Lancet 2:927-930 (Nov. 28) 1959 [London].

The authors, having been unable to find a description of an acute massive lesion of the anterior lobe of the pituitary gland caused by trauma, record 5 cases in which extensive infarction of the anterior lobe, due to rupture of the pituitary stalk, was found at autopsy shortly after head injury. A 6th case is recorded which showed the reverse picture —i. e., an anterior lobe without infarction despite a traumatic rupture which had separated the pituitary from the hypothalamus. In all these cases the pituitary was embedded in paraffin, and serial sections were cut.

The authors believe that, in the 5 patients in whom the infarct in the anterior pituitary was large, the infarction was due to rupture of the pituitary stalk at the time of the accident. Their reason for this belief is that the extent and situation of the infarct, together with the disribution of the small areas of surviving anterior-lobe cells, provide a picture which is remarkably similar to that which they observed in the pituitaries of patients who survived for only a short time after surgical pituitary-stalk section. Moreover, they saw essentially the same picture of extensive anterior-lobe infarction in laboratory animals killed shortly after pituitary-stalk section.

The anterior lobe is supplied solely by the hypophysial portal vessels, which arise in and run down the free part of the pituitary stalk. These are inevitably interrupted when the stalk is severed, and thus an extensive area of ischemic necrosis develops, mainly centrally, in the anterior lobe. A relatively small area of the anterior lobe, adjacent to the neural tissue, survives, because this area is supplied by the short portal vessels which arise in the lower infundibular stem (a continuation of the neural tissue of the stalk, which is actually embedded in the anterior lobe).

The 6th case, in which the anterior lobe of the pituitary was not infarcted, provided interesting information about the blood supply of the pituitary stalk and the anterior lobe. The pituitary stalk region was carefully examined. The stalk itself was found to be intact and continuous below with the pituitary, but its upper extremity had been torn away from the hypothalamus. As a result of the high level of the tear, the primary capillary bed and the portal vessels within the stalk were undamaged. The superior hypophysial arteries supplying the stalk were intact. Thus, the trauma which had produced separation of the pituitary from the brain had not interrupted the blood supply to the anterior lobe of the pituitary.

Dermoid Cysts of the Nose: A Review of 39 Cases. C. C. Nydell Jr. and J. K. Masson. Ann. Surg. **150**:1007-1016 (Dec.) 1959 [Philadelphia].

The authors review the literature on dermoid cysts of the nose and the 39 cases seen at the Mayo Clinic from 1915 to 1956 inclusive. The etiology of the dermoid cyst of the nose is closely involved in the embryologic development of the nose. Although the lesion is rare, recognition and differential diagnosis of it are not difficult. Treatment, however, has tended to be inadequate.

Among the 39 Mayo Clinic cases, male patients outnumbered female 23 to 16. In 23 cases the deformity had been noted at birth and had progressed. In 7 cases the time of onset was uncertain, which suggests that the cyst may have presented early in life. The commonest presenting complaints were swelling and a discharge. Despite the early appearance of the lesion, very few patients received definitive treatment early in life. The ages at which treatment was sought at the clinic ranged from 5 months to 51 years. In 26 cases a history of previous surgical treatment was obtained. In others, treatment with salves, caustics, and antibiotics had given inadequate results. In 2 of the 39 cases saddle-nose deformities developed, which necessitated subsequent plastic repair.

Treatment at the Mayo Clinic in the earlier cases was destruction of the cyst-lining epithelium by excision, or frequently by electrocautery. In the last decade the trend has been toward thorough anatomic dissection and total excision of the cyst, and primary closure of the defect. Complete excision, the optimal treatment for congenital dermoid cysts, means removal of all remnants, ramifications, and fistulas, for the cyst will recur if removal is not complete. Some cases are matters of simple excision; others require extensive dissection. Outlining of the tract and cyst with dye may simplify the task of finding all remnants. Facial deformities secondary to the extensive surgical measures sometimes necessary, or those caused by the growth of the cyst itself, may be corrected at the primary procedure or at a later date. If the supporting structures are missing, the use of local flaps or grafts of cartilage or bone, or a combination of these measures, may be required.

Cervical Diskography: A Contribution to the Etiology and Mechanism of Neck, Shoulder and Arm Pain. R. B. Cloward. Ann. Surg. **150**:1052-1064 (Dec.) 1959 [Philadelphia].

Cloward points out that diskography was first used by Schmorl in 1929, and was presented for clinical diagnosis by Lindbloom in 1948. Surgeons have been reluctant, however, to accept it as a routine diagnostic procedure because of fear of injury to a normal disk. Nevertheless, it has been used at the author's clinic in Honolulu in the diagnosis of ruptured lumbar disks since 1950, and more than 450 lumbar diskograms have been made during the ensuing 8-year period. Information obtained from this study of lumbar disks was a stimulus to the development of a similar procedure for cervical disks, and in the last 3 years 114 patients have been subjected to cervical diskography.

In performing cervical diskography, a needle is inserted into the intervertebral disk from its anterolateral surface. By applying deep digital pressure between the trachea and carotid artery, the anterior surface of the vertebral bodies can be palpated easily at a depth of less than 1 cm. the 2-needle technique is used: The first needle, a no. 20, 2 in.

long, is inserted diagonally into the outer anterolateral fibers of the annulus fibrosus of the disk; through this guide a second fine 2½-in. (no. 25) needle is inserted into the center of the nucleus pulposus. The positions of the needles are determined radiographically. Only 0.2 to 0.3 cc. of a radio-opaque solution can be injected into a normal cervical disk. The procedure is carried out in the x-ray room. A small amount of Novocain in the skin is the only anesthetic used. Since the patient is conscious and cooperative, he can inform the operator as to the location of pain when the needles are inserted and the injection made.

By injection of the disk for diskography and by stimulation at operation, the origin of referred pains has been determined. Sensory nerve endings in the lower cervical intervertebral disks and their ligamentous confines have been shown to be responsible for the clinical symptoms of pain in the neck, scapula, shoulder, and upper arm. Conspicuous by their absence were pains radiating into the precordium or suboccipital region, headaches, and pains referred to the face and jaw, all of which have been attributed to the cervical intervertebral disk. The author did not observe precordial pain as part of the cervical disk syndrome. In making cervical diskograms and stimulating the disk at operation, every patient has been asked if he experienced pain in the anterior surface of the chest. None has described or admitted to pain in this location.

The referred pains in the neck, shoulder, and upper arm are thought to be due to local reflex spasm (myalgia) of the muscles of the shoulder girdle. They are encountered in patients with acute injuries to the cervical spine (whiplash injury) or chronic cervical disk disease (spondylosis). They have their origin in the periphery of the cervical disk and the ligaments which surround it. Irritation of these sensitive structures is thought to be due to abnormal movement of the vertebral joint associated with cervical disk pathology. These symptoms can be relieved by arresting movement between 2 adjacent vertebral bodies. This is accomplished by a new surgical procedure, consisting of vertebral body fusion, by the anterior cervical approach.

Carcinoma of the Thyroid in Children. G. Crile Jr. Ann. Surg. 150:959-964 (Dec.) 1959 [Philadelphia].

Carcinoma of the thyroid, although fairly common in young adults, is rare in children. This report records the findings and responses to treatment in 18 consecutive cases of carcinoma of the thyroid in children, from 3 to 15 years of age. In 14 of the 18 children the parents were asked whether the children had received any form of radiation around the head and neck. Eleven had received radiation in the first 4 years of life—5 to the thymus as infants, 2 to the tonsils and adenoids, 2 to the skin for eczema, 1 to the mediastinum for enlarged nodes, and 1 to the cervical lymph nodes. The amount of radiation given was often very small. In the 15 years between 1924 and 1939, no children with cancers of the thyroid were seen at the Cleveland Clinic. Only 3 were seen between 1939 and 1950, but between 1950 and 1958 there were 15 cases.

In 14 of the 17 cases of papillary carcinoma, metastases in the cervical nodes were the leading sign of the disease. In 7 cases the primary tumor was occult. The papillary carcinomas in this series of children were more malignant than similar tumors are in adults; they invaded the thyroid more extensively, and metastasized more frequently and more extensively to lymph nodes and lungs. Treatment was individualized and included lobectomy, subtotal or total thyroidectomy, with unilateral or bilateral resection of grossly involved groups of nodes. Conventional radical neck dissections with sacrifice of sternocleidomastoid muscles were not employed; total thyroidectomy was not done unless all of the thyroid was involved; and most of the thyroidectomies and neck dissections were performed through transverse thyroidectomy incisions. Seventeen of the 18 patients are living, with an average survival time of more than 5 years. Since none of the patients with operable disease in this series has died of local recurrence or has evidence of persistent carcinoma in the neck, there seems to be no necessity of routinely performing either total thyroidectomy or the conventional radical neck dissection with removal of the sternocleidomastoid muscles. Most of the cancers of the thyroid which occur in children appear to be dependent on thyroid-stimulating hormone, and their growth can be at least partly controlled by the feeding of desiccated thyroid.

Surgical Aspects of Chronic Thyroiditis. C. J. Priebe Jr. and H. A. Patterson. Ann. Surg. 150:965-975 (Dec.) 1959 [Philadelphia].

Chronic thyroiditis was found in 44 of the 889 patients (about 1 in 20) who underwent thyroid surgery at Roosevelt Hospital, New York, in the 10-year period from 1947 to 1956. There were 20 cases of Hashimoto's type, 11 of Riedel's type, and 13 of an unclassified type. The first 2 types combined accounted for 31 (3.4%) of the total thyroid operations. These are the most important to the surgeon, for here the disease requires specific treatment, while in the unclassified type treatment is dictated by the associated pathological changes.

With regard to Hashimoto's type of chronic thyroiditis, the authors arrive at the conclusion that this type of thyroiditis should be suspected in any white woman with a diffuse goiter, discomfort in the neck, and a low basal metabolic rate. Diagnosis by frozen section is essential for the surgeon to evaluate a firm, diffusely enlarged gland, which is finely lobulated and tan on cross section. Operation is necessary for accurate diagnosis, for relief of pressure symptoms, and for cosmetic reasons. Bilateral thyroidectomy, consisting of resection of 50 to 75% of the gland, seems best to prevent recurrence, while preserving endocrine function.

Riedel's type of chronic thyroiditis is usually found in middle-aged women with recent, localized, firm thyroid enlargement. There may also be symptoms of neck pressure. At operation, a malignant thyroid tumor may be suspected because of hardness and adherence to surrounding structures. Diagnosis by frozen section is valuable, though not infallible. The surgeon should be conservative when distinction between carcinoma and thyroiditis is in doubt, because radical excision for chronic thyroiditis is a costly error. The amount of gland resected for chronic thyroiditis should not be greater than that required for accurate diagnosis and prevention of constriction. The unclassified type of chronic thyroiditis is essentially a secondary pathological process superimposed on an already diseased gland. It may simulate other types before operation, during operation, and on diagnosis by frozen section. Surgery is performed primarily for the associated lesion, and to rule out carcinoma. Resection in each case should be as conservative as the associated disease allows.

Experiences with Coarctation of the Aorta. C. P. Bailey, W. M. Lemmon and B. G. Musser. Am. J. Cardiol. 4:775-785 (Dec.) 1959 [New York].

While Bonnet's classification of aortic coarctation still has many adherents, the authors are of the opinion that it is inadequate to embrace all of the forms. Its primary basis is the division into the "adult" form, which is characterized by obliteration of the patent ductus arteriosus with extensive overdevelopment of a collateral arterial system, and the "infantile" form, in which there is little collateral development and the lower aortic segment is supplied with venous blood from the pulmonary artery by way of a patent ductus arteriosus. Yet, the "infantile" form may be seen in adults, and the "adult" form necessary must occur first in infants. Furthermore, a patent ductus may be present in the "adult" form.

The authors present the following new system of classification for coarctation of the aorta: Type 1 is the classically located coarctation with ligament (ductus arteriosus obliterated). Type 2 is the classically located coarctation with shunt; this type is subdivided into (*a*) ductus arteriosus present and patent to the upper aortic segment with left-to-right shunt and (*b*) ductus arteriosus present and patent to the lower aortic segment with right-to-left shunt. Type 3 is the coarctation with hypoplasia (usually of the entire descending aorta). Type 4 is the isthmus interruption; etiologically and pathologically, this condition differs from true coarctation in that a segment of the aorta actually is absent. Type 5 is coarctation occurring in an unusual location. The various types of oartic coarctation are illustrated in diagrams, and the surgical techniques used to overcome them are discussed.

The authors describe the results obtained in 58 patients operated on for coarctation of the aorta over a period of 9 years. Only one patient died in the hospital, making the surgical death rate 1.7%. Aspects of the surgical technique which permit rapid, safe, and adequate surgery are emphasized. Grafting was done less often than is usually the case. In 5 patients both aortic stenosis and coarctation of the aorta were found. In 3 of these patients the coarctated segment was removed and anastomosis performed, followed by transventricular aortic dilatation; these have done well. The other 2 patients had excision of the coarctated area and anastomosis alone; both of them subsequently died, one as a result of the valvular stenosis and the other because of complication of the required second operation. The rate of cure by operation for hypertension due to coarctation of the aorta is probably higher than for hypertension caused by any other condition. In 88% of the patients there was an immediate lowering of the blood pressure in the arms after the operation, and this has been maintained. All the patients followed up have excellent pulsations and/or normal blood pressures in the lower extremities.

The authors conclude that every practicing physician should have a high index of suspicion regarding the possibility of existence of coarctation of the aorta when confronted with a patient who presents with a systolic murmur and/or systemic hypertension. The diagnosis usually can be made by clinical examination in the physician's office. The anomaly is surgically curable, with an acceptable operative mortality and a high likelihood of a good clinical and physiological result if corrected early.

Prevention of Lymphoedema of the Arm in Radical Surgery of Cancer of the Breast. A. N. Canónico. Prensa méd. argent. 46:1666-1669 (June 26) 1959 (In Spanish) [Buenos Aires].

One hundred ten unselected women who had a radical mastectomy were managed by a certain scheme for preventing immediate postoperative lymphoedema of the homolateral arm. The preventive treatment consisted of (1) making an adequate incision so as to procure a resulting soft and flexible scar; (2) caution during the operation to prevent trauma to the axillary vein; (3) not using the homolateral arm for giving blood or blood serum transfusion; (4) administration of antibiotics during the first 3 days after the operation; and (5) placing the patient under care of the surgeon himself until the healing process had been completed. The homolateral arm was bandaged with a moderately elastic bandage, which was not removed for an entire week after the operation. The diet contained little salt and was low in calories. Diuretics were given to the patients, and small doses of thyroid hormone on certain indications.

Of the greatest importance for the prevention of immediate postoperative lymphoedema of the homolateral arm was the early establishment of postoperative kinesitherapy. Local massage and active and passive exercises were given only by a trained physical therapist. Muscular exercises, which were begun 24 hours after the operation, followed a slow progressive scale to obtain complete functional recuperation of the arm. Massage of the soft parts of the axilla, the shoulder, and the arm was started by the end of the first week after the operation and was continued for 4 or 5 weeks. When postoperative roentgenotherapy was indicated, it was given in association with kinesitherapy in order to prevent fibroretractile sequels.

A follow-up for more than one year showed excellent results in 102 patients (92%); the functional capacity of the homolateral arm was normal. Sixty-three patients in this series did not have lymphoedema of the homolateral arm at all; 39 patients had a mild degree of edema of not more than 2 cm., in the remaining 8 patients there was a moderate degree of edema of from 2.5 to 4 cm. Immediate postoperative lymphoedema of the homolateral arm after a radical mastectomy can be prevented by following the scheme described. Special importance is attached to kinesitherapy.

Bronchogenic Carcinoma: An Aggressive Surgical Attitude. J. M. Chamberlain, T. M. McNeill, P. Parnassa and J. R. Edsall. J. Thoracic & Cardiovas. Surg. 38:727-745 (Dec.) 1959 [St. Louis].

The authors report on 248 patients who were operated on for bronchogenic carcinoma during the period 1949-1958. Epidermoid carcinoma was present in 134 patients (54%), adenocarcinoma in 40 (16%), anaplastic carcinoma in 59 (24%), and bronchiolar carcinoma in 15 (6%). The sex incidence was 222 for men and 26 for women, a ratio of 8.5 to 1. "Standard" resection was performed on 120 patients, and "extended" resection on 33; the remainder had noncurative, palliative, and exploratory resections. Both standard and extended resections were considered potentially cured at operation. Surgical specimens of standard resection consisted only of pulmonary structures, parietal pleura when adherent, and mediastinal lymphatic tissue. Extended operation included removal of the extrapleural structures invaded by the carcinoma. The mean duration of the postoperative hospital stay was not increased significantly by extending the operation. There were 34 instances of operative complications. The most frequent of these were cardiorespiratory failure (6), bronchopleural fistula (5), empyema (4), hemorrhage (4), pulmonary embolus (3), and metastases (3). The complication rate for the extended operation was 30.2% (13 patients) compared with 13.4% (19 patients) for the standard operation. Hospital deaths numbered 23 (9.3%). The patients who had a standard operation have had a mean survival of 21.6 months at the time of writing; 36.7% of these patients are still living. The patients who had an extended operation have had a mean survival of 16.7 months; 50% of these patients are still living. Of 28 patients in the noncurative resection group, only one is living. Several years must pass before the customary 5-year survival data can be compiled. The trend of the preceding statistical data suggests that extended resection is not only justifiable, but is clearly indicated whenever it is technically feasible.

Scalenus Anticus Syndrome: Result of Operative Treatment of 20 Cases, Including 16 with Cervical Costae. P. Rasmussen and N. G. Simonsen. Nord. med. 62:1572-1573 (Oct. 29) 1959 (In Danish) [Stockholm].

Sixteen patients, 4 men and 12 women, with scalenus anticus syndrome were treated at the Aarhus District Hospital, in Denmark, from April, 1943, to April, 1957. In addition, 4 patients had bilateral symptoms which had developed at intervals in the course of several years, so that, in all, 20 patients were operated on. At the start of the disease the patients ranged in age from 15 to 50 years. On admission, the symptoms had lasted from less than a year to 10 years. Pain was the most frequent symptom. Of the 3 patients without pain, 1 had motor symptoms exclusively, and 2 had vascular symptoms exclusively. Scalenotomy was performed in the 20 cases. The cervical ribs were extirpated or resected in only 9 of the 16 patients with costa cervicalis syndrome. In 8 cases a fibrous string was cut. The time of observation averaged 4.6 years. Recovery or marked improvement resulted in 14 patients, and slight improvement followed in 4; there was no change in 2 patients. The results were best in the costa cervicalis group in which only scalenotomy was performed.

The Surgical Treatment of Cylindroma (Adenoid Cystic Carcinoma) and Muco-Epidermoid Tumors of the Bronchus. W. S. Payne, F. H. Ellis, L. B. Woolner and H. J. Moersch. J. Thoracic & Cardiovas. Surg. 38:709-726 (Dec.) 1959 [St. Louis].

One hundred sixty-two malignant tumors originating in the bronchial mucous glands were diagnosed at the Mayo Clinic from 1927 through 1958. Of these, 13 were cylindromas (adenoid cystic carcinomas) and 4 were mucoepidermoid tumors of the bronchus. There was no sex predilection. The symptoms were mainly those of bronchial dilatation or bronchial obstruction and pneumonitis. Roentgenologic studies demonstrated massive collapse of one entire lung in 4 patients with mucoepidermoid tumors and in 4 with cylindromas, also lobar collapse in 7 patients with cylindromas. There was no sign of abnormality in 2 patients at the time of diagnosis. The bronchoscopic description of a cylindroma was a polypoid infiltrative tumor; that of a mucoepidermoid tumor was a large polypoid endobronchial mass that completely obstructed a primary bronchus.

The gross specimen of lung containing the primary tumor was available for review in 7 of the 13 patients with cylindromas. All these tumors involved major bronchi, and none presented as a peripheral pulmonary lesion. At the margins of the gross tumors there was extensive subepithelial infiltration of the mucosa. They all showed deep penetration and peribronchial extension, with destruction of bronchial cartilages and invasion of neural elements. Microscopic sections of the 4 mucoepidermoid tumors showed that they were covered with metaplastic squamous bronchial epithelium. None of these 4 tumors showed destruction of cartilage or involvement of nerves, lymph nodes, blood vessels, trachea, mediastinal structures, or distant organs. Seven patients with cylindromas and 2 patients with mucoepidermoid tumors were treated surgically. At the time of follow-up study, 4 of those operated on for cylindroma were alive and well 1 to 13 years after treatment. Also, the 2 patients who were surgically treated for mucoepidermoid tumor were living and well 8 to 10 years after the operation.

The Surgical Treatment of Ulcerative Colitis. J. H. Garlock. Dis. Colon & Rectum 2:529-533 (Nov.-Dec.) 1959 [Philadelphia].

The markedly improved results of the surgical treatment of nonspecific ulcerative colitis over the past 20 years have been owing largely to the elimination of ileostomy complications and a better understanding of the physiological changes which occur after operations. Complete rehabilitation of patients after appropriate surgical procedures may be expected in the great majority of these cases. From his own experience with about 500 cases of ulcerative colitis and careful appraisal of results, the author points out that (1) acute fulminating disease, (2) severe, uncontrollable hemorrhage, (3) perforation with peritonitis, and (4) extensive polyposis with or without carcinoma are definite indications for surgical treatment. Other important indications for surgical intervention are concerned with the pathological complications of colitis, comprising mainly pericolonic and extrarectal extensions; they are abdominal wall abscess and fecal fistula, rectovaginal fistula, and internal fistula.

The author points out that the routine use of proctocolectomy in one stage for all cases of ulcerative colitis is to be deprecated, mainly because this removes forever the possibility of reestablishment of intestinal continuity. The problem of reconnection, i. e., ileorectal anastomosis, demands serious consideration. It is extremely doubtful whether this operation should be carried out in the presence of active disease in the rectum or any rectal complications, such as fistula, anal incontinence, polyposis, and stricture. There is urgent need for individualization and careful appraisal of each patient.

Gastrectomy for Massive Gastrointestinal Haemorrhage of Unknown Cause. J. Bruce and H. A. F. Dudley. Lancet 2:992-994 (Dec. 5) 1959 [England].

The authors report on 19 men and 12 women, between the ages of 20 and 80 years, with massive gastrointestinal hemorrhage, in whom an obvious lesion was not present on external examination or on palpation of the stomach and duodenum, and who underwent a standard two-thirds to three-quarters gastrectomy ("blind" gastrectomy) in the surgical units of the Edinburgh Royal Infirmary and the Western General Hospital in Edinburgh. Of the 31 patients, only 3 were aged less than 40 years. In 7 patients the operation was performed within 24 hours of admission; in 9, it was delayed up to 2 days, and in 15, from 2 to 10 days. In all the patients there was no obvious evidence of an active peptic ulcer at laparotomy. In 6 patients it was considered that there might possibly be a healed ulcer, but pathological confirmation in the resected specimen was obtained only once. Superficial gastric ulcers or gastric erosions, thought to be the cause of the hemorrhage, were found in 19 specimens, and a duodenal ulcer, in 2. Microscopic examination suggested that the line of section had passed through an ulcer of the lesser curvature of the stomach in 1 patient, and in another an unresected ulcer was found in the duodenal stump. The remaining 2 patients had large hiatus hernias; the resected specimen of one of them contained a superficial gastric ulcer, but in the other a cause of bleeding was not found. Gastrotomy was carried out only once and revealed a superficial gastric ulcer. There were 3 deaths—one from intractable paralytic ileus; the second from repeated hemorrhage owing to a small anterior ulcer in the duodenal stump, which had not been detected at the gastrectomy; and the third from a pulmonary embolus.

Many patients with gastrointestinal bleeding of unknown causation, whose bleeding is less severe, may recover with medical treatment. Results in the 31 patients suggest, however, that lack of a clear history of digestive upset does not preclude the existence of a superficial ulcer, usually gastric but occasionally duodenal, from which fatal bleeding will occur if gastrectomy is not performed. The delay of gastrectomy in the 31 patients reflects the natural unwillingness of both physician and surgeon to submit a patient to surgical treatment without good evidence of the cause of the bleeding. A subtotal gastric resection will remove the lesion in 75% of the patients and will arrest the bleeding in most of the remainder. The over-all mortality in this group should be no more than 10%. If massive bleeding continues after gastrectomy, only reoperation is likely to save the patient.

Surgical Implantation of Hodgkin's Disease of the Stomach to the Skin of the Abdominal Wall. F. C. Jackson, E. C. Ney and E. R. Fisher. Ann. Surg. 150:1000-1006 (Dec.) 1959 [Philadelphia].

The patient was a 47-year-old man who was first seen in September, 1954, complaining of postprandial epigastric pain and a loss in weight of 33 lb. (15 kg.) over the preceding 3 years. The radiologist's impression was "hypertrophic gastritis" with a "polypoid mass." Laparotomy revealed an infiltrating tumor of the fundus and greater curvature of the stomach extending almost to the pylorus. After extending the incision into the chest, a biopsy of the fundus was taken where tumor invaded the serosa. The pathologist's diagnosis on frozen section was "malignant lymphoma." Total gastrectomy, omentectomy, splenectomy, and resection of the tail of the pancreas were performed with a loop esophagojejunostomy and distal enteroenterostomy. Microscopic examination of the surgical specimen revealed that much of the gastric mucosa was replaced by malignant neoplasm, a polymorphous infiltrate of reticulum cells, plasma cells, and lymphocytes. Many reticulocytes were atypical and exhibited frequent mitoses. Multinucleated forms of the Reed-Sternberg cells were also seen. Sections from lymph nodes, spleen, and pancreas revealed no neoplasm.

On the 11th postoperative day an abscess appeared at the costal margin of the wound, which was drained. Postoperatively, 10 mg. of nitrogen mustard was administered intravenously every other day for 4 doses—a total of 1.4 mg. per kilogram. A draining sinus was still present when the patient was discharged. When he was readmitted 3 months later, the edges of the defect were excised. Sections of the abdominal skin revealed a dense infiltrate of the upper corium, as well as focal areas of the subcutaneous tissue and periappendageal tissues, by plasma cells, lymphocytes, occasional eosinophils, and moderate numbers of reticulum cells. Many of the latter appeared atypical, and occasional giant cells of the Reed-Sternberg type could be identified. A total of 2,400 r (air dose) of radiation was delivered to the old area of the wound sinus in a period of 15 days. After that the wound healed. In 1957, because of tryptic esophagitis, the loop jejunostomy was converted to a Roux-en-Y esophagojejunostomy. This procedure permitted a "second look." No gross tumor was found in organs or lymph nodes. The patient is alive and well 3 years and 6 months after excision and local radiation to the site of implantation and almost 4 years after removal of the primary gastric tumor. This is the first reported instance of implantation of Hodgkin's disease of the stomach. It is suggested that with increase in surgical treatment of unifocal Hodgkin's disease other instances may be reported in the future.

The authors cite the following factors as evidence of implantation: 1. The tumor barrier was violated during operation by direct biopsy. 2. The characteristic morphologic appearance of Hodgkin's granuloma with Reed-Sternberg cells was demonstrated in the wound. 3. The patient had no other manifestations of Hodgkin's disease in the skin. 4. Studies on the scalene and axillary lymph nodes more than 2 years later revealed no evidence of Hodgkin's disease, and indicated that the stomach lesion was unifocal.

Treatment of 126 Cases of Malignant Melanoma: Long Term Results. S. L. Gumport and H. W. Meyer. Ann. Surg. 150:989-992 (Dec.) 1959 [Philadelphia].

While up to 1940 the general impression was that treatment was of little or no value in malignant melanoma, more recent reports indicate that this is no longer true. This report is concerned with 126 of the 192 patients who were operated on for malignant melanoma by members of the tumor service of New York University postgraduate medical school at University Hospital, New York, since 1944. In these 126 patients more than 5 years have elapsed since the surgical treatment. All diagnostic and therapeutic procedures took into account the ease with which a melanoma may spread by way of either the blood stream or the lymphatics. In the presence of a pathognomonic lesion, biopsy was omitted. The entire lesion was removed as a total excision biopsy, rather than an incisional biopsy, when biopsy was deemed necessary.

Surgery consisted of wide and deep excision of the primary lesion, including the underlying fascia, and grafting was usually necessary. The regional lymph nodes were removed in continuity whenever it was technically feasible. Gentle handling of the tissues and sterilization of instruments after each individual use were emphasized in order to prevent implantation. The use of sharp retractors and of local anesthesia was avoided for the same reason. When it was not practical to remove the regional lymph nodes in continuity, they were removed several weeks later, after the site of the primary lesion was well healed. The removal of the regional lymph nodes should not be postponed until they are grossly involved. When there was clinical evidence of involvement of the nodes, triethylene thiophosphoramide was administered at the time of operation. The same substance or phenylalanine mustard was administered when the disease had advanced to inoperability.

Dissection of the nodes was not carried out in 41 of the 126 patients. Of these, 11 are living and well, 8 could not be traced, and 22 either have died or have had recurrence. The best results were obtained in the 40 patients in whom lymph nodes were removed which were both clinically negative and microscopically free of tumor; 52% of these patients lived 5 years or more. However, even when the nodes were microscopically positive, 46% of the patients survived 5 years or more if the nodes had been clinically thought to be free of tumor. The 5-year survival rates dropped precipitously when the nodes were clinically involved.

NEUROLOGY & PSYCHIATRY

Cerebellar Atrophy with Oculocutaneous Telangiectasis and Bronchiectasis as a Familial Syndrome. A. Biemond and J. H. van Bolhuis. Nederl. tijdschr. geneesk. **103**:2253-2258 (Nov. 7) 1959 (In Dutch) [Amsterdam].

The authors present the case histories of 4 children, coming from 2 unrelated families. The first 2 were girls, born in 1940 and 1944, respectively; the other 2 were boys, born in 1944 and 1948. Both of he girls died, one at 17 years of age, and the other t 12. Autopsy studies were done on the younger of the 2 girls and on one of the boys, who died at 12 years of age. All 4 children presented a characteristic, progressive syndrome, consisting of cerebellar ataxia, later complicated by choreoathetosis; recurrent and chronic respiratory infections resulting in bronchiectasis; and telangiectasis, at first limited to the bulbar conjunctiva, but later developing in regions of the skin. Autopsy revealed bronchiectasis and diffuse fibrosis in the lungs. Clubbing of the fingers was also noted. The marked cerebellar atrophy was mainly confined to the vermis cerebelli.

The development of neurological disorders in these children with recurrent respiratory infections and the development of telangiectatic lesions in the bulbar conjunctiva had impressed van Bolhuis as a special syndrome some years ago. The difficulties encountered in the evaluation of the gradually developing neurological aspects led to neurological studies on the 4 children by Biemond in 1954. At this time the children were also examined by an ophthalmologist. The study was completed in 1956 when autopsies were performed on 2 of the children.

Biemond made a report on this syndrome at the International Neurological Congress in 1957. During the same year and in 1958 several reports of this syndrome appeared in the American and British literature, a total of about 20 cases having been reported so far. The authors feel that the term "ataxia-telangiectasia," applied to the syndrome by American authors, while practical, has the disadvantage of giving an incomplete description of the very characteristic triad; moreover, it suggests that the cerebellar lesion is the result of (cerebellar) telangiectasis, which is not the case.

Agranulocytosis During Treatment with High Doses of Chlorpromazine: Report of Case with Recovery and Review of Literature. F. O. Bastos, H. M. Carvalho and C. R. M. Arantes. Rev. Hosp. clin. **14**:300-311 (Sept.-Oct.) 1959 (In Portuguese) [São Paulo, Brazil].

A patient with paranoic schizophrenia of 4 years' duration was hospitalized at the psychiatric clinic of the Faculty of Medicine, University of São Paulo, Brazil. Previous treatment consisted of electroshock or insulin shock therapy, which had given the patient temporary relief. Neurological examination and laboratory tests (cerebrospinal fluid and basal metabolism) gave normal results. Chlorpromazine therapy was instituted by the "impregnation technique," starting with a dosage of 75 mg. daily during 3 days and increasing it gradually until it reached 2,400 mg. during 5 days. On the 55th day of treatment the patient developed fever, diarrhea, and vomiting. He was given sulfaguanidine and injections of Dibiotyl (penicillin and dihydrostreptomycin). The following day, as his condition was worse, the dose of chlorpromazine was reduced to 1,600 mg., and several laboratory and roentgenographic tests were performed. The hemogram showed agranulocytosis, with 700 leukocytes per cubic millimeter, 5% neutrophils, and 84.5% lymphocytes. The chlorpromazine treatment was suspended and a new therapy instituted, with administration of crystalline penicillin, whole blood transfusion, liver extract, vitamin B complex and vitamin B_{12}, plus isotonic sodium chloride solution and hypertonic dextrose solution. The patient recovered within a month from the onset of the toxic condition. This is the 54th case in the medical literature reviewed by the authors. The mortality in this reviewed series is 27.8%, with death occurring within 2 to 12 days after the onset of agranulocytosis.

Cerebral Thrombophlebitis in Children: A Clinical and Electroencephalographic Study. G. Carels and J. Henneaux. Acta paediat. belg. **13**:253-278 (no. 5) 1959 (In French) [Brussels].

Three cases of cerebral thrombophlebitis in children are reported. The course of the disease was documented by electroencephalograms taken periodically. Each of the 20 electroencephalograms taken for each patient was confronted with the clinical picture present at that particular phase, and thus the lesion was correctly localized after the start of the disease. The patients were 2 boys, aged 13 and 7 years, respectively, and one 11-year-old girl. In the first patient a meningitis syndrome, with crises of jacksonian epilepsy, had a sudden onset after a fall, during the course of an acute rhinopharyngitis and maxillary sinusitis. In the second patient a meningitis reaction, with total monoplegia of the left lower extremity, occurred during the course of a right ethmofrontomaxillary sinusitis. In the third patient a mild meningitis syndrome, with motor aphasia and right hemiplegia, occurred in the course of whooping cough. The diagnosis in the 3 patients was thrombosis of the rolandic vein. The treatment consisted of the intravenous administration of broad-spectrum antibiotics in massive doses, anticoagulants (heparin being administered successfully to one patient), hypertonic sodium chloride solution, and procaine. The 3 patients recovered within one month.

The prognosis in cerebral thrombophlebitis of children depends on early treatment, which requires an early diagnosis. Intense and early disturbances of consciousness have an unfavorable prognostic meaning. Electroencephalograms should be taken periodically for early localization of the lesion and for differentiation between cerebral thrombophlebitis and cerebral tumors or vascular malformations. Anticonvulsive treatment is in order even before the onset of any convulsive manifestation, and it should be maintained for some time after the clinical recovery. Infections, even if not suppurative, may be the source of cerebral thrombophlebitis. An investigation of such infections, which sometimes are moderate and undetected, should be part of the routine examination whenever a clinical picture of headache and malaise is followed by neurological symptoms.

PEDIATRICS

Study of Chronic Tetany in Late Childhood. H. P. Klotz and S. Tomkiewicz. Semaine hôp. Paris 35: 3239-3253 (Nov. 28) 1959 (In French) [Paris].

The authors report 20 cases of chronic tetany in older children and adolescents. The most frequent behavior signs and symptoms in the 20 patients were fits of rage, enuresis, nightmares, fainting, and spasmodic sobbing, and in 9 of them these behavior problems required special care. Trophic and somatic signs were defects of dental enamel and endocrine cataract. The prognosis is more favorable when the cataract is an isolated sign or when it appears in the midst of a polydystrophic tetany. Although the different forms of so-called idiopathic tetany of late childhood represent varieties of the same disturbance of calcium metabolism with several transitional types, 3 groups can be distinguished from the therapeutic and the prognostic points of view. The authors offer the following classification: 1. Chronic hypocalcemic tetany or idiopathic hypoparathyroidism. This is a rare condition and carries an unfavorable prognosis except when treated early. 2. Chronic normocalcemic or constitutional tetany. This is a frequently observed condition which carries a favorable prognosis and requires treatment only during periods of decompensation. 3. Multidystrophic chronic tetany or pseudohypoparathyroidism, which is frequently accompanied by serious mental disturbances and irreversible epilepsy.

It is the resistance to treatment and the prognostic value that constitute the main interest in distinguishing between the various clinical forms of chronic tetany in late childhood. The essential value of an early diagnosis is the possibility of curing, preventing, or minimizing a number of disturbances by means of a simple vitamin and calcium therapy. The presence of convulsions, of behavior or mental disorders, and of an incipient cataract in a child calls for an investigation of the familial background, for an electromyographic study, and for determination of calcemia and phosphoremia.

Kernicterus in Premature Infants. B. Yoffer, J. E. Howard, I. Ebensperger and others. Rev. chilena pediat. 30:205-213 (Sept.) 1959 (In Spanish) [Santiago, Chile].

A study of kernicterus not associated with hemolytic disease was made at the center for premature children of the Luis Calvo Mackenna Hospital in Santiago, Chile. The records of the premature infants who died of kernicterus without hemolytic disease, between 1956 and 1958, were compared with the records of 100 premature infants who entered the center during the same period. The 2 groups were analyzed in relation to obstetric circumstances, weight at birth, medication received (vitamin K and antibiotics), clinical picture, and laboratory tests (bilirubinemia and blood count). The 16 infants who died of kernicterus represented 1.6% of the 969 premature infants who entered the hospital and 6.6% of the total number of deaths at the center during the 2-year period studied.

Blood groups were compatible in 13 of the 16 infants in the kernicterus group, although there was a possibility of incompatibility in 3 of them. A definite correlation was found between the weight at birth and the incidence of kernicterus, represented by a frequency of 56.25% among all the infants weighing from 1,000 to 1,500 Gm. (approximately 2 to 3½ lb.) at birth, who were registered at the center during the period in study. Seventy-five per cent of the infants in the kernicterus group and 52% of those in the control group received vitamin K. The authors call attention to the fact that the highest rates of bilirubinemia were found among the infants who did not receive vitamin K, or who received it in lower doses. It was also found that, although the average maximum level of bilirubinemia in the kernicterus group (14.5 mg. per 100 cc.) was higher than the average maximum level in the control group (11.8 mg. per 100 cc.), hyperbilirubinemia was not necessarily associated with the disease. One infant in the kernicterus group had a bilirubinemia level of 6.8 mg. per 100 cc. on the 5th day of life. Seventy-five per cent in the kernicterus group and 50% in the control group received antibiotic therapy (sodium penicillin in doses of 100,000 units per kilogram of body weight over a period of 72 hours). Gastric aspiration, which was part of the routine examination at the center for premature infants, yielded abundant fluid and blood only from the 6th day on, associated with jaundice and neurological signs.

The pathological study of the infants who died of kernicterus confirmed the characteristic yellow impregnation of the cerebral nuclear masses, which may be associated with intracranial and pulmonary hemorrhage. The study showed that kernicterus is a disease of the small premature infant, and that an early diagnosis is very difficult.

Hemolytic Disease of the New-Born: An Analysis of Family Histories and Serological Findings. R. J. Walsh and H. K. Ward. Australasian Ann. Med. 8:262-266 (Nov.) 1959 [Sydney, Australia].

A sample of blood was collected for titration from 395 immunized women. Titers of the complete antibody were measured against D-positive red blood cells suspended in isotonic sodium chloride solution, and titers of the incomplete antibody against D-positive red blood cells suspended in 10% polyvidone solution. A history of pregnancies, including miscarriages, and of transfusion was obtained from each patient. Four categories, descriptive of the degree of severity of the hemolytic disease affecting children of these women, were established: (1) mild disease (the infant had not received any transfusion); (2) severe disease (transfusion treatment with recovery); (3) severe disease (transfusion treatment with death of the child); and (4) stillborn infant.

One hundred seventy-five women had not had another pregnancy after the first affected child, at the time of the examination. Thirty-one (approximately 14%) of the 220 children born after a first affected child were unaffected by Rh immunization. The highest percentage of unaffected children (19.6%) was found in the group in which the first affected child had experienced a mild form of hemolytic disease; the highest percentage of stillborn infants (44.6%) was found in the group in which the first affected child had also been a stillborn. It was also found that 34.2% of the first, 49.4% of the second, 51.3% of the third, and 45.7% of the fourth affected children died, which indicates no progressive increase in mortality. No correlation was found between the mother's parity and the degree of gravity of the hemolytic disease in the first affected child.

Although the severity of the disease increased with the mean titer of antibody, there were many exceptions to this picture, as indicated by the finding of 30 mildly affected infants associated with maternal titers of 256 or more, whereas 5 stillborn infants were associated with titers lower than 16. The effects of immunization by a blood transfusion were similar to those of immunization after a pregnancy, as indicated by the fact that the frequency of stillbirths was not significantly greater when immunization followed a transfusion. The most definite conclusion is that, if the first child is mildly affected, the subsequent children are more likely to survive than to die; the severely affected first born is more likely to be followed by a stillborn or a fatally affected infant.

PATHOLOGY

Primary Dissecting Aneurysm of Peripheral and Pulmonary Arteries: Dissecting Hemorrhage of Media. A. G. Foord and R. D. Lewis. A. M. A. Arch. Path. 68:553-577 (Nov.) 1959 [Chicago].

The authors report on 17 patients with primary dissecting aneurysm of peripheral or pulmonary arteries, in whom one or more arteries were involved. Only 2 patients were younger than 52 years. Hypertension was present in 12 patients. Direct traumatic injury of the involved artery took place in 2 patients. The renal artery was involved in 7 patients. There was involvement of the left anterior descending coronary artery in one patient, with fatal outcome. The superior mesenteric artery was involved in 3 patients; this artery was markedly narrowed, causing infarction of a long segment of the small intestine in 2 patients, and a branch of the superior mesenteric artery was involved in one patient. The other arteries involved in this series were: celiac, splenic, hepatic, and branches of left gastric (1); common hepatic (1); pulmonary, main and right (1); branch of right pulmonary (1); left common carotid (1); and left superior thyroid (1).

Dissection of the entire circumference of the artery involved was observed in 5 patients. Thrombosis in the lumen of an artery in which a dissecting aneurysm had developed took place in 2 patients. Infarction of the artery was present in 6 patients. Dissecting aneurysm appeared to have played a major role in causing death in 8 patients. The authors also collected 31 cases which had been reported in the literature. The conclusion is that there is no evidence of a lesion which is specific for peripheral arteries subject to dissecting aneurysm.

BOOK REVIEWS

The Viruses: Biochemical, Biological, and Biophysical Properties. Volume 1: General Virology. Edited by F. M. Burnet and W. M. Stanley. Cloth. $16.50. Pp. 609, with illustrations. Academic Press, Inc., 111 Fifth Ave., New York 3; Academic Press, Inc. (London) Ltd., 40 Pall Mall, London, S. W. 1, England, 1959.

Scientists who are tempted to study viruses today must be prepared to have a little knowledge of zoology, genetics, biochemistry, biophysics, microbiology, immunology, and, if they choose to become "quantifiers," mathematics. Up to now, they had to study textbooks of the respective disciplines in order to be versatile enough to find their way in virology; however, this book should make their lives easier. Instead of studying books on physics and biophysics, the future virologist will have the pleasure of reading chapter 3, which contains a brief, lucid, and informative account of Schachman and Williams dealing with the physical properties of the infective virus participles. This material should provide him with a sufficient background of physics to enable him to approach his problems in this field in an intelligent manner.

Pursuing further the application of biophysics to the knowledge of viruses, Schwerdt, in chapter 4, describes methods of counting virus particles and discusses the relationship between the physical count and the biological function of the virus particles. The major part of the book is devoted to the chemistry of viruses and the biochemical problem faced by a cell infected by a virus.

In chapter 6, Fraenkel-Conrat describes his study on the determination of the chemical structure of a tobacco mosaic virus, which belongs to the group of viruses that affect plants, as well as the results of pioneering studies conducted by Schram and coworkers at Tübingen. Pursuing the same theme, Bergold, in chapter 9, describes the biochemistry of insect viruses. The chemistry of bacterial viruses (bacteriophages) and animal viruses is analyzed in chapters 7 and 8 by Evans and Schafer respectively. Attempts are made in these two chapters to link the functional activity of viruses with their chemical composition or with what is known about their chemical structure.

One of the most important and well-written parts of the book is chapter 2, in which Seymour Cohen turns to the almost forgotten partner of virus infection, the host, and describes the intricate system of metabolic processes that take place in a normal cell and in one invaded by a virus. In chapter 11, Luria discusses the problem of viral genetics, which assumes a paramount role in the study of viruses, and the question of reproduction of bacterial, plant, and animal viruses. More practical aspects of virology are discussed in chapter 10 by Burnet. He describes different immunological reactions used to characterize viral properties.

Gard and Maaløe, chapter 5, deal with the problem of inactivation of viruses. The editors have provided an admirable introduction to the problems of virology. The book is primarily for graduate and young postgraduate students. It was not written for medical practitioners but it should be a valuable reference book for the experienced virologist. In order to satisfy the latter group, it will have to be brought up to date frequently, since the rate of progress in this field is formidable.

Principles of Nutrition. By Eva D. Wilson, Professor of Foods and Nutrition, Katherine H. Fisher, Associate Professor of Foods and Nutrition, and Mary E. Fuqua, Associate Professor of Foods and Nutrition, all at Pennsylvania State University, University Park. Cloth. $5.95. Pp. 483, with illustrations. John Wiley & Sons, Inc., 440 Fourth Ave., New York 16; Chapman & Hall, Ltd., 37-39 Essex St., Strand, London, W. C. 2, England, 1959.

For the student just being introduced to the study of nutrition, an up-to-date readable textbook is a real boon. The authors of this excellent book have done an admirable job in presenting basic nutritional information in a way that does not depend on a background of chemistry and physiology. The first chapter defines nutrition as the science of nourishing the body; the second chapter discusses the basic terms that one should know for the study of nutrition. This enables the student without a background in science to embark on his course of study without being unduly penalized for his vocabulary deficiency.

The first part of the book discusses the principles of nutrition, including information on energy, metabolism, and nutrients; emphasis is placed on the needs of the college student. The remainder of the book shows how these concepts apply to the requirements of children, pregnant and lactating women, and older persons. Problems concerned with nutrition as related to obesity, dental health, and other special considerations are taken up in the last section.

The discussion of the treatment of obesity and food fads and fallacies is timely and well presented. The roles of the Food and Drug Administration and the various other groups concerned with accurate nutritional information are stressed. An entire chapter tells the student how to select an adequate diet. This book should appeal not only to the student but also to the nutritionist, dietitian, and homemaker. The physician desiring a concise, comprehensive source of nutritional information would do well to add this volume to his library.

The Mediastinum. By Ted F. Leigh, M.D., Professor of Radiology, Emory University School of Medicine, Emory University, Georgia, and H. Stephen Weens, M.D., Professor of Radiology and Chairman of Department of Radiology, Emory University School of Medicine. Cloth. $11.50. Pp. 246, with 290 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

The mediastinum, though a small anatomic compartment, contains more vital structures than any other compartment in the body. Practically every organ system is included in this area. The lesions that arise from these systems are many, yet they may so closely resemble each other that they almost defy differentiation. The lesions are similar as they produce the same symptoms and have similar roentgenographic features. An attempt to separate these lesions by their symptoms would prove discouraging. The best approach is by their roentgenographic appearance.

The authors first discuss the normal roentgenographic features of the mediastinum and its contents. From this point the various mediastinal tumors are dealt with according to the organ systems from which they arise. Only the diagnostic features are discussed and illustrated by numerous roentgenograms gathered from many sources. The lesions are not discussed from therapeutic or prognostic viewpoints. This is justifiable as the purpose of the work is the accurate differentiation of mediastinal lesions prior to exploration.

The authors have dealt with the subject thoroughly and concisely and have included many excellent illustrations. The book is highly recommended to those who are confronted with the problem of accurate diagnosis and treatment of mediastinal diseases.

Physiology of the Eye: Clinical Application. By Francis Heed Adler, M.A., M.D., F.A.C.S., William F. Norris and George E. de Schweinitz, Professor of Ophthalmology, University of Pennsylvania School of Medicine, Philadelphia. Third edition. Cloth. $16. Pp. 790, with 372 illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3; Henry Kimpton, 134 Great Portland St., London, W. 1, England, 1959.

Students of ophthalmology are fortunate that this book has appeared in a new enlarged edition. The general plan and chapter headings remain the same as in earlier editions. The excellent bibliographies that follow each chapter have been brought up to date and constitute a valuable feature of the book. There have been extensive additions to those chapters dealing with subjects in which there has been much investigative work in the past six years. This particularly applies to the chapters on aqueous humor, intraocular pressure, and ocular motility. The author has the faculty of expressing himself clearly and succinctly so that even the most complicated matters appear simple. The format of the book is pleasing and the illustrations are good. This book should be required reading for all students of ophthalmology, clinicians, investigators, and residents.

Lectures on the Interpretation of Pain in Orthopedic Practice. By Arthur Steindler, M.D., F.R.C.S., F.R.S.M. With anatomical dissections by Dr. Rodolfo Cosentino. Cloth. $18.50. Pp. 733, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

The author believes that there are two concepts against which the student should be thoroughly immunized. The first is the idea that one must be dealing with a psychoneurosis if the origin of a pain cannot be established. The other is the defeatist viewpoint expressed by telling the patient that he will just have to live with his pain. The physician should determine whether a certain painful syndrome is of peripheral origin, such as that caused by the pressure of a herniated nucleus pulposus on a nerve root, or if is of central origin and within the domain of the neurologist and neurosurgeon. Pain speaks its own language. If pain is premonitory of a presenting sign, a careful analysis may reveal the condition while it is still in a reversible stage.

The broad coverage of this subject is indicated by the following list of subjects discussed: the perception, conduction, allocation, and appreciation of somatic pain; interpretation of pain; evaluation of pain and the clinical analysis of pain syndromes; the autonomic nervous system in the pain syndromes of orthopedic conditions; joint pain; pain in muscles, tendons, and fasciae; bone pain; neuralgia; causalgia, and phantom pain; central pain and orthopedics; the cervical pain syndrome; the pain syndromes of the thoracic spine; lumbosacralgia and sciatica; the shoulder pain syndrome; the shoulder-hand syndrome; pain syndromes of the elbow and forearm; pain syndromes of the hand and fingers; the pain syndrome in disturbances of the hip and knee joint; and pain syndromes of the foot, ankle, and leg. Most of the illustrations are instructive.

The orthopedist is confronted with three principal complaints: deformity, dysfunction, and pain. Pain has become a stepchild of orthopedic investigation compared to deformity and dysfunction, on which much energy is expended. Every type of orthopedic situation is analyzed here from the standpoint of pain syndromes for the purpose of diagnosis and therapeutic indications. The analysis of pain is presented as a special feature in diagnosis and therapeutic indications. The author is to be commended for so ably bringing this subject to the attention of the profession.

QUESTIONS AND ANSWERS

ERYTHEMA NODOSUM

To the Editor:—*What percentage of patients with erythema nodosum also have enlarged hilar lymph nodes? What is the cellular appearance of the enlarged nodes when examined microscopically? Has any relationship between erythema nodosum, hilar adenopathy, and sarcoidosis been established?*

Martin A. Thomas, M.D., Tampa, Fla.

Answer.—Erythema nodosum may occur in patients concurrently with or after they have had many diseases, including upper respiratory infections, tuberculosis, leprosy, sarcoidosis, various pulmonary disorders, infections with beta hemolytic streptococci, peritonsillar, prostatic, or axillary abscesses, appendicitis, eye infections, dental infections, brucellosis, meningococcemia, the communicable diseases, influenza, herpes zoster, coccidioidomycosis, venereal diseases, ulcerative colitis, regional ileitis, and Hodgkin's disease and other neoplasms, or after drug ingestion. Erythema nodosum is considered to be a hypersensitivity reaction to a variety of infectious agents, drugs, and other allergens.

Regardless of the etiological factors involved, enlarged hilar lymph nodes with or without pulmonary changes occur in about 9 to 10% of patients with erythema nodosum. In selected series the incidence of hilar adenopathy has been reported as from 2 to 95%.

When adenopathy is due to a primary disease such as tuberculosis, sarcoidosis, Hodgkin's disease, or coccidioidomycosis, the microscopic appearance is usually specific for that disease. When adenopathy is the result of a streptococcic infection, a drug reaction, or some other hypersensitivity reaction, it presents the appearance of nonspecific adenitis.

Erythema nodosum occasionally occurs in a patient with sarcoidosis, but determination of the incidence is confusing because the appearance of the chest roentgenogram in the two conditions may be identical and the clinical appearance of the skin lesions indistinguishable. Microscopic study of the early skin lesions of erythema nodosum shows them to be infiltrated with neutrophils, lymphocytes, occasional histiocytes, and eosinophils, and in some specimens severe vasculitis is present. In the late stage of the disease, small nodules with epithelioid cells in a radial or palisaded pattern and foreign body giant cells also may be present. Since the erythema nodosum lesions can be confused with those due to sarcoidosis, differentiation of the two conditions must be made on the basis of the full clinical picture exhibited by the patient as well as the results of pathological studies.

DIFFERENTIAL WHITE BLOOD CELL COUNTS

To the Editor:—*The results obtained from the differential blood cell counts performed on the medical patients admitted to our hospital have shown less than 1% monocytes and eosinophils (average obtained from groups of 10 to 40 patients). Most of the reports of blood cell counts do not list either of these cells as present. The physician director of the laboratory insists that these monocyte and eosinophil counts are not necessarily in error and that the variation from "normal" is due either to the patient's illness or to the medicaments he is taking. Is this explanation valid?*

M.D., Michigan.

Answer.—Failure to record the presence of either eosinophils or monocytes in the routine admission differential blood cell counts of a majority of patients suggests some error in the technique of staining or of counting, or a variation in the interpretation of cell type. In my experience, less than 20% of initial differential counts fail to show 1% or more of either eosinophils or monocytes in a count of 100 cells.

The eosin-staining quality of the stain being used may vary with the batches of stain and with differences of staining technique, so that the eosinophilic coloring of the cell may not be evident. Variation in staining quality or technique usually does not influence the appearance of the monocyte; hence *the failure to record the presence of monocytes is* more likely to be due to differences in interpretation of the cell type by the persons who are doing the counts. Monocytes can be recorded as metamyelocytes, a recent trend in some laboratories, or they may be recorded as large lymphocytes. Since an accurate differential blood cell count must enumerate 100 different cells, it is important to avoid repetitive scanning of the same area of the smear. A *microscope-slide carrier*, which may be moved accurately from side to side and up and down, is useful for this purpose.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any medical or other organization unless specifically so stated in the reply. Anonymous communications cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

No drug commonly administered to patients prior to their admission to a hospital would alter the number of eosinophils or monocytes in the stained blood smear.

FINGER DERMATOSIS OF UNKNOWN CAUSE

To the Editor:—*A 50-year-old patient has had a dermatosis of the palmar surface of the fingers, confined to the distal half of the phalanges, for two years. The lesions first appeared as brownish spots less than 0.5 mm. in diameter. Later, the skin overlying the spots cracked, desquamation occurred, and on examination small excavations filled with a serous fluid were found. What are the diagnostic possibilities?*

M.D., New York.

Answer.—Cultures of the vesicular fluid, grown on both regular agar for bacteria and on Sabouraud's agar for fungous infections, are mandatory for this inadequately described condition. The possibility of contact dermatitis must be considered, and, if necessary, the patient should have a patch test for industrial allergenic materials.

The vesicles could also be an "-id" reaction caused by a focus of infection in the tonsils, ears, prostate gland, or other organs.

EUGENIC COUNSEL IN ALZHEIMER-PICK SYNDROME

To the Editor:—*A 47-year-old woman has presenile sclerosis (Alzheimer's disease). Her father received continuous institutional care for mental deterioration for eight years prior to his death at the age of 50 years. The patient's husband would like to know whether their two sons should marry and have children. What advice can I give him?*

Stephen B. Yohalem, M.D., New York.

Answer.—Giving eugenic counsel to a family afflicted by a condition such as the Alzheimer-Pick syndrome is extremely difficult, since the mode of inheritance is not yet defined and specific advice about the probability of affected offspring cannot be given with any degree of statistical significance. Another complication is that the differential diagnosis between Alzheimer's and Pick's disease usually cannot be definitively confirmed without performance of a histopathological examination of the brain tissue.

The best genetic description of the Alzheimer-Pick syndrome has been done by Sjogren and coworkers (*Acta psychiat. et neurol. scandinav.* [supp. 82] 1952). While in Alzheimer's disease the morbidity risk for the parents of probands appears to be about 10±4% and for the siblings of probands about 3.8± 2.1%, the corresponding figures for Pick's disease are 19± 5% and 6.8± 2.9% respectively. The mode of inheritance in Alzheimer's disease appears to be multifactorial (a polygenetic disturbance with cumulative action of genes), and the picture is possibly complicated even more by some environmental factors. Pick's disease is thought to be due to an autosomal dominant gene and other modifying genes. Eugenic counsel would consist of an explanation of the factual information about the disease to the family. No suggested course of action can be outlined.

CYANOSIS DECREASED BY CRYING

To the Editor:—*What causes a baby to have a cyanosis that becomes less severe when it cries?*

M.D., South Carolina.

Answer.—To answer the question with accuracy, more information, such as the infant's age, nutritional status, respiratory rate, characteristics of its cry, and whether a cardiac murmur is present, is necessary. Asphyxia is characterized by cyanosis which decreases with crying and in children often is caused by atelectasis. Other causes of asphyxia, such as increased intracranial pressure, should be investigated. The infant may also have persistent atrioventricularis communis, which is a congenital malformation of the heart.

ATOPIC ECZEMA AND VACCINATION

To the Editor:—*With reference to the item, appearing in the Questions and Answers section of* The Journal, *June 27, 1959, page 1137, "Atopic Eczema and Vaccination," although a smallpox vaccination within three years is required for persons entering the United States, consideration will be given to a physician's statement that vaccination is medically contraindicated. The person should present the statement to the quarantine officer at the time of arrival. That officer will determine what procedures are applicable to the individual case, depending on the possibility of exposure to smallpox. The person may be placed under surveillance (reporting to the health officer at the point of destination) or in isolation. The period of surveillance or isolation is 14 days from the date of the last possible exposure to smallpox. The decision will be based on the presence or absence of smallpox in areas visited or contacts en route during the same period. As a basis for the above judgment, the foreign quarantine officers at United States ports of entry are kept currently informed on the occurrence of smallpox throughout the world. Complete information concerning the requirements for entrance into the United States is given in section 4 of the U. S. Public Health Service booklet "Immunization Information for International Travel."*

Drug Hearings Criticized . .
Tighter Labeling Law . .
International Research Bill . .

COMMITTEE OPENS SESSIONS ON SOCIAL SECURITY CHANGES

The House Ways and Means Committee launched crucial hearings on proposed amendments to the social security program. The controversial Forand proposal was one of the items on the agenda.

First witness at the closed-door sessions was Arthur S. Flemming, Secretary of Health, Education, and Welfare. He was reported to have told the Committee members that he was not prepared then to discuss the administration's stand on important social security changes, because this was still under study by the administration.

Flemming was asked to come back at a later date with the administration's recommendations. The HEW Secretary has indicated repeatedly that the administration would offer some type of alternate to the Forand proposal this year, but there was no certainty, as the hearings opened, whether this would be done or what form it might take.

The proposal would broaden social security to include financing of partial health care of the elderly through higher taxes. Rep. Aime Forand (D., R. I.), sponsor of the legislation that is opposed by most business and health organizations as the first step toward complete government control of medicine, said that if the Committee failed to act on the measure he might resort to the seldom-used discharge petition to bypass the Committee and bring the bill up for a vote by the full House.

Meanwhile, the American Farm Bureau Federation wrote the members of the influential ways and means group urging them to turn down the Forand proposal. Enactment "will lead to the socialization of medical and hospital care," said the organization. "This legislation is based on the false assumption that most aged persons cannot finance their own health care needs."

MEDICARE EXPANSION SEEN

The Defense Department's Medicare program, which provides medical care in civilian and military hospitals for qualified dependents of military personnel, will cost more in the future "as the military dependent population grows."

Gen. Floyd L. Wergeland, executive director of the Medicare program, told Congress that the number of families eligible for Medicare will rise to about 3,700,000 in the fiscal year starting July 1, an increase of 200,000 since 1959.

Cost of the program next fiscal year will be about $71,600,000, he told the Senate military appropriations subcommittee, about $2,100,000 above the current fiscal year's cost.

Care for service families in both military and civilian hospitals will rise by about 550 patients a day in fiscal 1961, with the average daily load in civilian installations increasing to 3,200. In military hospitals the daily family load will climb from 9,470 to more than 9,700.

The program, according to the witness, is "now sound and stabilized" and will "increasingly improve the stamina and morale of servicemen."

General Wergeland also said that "a permanent control feature of the program" will be the current permit system under which civilian dependents residing away from their sponsors are required to have permits stating that care in military medical facilities is unavailable as a provision for admission into civilian facilities.

The biggest user of Medicare is the Air Force, accounting for 40% of the cost. The Navy and Marines follow with about 32% and the Army with 24%. The remainder is accounted for by the Coast Guard, the Public Health Service, and the Coast and Geodetic Survey.

Other figures given the subcommittee by General Wergeland included:

Cost per patient per day in civilian hospitals averaged $52.65 this year and will rise to $55.60 next fiscal year. Last year the figure was $50.06.

Of the total $212,600,000 spent on the program since December, 1956, 49.3% represented physicians' claims, 48.5% hospital claims, and 2.2% administrative costs.

Referring to retention of the permit plan, General Wergeland said, "Of prime importance is the fact that the Medicare permit system is operating very effectively to channel patients into service hospitals and it does reduce substantially the cost of the civilian portion of the program."

DRUG HEARINGS SCORED

The dean of Temple University's school of pharmacy charged that Senate investigators were distorting the facts in their inquiry into drug companies' pricing practices.

Dean Joseph B. Sprowls, in a letter to Senate minority leader Everett Dirksen (R., Ill.), said, "If we are to have legislation which prevents the making of honest profits on the manufacture and sale of drugs, then our country and our government have certainly reached their declining years."

The only alternative, he said, is "total socialism—government-directed medical practice and research."

Noting criticism of the drug industry by Sen. Estes Kefauver (D., Tenn.), chairman of the Senate antitrust subcommittee that is currently investigating drug companies, Sprowls said, "Attempts to demonstrate excessive profits by the use of calculations involving only the basic cost of ingredients and the ultimate selling price of finished products are . . . gross misrepresentations of the truth."

Medical and drug research owe their stimulus to the "highest of humanitarian ideals—the desire to relieve suffering and to save lives," he said. "On the other hand, the motive which stimulates the investment needed to make such research possible is the profit motive."

Sprowls said proposals by Kefauver for tighter federal supervision of some industry practices would seriously curtail research efforts and impair the discovery and development of new drugs. "Let us hope that an enlightened electorate will never permit this to happen," he said.

In a speech on the Senate floor, Senator Dirksen, a member of the subcommittee, also attacked the investigation. He said "misleading and unfair exhibits" had "crept into" the hearings and noted various newspaper editorials supporting his charges.

A. M. A. URGES BROADER LABELING BILL

The American Medical Association asked a House commerce subcommittee to strengthen a bill for labeling hazardous substances in order to provide broader safety coverage and clearer warning symbols.

Dr. O. Benwood Hunter Jr., a Washington, D. C., pathologist speaking for the American Medical Association, told the subcommittee that while the need for appropriate labeling of household substances has been amply demonstrated, there is also need for such protection for those engaged in nonmanufacturing occupations.

Neither the bill before the House group nor one that has been approved by a Senate Commerce committee would cover the latter category.

Noting that manufacturing concerns such as large chemical plants "are among the safest places to work because of enforced safety rules." Dr. Hunter pointed out that this does not apply to two-thirds of business enterprises, which are either retail trade establishments, such as grocery stores and filling stations, or service establishments, such as hotels and laundries.

"These firms employ a major portion of the labor force and provide the least organized medium for maintaining the workers' safety," said Dr. Hunter.

"While no information is available as to the number of injuries associated with unlabeled or poorly labeled chemical products, our concern is based on the belief that warning statements of the hazardous ingredients are needed just as much by workers who do not have the benefit of safety programs as they are in the home."

Dr. Hunter also recommended that the bill be changed to include such symbols as the skull and crossbones to emphasize the danger in addition to words as "danger," "caution," and "warning."

At present there is no national law requiring the precautionary labeling of hazardous substances, other than those used in foods or drugs or caustic poisons. The legislation in Congress was modeled to a large extent on the recommendations of the A. M. A.'s Committee on Toxicology. Accompanying Dr. Hunter at the subcommittee session were Bernard E. Conley, Ph.D., Secretary of the Committee on Toxicology, and Paul R. M. Donelan, A. M. A. Legislative Attorney.

SCALED-DOWN INTERNATIONAL MEDICAL RESEARCH BILL APPROVED

A House commerce subcommittee unanimously approved a measure authorizing 10 million dollars for a program of international medical research cooperation. Under the legislation, an office to carry out the program would be established in the Department of Health, Education, and Welfare. The widest possible use should be made of foreign currencies derived from the sale of U. S. food surpluses for international medical studies, said the subcommittee.

The Senate last year approved a broader bill authorizing a 50-million-dollar appropriation and creating a separate Institute of Health to administer the program. The administration opposed the measure on grounds it was not necessary and that instead existing programs should be strengthened. The American Medical Association has endorsed the principle of the legislation but proposed that final action be held off until an over-all assessment can be made of various proposals before Congress dealing with domestic and international research.

Commenting on the subcommittee bill, HEW Secretary Arthur S. Flemming said, "I am glad to note that the subcommittee has moved in the direction of the recommendations we made."

The bill is sponsored by subcommittee chairman Kenneth Roberts (D., Ala.).

MISCELLANY

The U. S. Court of Appeals in New York upheld a lower court decision compelling commercial airline pilots to retire from the cockpit at the age of 60 years. The decision came on a protest by the Air Line Pilots' Association against a Federal Aviation Agency order that pilots of commercial passenger planes could not be more than 60 years old. The ALPA said the order was arbitrary and threatened to carry the fight to the Supreme Court and Congress. Meanwhile, about 40 pilots over 60 years of age were forced to quit commercial flying.

"Mongolism—Hope Through Research," a booklet published by the Public Health Service, tells of research efforts at the National Institutes of Health to find the cause and prevention of the disorder. A new finding suggests that mongolism could begin with an irregularity in the human egg before it is fertilized.

The Federal Trade Commission charged that advertisements for a book entitled "How to Live 365 Days a Year" misrepresented that the method set forth in the book would effectively treat asthma, arthritis, cancer, heart trouble, and other ailments. The publishers of the book, written by Dr. John A. Schindler, agreed to discontinue the claims.

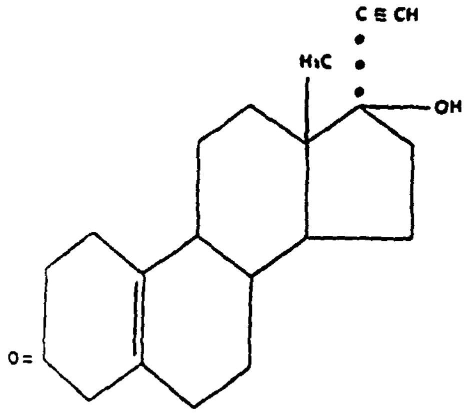
ENOVID®

EXERTS NO ANDROGENICITY



NORETHYNODREL, the principal constituent of Enovid, *is the only progestin with the double bond in the position shown, thus differing from androgens and estrogens.* Norethynodrel possesses intrinsic estrogenicity (*3 to 7* per cent that of estrone) in addition to its potent progestational activity.

Thus, its administration is free of risks of virilism even on long-term administration at high dosage.

Each 10-mg. tablet of Enovid contains 9.85 mg. of norethynodrel and 0.15 mg. of ethynylestradiol 3-methyl ether. (–The estrogen is added in optimal amount to avoid breakthrough bleeding during prolonged use.–)

NORETHYNODREL...

1. A *steroid*[1] *with both progestational and estrogenic effects.*
2. Retains its biologic integrity[2] following oral administration.
3. Is progestational and estrogenic in experimental animals.
4. Is progestational and estrogenic in clinical practice.
5. Is not androgenic[1] in experimental animals.
6. Is not androgenic[3] in clinical practice.

Enovid represents a positive advance in the treatment of threatened or habitual abortion[4] and in the treatment and control of endometriosis[5]. Physicians may prescribe Enovid confidently without producing androgenic manifestations.

DOSAGE OF ENOVID FOR THREATENED ABORTION

Two or three tablets daily on appearance of symptoms. This dosage may be reduced to one or two tablets daily when symptoms disappear. The reduced dosage should be continued to term and increased if symptoms reappear.

DOSAGE OF ENOVID IN HABITUAL ABORTION

Two tablets daily as soon as pregnancy is diagnosed and continued without interruption at least through the fifth month. Enovid may be safely continued to term if desired.

DOSAGE OF ENOVID FOR ENDOMETRIOSIS

The daily dose for the first two weeks is one tablet, two tablets daily for the next two weeks, then three tablets daily for the following two weeks and finally four tablets daily for three to nine months.

Basic

When more than your personal assurance

is required to relieve the emotional distress

common to every illness,

EQUANIL may confidently be prescribed

to relax mind and muscle.

EQUANIL is the most widely used ataractic agent;

its efficacy and wide margin of safety

in the control of tension, anxiety and muscle spasm

are thoroughly documented

in hundreds of published papers.

The action of EQUANIL is predictable.

Side-effects are rare.

Because it is rapidly metabolized,

effects are not cumulative.

Because it does not cloud consciousness,

your patients remain alert and cooperative.

PSYCHOTHERAPY

Kenneth E. Appel, M.D., Philadelphia

Physicians and surgeons in the future will be called on to do more psychotherapy than ever. Various methods of psychotherapy are available to the general practitioner: ventilation psychotherapy in repeated, unhurried interviews; supportive psychotherapy based on facts of physical examination and implemented by physiotherapy and hydrotherapy; manipulative psychotherapy, including occupational and recreational guidance; explanatory psychotherapy; and dynamic growth therapy. The case history of a patient with recurrent asthma and eczema illustrates the need for establishing basic human contact with patients. In many cases it is possible to achieve solid recovery without insight when enough time is allowed for the readjustment of the instinctive id and the social superego forces of the patient.

PSYCHOTHERAPY is widely misunderstood by many persons, including doctors and many psychiatrists. It is not a transfusion of ideas to the patient. It is not an injection of correct notions. It is not soothing him with platitudes, pacifying pronouncements, or phrases. It is not making decisions for the patient or solving problems for him. It is not manipulating a patient with a formula or prescription as one applies an orthopedic brace or gives iron therapy or an enema. It is not giving insight. It does not preclude the use of drugs; drugs may facilitate psychotherapy. It is a collaborative search for better adjustment to rectify a seriously disturbed emotional or conditioned state. It is either a search for a better resolution of frustrations, disappointments, resentments, depression, fears, guilts, distrust, insecurities, and resulting overdependency or compensatory overconfidence, or it may be guidance in meeting disturbances caused by multiple or long-continued stresses due to work situations, physical illness, or social pressures. It is helping the patient develop solutions, capacities, confidence, and respect through discussion, guidance, talking things out, and the release of pent-up feelings. It is a collaborative, searching, prospecting adventure from which confidence, resourcefulness, and help develop. Santayana has really described it, in his essay on Faust, as a drama of search, acceptance or forgiveness, and healing. Dostoevski has much to say about these functions.

Psychotherapy is a deceptive word, used glibly by physicians and laymen alike as if it were a simple process, well understood and easily applied. It is ancient but enigmatic, involving both science and art, fact and fiction, whose nature is often violently disputed by many. When one speaks of it as art, one implies that there is something intuitive and emotional about it—not unlike the feelings and resolutions that come at the end of great esthetic experiences. A resolution of feelings and new dedications take place, so that one is on a new plane or new road of living, with new purposes, resolutions, strengths, and directions. Successful psychotherapy,

---

Professor and Chairman, Department of Psychiatry, University of Pennsylvania, School of Medicine.

Chairman's address, read before the Section on Nervous and Mental Diseases at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 10, 1959.

it appears to me, is of a similar nature, in addition to its ideological, intellectual, and formally psychodynamic aspects. Neglect of the nonintellectual esthetic aspect often accounts, it seems, for many of the failures of psychotherapy.

Physicians and surgeons will be called on to do more psychotherapy than ever, since the introduction of the new tension-reducing drugs. Psychiatrists, who number only between 4 and 5% of the physicians of the United States, can never do the complete psychiatric job. Mental and emotional health is the job not only of the community but especially of the physicians who see patients in their homes and at the inception of illness. It is important that medical schools recognize these facts and afford instruction and training in the basic principles of psychotherapy.

The goal of psychotherapy is the development or restoration of mental or emotional health. Some of the characteristics of mental health may be listed, as follows: reasonable independence; self-reliance; self-direction; ability to do a job; ability to take responsibility; reliability; ability to make needed efforts; persistence; ability to get along with others; cooperation; accommodation—ability to work with others; ability to work under authority, rules, and difficulties; ability to show friendliness and love; ability to give and take; tolerance of others and of frustrations, tensions, and unpleasantness; ability to accept difference; ability to contribute; a sense of humor; devotion beyond oneself; and ability to find recreation, as in hobbies. Tolstoi expressed the goals of life as what men live by: love, play, work, and worship.

Causes of Emotional Illness

A few remarks about etiology and psychopathology may be helpful. Freud in Vienna and Adolph Meyer at Johns Hopkins University looked on most neuroses and psychoses as developmental processes rather than products of heredity and constitution, although these latter elements were not eliminated. These conditions they thought of as reactions to persons and circumstances during growth, developing predisposing tendencies or habits. The normal process of growth produces effectiveness, ability to solve problems, satisfactions, and health. Growth is an expanding, outgoing, and organizing series of processes or manifestations of the organism. Freud used the words libido, sex, and love to mean much of what I mean by the word growth. There is something creative about this.

Various interferences or blocks in the normal processes of growth, or blocks in personal effectiveness, goals, or ideals, produce fear, anxiety, anger, hostility, guilt, ineffectiveness, suffering, and illness. The interferences may be many: unusual runs of illness, misfortune, catastrophe (financial or personal) or death; or they may be blocks, due to disturbed human relationships, which result in feelings of frustration, neglect, rejection, domination, or overdependency, or factors of constitution or heredity. One sees here many factors entering into the formation of habits, inclinations, predispositions, aversions, temperament, and expectations. One's expectations are, whether conscious or unconscious, tremendously important in the development of health or illness. One sees here reasonable doubts as to the amount of responsibility one can attribute to an individual person and some of the reasons why logic and will power have their limitations in dealing with strong, prerational forces and dispositions.

Anxiety develops in response to excessive hostility, aggression, or eroticism. Anxiety is buffered by the various defense mechanisms: repression, dissociation, rationalization, extroversion, introversion-introjection, projection, conversion, reaction-formation (rituals), identification with the aggressor, and regression. Intense expressions of these defense mechanisms appear in illness—the manic overactivity of extroversion, the depression of introversion, the suspiciousness of projection, the physiological disturbances of the conversion of emotional tensions into bodily reactions, the antithetic reactions of the meticulous, obsessive perfectionist, and the regression of the extreme schizophrenic.

Psychiatry deals with personal and social stresses, whether in the past or in the present, the past being predisposing and the present being precipitating. Experience—handicapping, frustrating, or disturbing—is the source of ineffective direction of energies and the associated feelings of frustration, disappointment, and depression. Personal, social, and emotional experiences are causally related, in the present state of knowledge, more often than are such things as infection, trauma, toxic agents, deterioration, or tumor. The stresses of experience can be injurious (castrating) in a predisposing or in a precipitating way. Psychotherapy is counteracting or corrective experience. It is experience and practice, prospecting and searching, not just discussion, exhortation, reasoning, or handing over correct ideas to the patient. If handicapping, or traumatic, experiences have made a person oversensitive to people and situations and predisposed to emotional illness, psychotherapy must provide a healing experience. The effects of destructive experience can be changed only by a new and constructive experience such as psychotherapy can provide.

Psychotherapy is experience. It is broader than the verbal, intellectual, rational, ideal level of the personality. Infants have personalities, with strong emphases, predilections, and aversions, long before the intellect is much developed. They cannot be appealed to by reason, but they can be won or maneuvered by appropriate operations and procedures and so can patients with neuroses and psychoses. They are moved by subrational forces and systems. Reason and will power are often limited or impotent before the great surge of prerational forces. This does not mean that we cannot learn to understand these subrational systems and help them become more effectively modified and integrated into effective and mature systems of organization, action, and feeling.

Psychotherapeutic Methods

Various methods of psychotherapy, as summarized by H. Yaskin, are available to the general practitioner: 1. Aeration or ventilation psychotherapy begins with history-taking and continues by means of repeated, unhurried interviews in which the patient is given the opportunities for "confession" and discussion of his life history. 2. Supportive psychotherapy may start with the physical examination and judicious reassurance, establishing rapport and the opportunity for healthy identifications. Suggestions and the giving of illuminating information may follow, and therapy may include medical and physical treatment, including physiotherapy and hydrotherapy. 3. Manipulative psychotherapy may consist in occupational therapy, the development of hobbies, establishment of a daily routine, including diversion and entertainment, and vocational guidance, by these means producing a change in the patient's environmental attitudes. 4. Explanatory psychotherapy includes desensitization, persuasion, and reeducation by means of suggestion, direct or implied. 5. Finally there is a method which I term dynamic growth therapy, described in this paper.

Psychoanalysis is reserved, as are some other methods, for the specialists. However, psychoanalytic theories and practice have great influence on standard psychotherapy today. All methods can be used appropriately at different times in treating the same patient or different patients. A multifactorial approach is more often than not indicated—often including the use of drugs. Experience enables one to select a number of these procedures that seem possible and helpful at a given time. There are dangers in authoritarian direction, except in the severest conditions; it may arouse antagonism, uncooperativeness, or unwholesome dependency. Suggestions of alternatives for decision and action for the patient to select may stimulate the patient's initiative, resourcefulness, and independence, but many suggestions contain the danger of contrary-to-fact assertions on the part of the physician and work toward his diminished effectiveness or downfall in serious conditions.

Psychoanalysis

Psychoanalysis has been largely incorporated into general psychiatry. Among the psychoanalytic concepts now recognized are those of the unconscious, repression-resistance, dissociation, defense mechanism, transference, abreaction, analysis, and insight. In fact, except for the use of the couch, the depth of analysis, the emphasis on the Oedipus and castration complexes, and the interpretation of dreams, fantasies, and infantile impulses, general psychiatry borrows greatly from psychoanalysis. The principles of psychoanalytic therapy, and the various aspects of it, may be summarized as follows.

The relationship with the therapist is of basic importance; it may be at various times one of confidence, support, submission, distrust, antagonism, marked dependence, or independence. The patient's feelings often are intense, exaggerated, distorted, or inappropriate. The concept of abreaction means the ventilation or free expression of feelings. Transference is a process of displacement, often inappropriately, of feelings from an important person in the past to the analyst. Other techniques include free association, with subsequent intellectual analysis, and interpretation of dreams, fantasies, symptoms, displacements, and resistances.

Free association, analysis, and the interpretation of dreams and fantasies are not employed in psychotherapy with anything like the detail and consistency that they are in psychoanalysis. A definition of psychotherapy that has been useful is the following one: helping people handle their feelings, motivations, and behavior more effectively. This indicates the broad nature of psychotherapy and also indicates that it is not limited to words, planned rational discussions, reasoning, or argument. People can often influence others more effectively by what they do, their manner, and their attitude than by what they say. What is left unsaid is sometimes more important in human relations and in treating emotionally sick patients than what is said. It is a great art to know when not to voice the truth. Dr. Samuel Crothers said that the ability to know what people do not want to hear about themselves and not to say it is a good definition of tact.

Report of an Illustrative Case

A patient in her early 20's had been ill for most of her life with eczema and asthma. She had had treatment both in the United States and abroad in many clinics. Many forms of drug therapy and chemical treatment had been used. She was becoming increasingly depressed. Injections of allergens did not help. It seemed to me that, essentially, her problem was one of lack of security, dating from an early age. She came from a home in which there was an asocial alcoholic mother and an alcoholic father who committed suicide. In the several years before I saw her she had had such severe attacks of asthma that the internist thought she might die. Along with these attacks came terrific outbreaks of eczema. It seemed to me that this young woman needed security. She received treatment with mild doses of sedatives during the day and hypnotics at night. The chief concern was to see her, be with her, and give her all the security possible. This was done, whether for five minutes a day or a half-hour or hour. Some days, of course, she was not seen. Everything that was on her mind was talked about. She discussed what she read, what movies she had seen in the past, and how she felt about friends and relatives. An effort was made to build a solid, secure relationship with her. Sometimes she sat like a frightened animal underneath the table in her hospital room. I frequently sat on the floor beside the table and talked to her. It seemed essential to establish basic human contact with this patient. She got well, and I think I had something to do with her recovery. I do not think that without some kind of rational treatment based on understanding her personality, her experiences, and her needs she would have become well. She had shown no improvement for 20 years. She married and has been well for seven years, living in one of the most competitive cities of the United States. This therapy was social, psychological, and emotional therapy. Her cure was not the result of drugs or chemicals or the result of geographical change. Her cure, it seemed to me, was the result of the establishment of a secure understanding relationship with her therapist—helping her develop a workable amount of security.

Psychotherapy here was not explaining to her how she became ill or making clear to her the linear sequences of her personality development, although the search for clarification is always important. An understanding of the personality development of the patient and the dynamics of the illness on the part of the therapist is much more helpful than it is on the part of the patient. It was not reasoning or explaining how she became ill or the psychology of rejection and insecurity, hostility and guilt; it was not a discussion of psychosomatic medicine or the influence of the emotions on the body. It was providing a setting for her, an opportunity for growth, a search for effectiveness and the acquisition of security. She had new experiences to which she was conditioned, much as the dogs of Pavlov were conditioned. This experience was not just intellectual, it was social and emotional. There was much release of feeling or abreaction. Much of this kind of therapy goes on without the patient's awareness. It is automatic and unconscious. An unconscious readjustment of the forces of the personality takes place. The automatic readjustment does not take place merely as the result of intellectual understanding and reasoning. This patient made a solid recovery, as do many patients, without insight. A readjustment of the instinctive and the moral superego forces of the patient takes place so that the intellectual and ego, or executive, forces of the psyche can take over. Psychotherapy is thus a process of conditioning and reconditioning. It takes time and cannot be done, in severe conditions, by brief exhortations and reasoning.

A factor of great importance in psychotherapy is identification. The patient gradually sees the physician tackling difficult problems and proceeding in certain ways. The doctor asks himself, "What are the things to do, what are the possibilities, what has contributed to this?" Through questions the physician establishes a certain amount of identification with the patient. He moves beyond the patient's immediate problems and says, "There is probably something that we can do with this." No situation is so terrible that something constructive cannot be done. The patient gradually takes over. This is an automatic process of identification with the physician and the role he performs.

The Structure of the Personality

The structure of the personality in its three elements, the intellectual perceptive ego, the instinctive id, and the social superego, may be summarized as follows. The conflict often is between the id and the superego. The ego is the rational component, whose functions include perception, classification, correlation, the search for truth, reasoning, planning, and problem-solving. The id is the emotional component, containing forces arising from body chemistry and metabolism. It is the reservoir of psychic energy of the emotions and impulses, love (the impulse to be with), fear (the impulse to be away), and hate (the impulse against). Love has many expressions, including *élan*, eros, libido, growth, curiosity, multiplicity of interest, productivity, and creativity.

The superego is the social component, providing motivations for attraction (liking) and aversion (disliking), identification (transference), opposition (reversal), expectations, and aspirations, and containing the basic elements of the person's standards, values, and concept of duty. Basic needs of the whole personality include those for security, affection, "belonging," individuality, difference, respect, understanding, and change.

The patient with asthma had persistent insecurity, stemming from her fear of her mother and father, which was transferred to people in general. When the lack of trust in people became intense she had her asthmatic attacks. The therapeutic beginning was to find someone with whom she could find security and confidence. When this was established with the therapist and hospital personnel, it spread to other relationships and the violent autonomic responses subsided and disappeared. She was not aware of these mechanisms. This is what is meant by unconscious therapy, which can take place without insight. One of the most important aspects of therapy is for the physician to tap the constructive forces in the eros, *élan*, or growth impulses of the patient. Psychotherapy should search for and mobilize the interests, assets, and resources of the patient, as well as consider inadequacies and mistakes. This approach enables the patient to expand, take initiative, and develop constructively. Patience, consideration, understanding, and hope are great therapeutic forces.

The words of a great physician can yet guide the psychiatrist: "The good physician knows his patients through and through, and his knowledge is bought dearly. Time, sympathy, and understanding must be lavishly dispensed, but the reward is to be found in that personal bond which forms the greatest satisfaction of the practice of medicine. One of the essential qualities of the clinician is interest in humanity, where the secret of the care of the patient is in caring for the patient."

THE PSYCHOTHERAPY OF PARALYSIS AGITANS

Lewis J. Doshay, M.D., Ph.D., New York

Patients with paralysis agitans need the help provided by antiparkinsonian drugs, by new tranquilizers, antihistamines, muscle relaxants, and cerebral stimulants, and by physical therapy. But it is the psychotherapeutic approach of the physician that binds the entire treatment together. Patients in the early, ambulatory stages of the disease afford favorable prospects for long-term care by the family physician. It is important to maintain their confidence and cooperation and to keep them optimistic and active, since research in this field is progressing and promises increasingly effective remedies.

Probably in no other branch of medicine is psychotherapy as important or effective as in paralysis agitans (Parkinson's disease). It is the psychotherapeutic approach of the physician that serves to bind the entire treatment together. Without it the patient loses confidence in his medicaments, discontinues visits to the physiotherapist and doctor, and deteriorates in a relatively short span of time. The writing of this paper was prompted by the fact that little attention has been given this subject in the literature. There has been an effort to point up what the psychiatrist can accomplish for patients with paralysis agitans by means of group psychotherapy.[1] However, no one has outlined a practical plan of everyday psychotherapy that would be useful to general practitioners in the treatment of 98% of their patients.

Why are these patients especially suitable for psychotherapy? Because, aside from symptoms caused by damage to the basal ganglions, the brain proper (cortex) and its pathways are not involved. These people have symptoms of rigidity, tremor, akinesia, and loss of automatic movement,[2] but they have good preservation of all mental faculties. They can be reasoned with and properly directed. True, ignorance with regard to the nature of the illness and fear of later invalidism may lead some of them to become unduly alarmed and depressed. However, under suitable orientation and reassurance, they generally manage to steer a stable course.

Patients with paralysis agitans are of fundamentally sound character. Sands[3] once described them as good citizens—hardworking, self-sacrificing, and devoted to the welfare and interests of others, especially the immediate family. They are people who have given a lifetime of service to their families and communities and hence are deserving of help in their hour of need. Clinical experience has shown that selfish people hardly ever develop paralysis agitans, habitual criminals almost never, and imbeciles and idiots never.

Nature of Psychotherapy

Every doctor can and often does employ psychotherapy, sometimes even without realizing it. It basically consists of four elements: (1) orientation of the patient as to the nature of his illness, (2) concern for the patient's symptoms and ailments, (3) lending a sympathetic ear to the patient's personal problems, and (4) reassurance of the patient and family during each visit.

From these elements it should be obvious that one does not have to be a trained psychoanalyst to provide effective psychotherapy to patients with paralysis agitans. Psychoanalysis is almost never required in such patients, since we are dealing with an organic ailment and patients are usually past the age of crises that arise from sexual cravings or frustrations. Similarly, hypnosis is of little or no value in patients with this illness, since even when used with maximum skill it affords but momentary benefits.

The general practitioner is fully equipped by training and experience to provide all the psychotherapy that is required by his patients if he takes the interest and time. In only about 2% of such cases does the occasion arise when he has to obtain the help of a qualified psychiatrist.

Orientation of Patient.—The patient can and should be fully prepared to understand the nature of his illness. He must not be left to rely on stray bits of information, or misinformation, from neighbors, friends, newspapers, or magazines. He should be advised that the chief symptoms are rigidity and tremor, which can be helped by current treatment if he cooperates faithfully with his doctor. Under such conditions, 86% of these patients can be maintained in a good state of vocational and functional usefulness for 10 or more years at work, in caring for home and children, or in self-care. Cooperation entails regular visits to the office or clinic once a month if possible.

Every patient must learn the following facts. Paralysis agitans is neither inherited nor contagious. Since the brain proper is spared in this illness, speech and mental faculties are not affected and there is no paralysis or numbness. The reasons for this should be explained clearly. Better medicaments are being discovered for the control of tremor. Rigidity is helped not only by medication but by physiotherapy and exercise. Tremor is rarely of

---

From the Department of Neurology, College of Physicians and Surgeons, Columbia University, and the Neurological Institute of Presbyterian Hospital.

serious consequence to the patient's health and welfare, except when it affects employment or in instances of major tremor.[4] There is no pain in this illness unless contractures develop, usually as the result of neglect. There are far worse ailments than paralysis agitans; examples are brain tumor, leukemia, and multiple sclerosis. For reasons as yet unclear, this disease tends to protect the patient against developing cancer, coronary disease, hypertension, tuberculosis, and certain other ailments that afflict mankind. Better drugs continue to be created by the pharmaceutical houses, and tomorrow, next month, or next year, we may have drugs that are 10 times better than any we have today. New procedures and tools in the field of brain surgery are being studied for relief of tremor and rigidity among patients who fail to respond to conservative treatment. Within the past three years, chemical substances have been discovered that can produce the symptoms of paralysis agitans in "normal" people. This unfolds the unprecedented possibility that other chemical substances may be found that will act as antidotes and prevent the symptoms, or arrest them after they have set in. Quite recently two research foundations have been established for the purpose of doing research on the cause and prevention of paralysis agitans, for discovering better treatment measures, and for creating better facilities for afflicted persons. The National Parkinson Foundation has just embarked on a basic research project at the biological science department of the University of Chicago, and the Parkinson's Disease Foundation has established the first brain bank in this country, geared to research in pathology of paralysis agitans. Other programs will no doubt soon get underway.

These and other points of orientation, with amplification and illustration where possible, should be presented to the patient and family in order to provide hope, confidence, and purpose to treatment. They also serve to cement a lasting and beneficial relationship with the doctor. In this illness, confidence of the patient is of paramount importance. For example, in an acute illness such as pneumonia, the entire aim of treatment is geared to the destruction of the infective process, with little, if any, regard to the patient's attitudes, personality, or confidence. It is different in cases of paralysis agitans, where we are not dealing with a germ but with a chronic degenerative illness in which treatment can prove totally useless without the confidence and cooperation of the patient.

Concern for Patient.—In order for the doctor to merit the continued cooperation of the patient, he must exercise true concern for his needs and welfare. The needs of the patient are to carry on successfully, despite his ailment, and to be protected against later disabilities to the maximum extent. To meet these needs, the doctor must keep abreast of the latest advances in medication and pay close attention to the three essentials of therapy.[5] To those so prepared, paralysis agitans disease affords highly favorable rewards, since it is actually one of the easiest ailments to treat.

The patients do not expect a cure and are appreciative of any betterment in their condition. Daily automatic acts, such as putting on a coat or getting out of bed, which to us have little meaning, may be of great moment to such a patient. When the patient's ability to get out of bed is restored, he is spared the aggravation of having to awaken his family five times a night in order to get him safely to the bathroom.

No complicated tests or hospital stays are required, as in other disease, in order to establish the diagnosis of paralysis agitans. Generally, a glance at the patient, with his fixed facies, absent swing in the arms, shuffling gait, slow movement, and tremor of a limb, suffices. The cogwheel rigidity of wrist, elbow, knee, or ankle and the monotone quality of speech add further confirmation.

We have a growing armamentarium of effective remedies. Among these are standard medicaments such as trihexyphenidyl (Artane) hydrochloride,[6] cycrimine (Pagitane) hydrochloride,[7] procyclidine hydrochloride (Kemadrin),[8] benztropine (Cogentin) methanesulfonate,[9] ethopropazine (Parsidol) hydrochloride,[10] orphenadrine (Disipal) hydrochloride,[11] and chlorphenoxamine (Phenoxene) hydrochloride.[12] In addition, the physician has at his disposal many other suitable and helpful preparations such as dextro amphetamine (Dexedrine) sulfate, diphenhydramine (Benadryl) hydrochloride, hyoscine hydrobromide, and a number of new tranquilizers, antihistamines, muscle relaxants, and cerebral stimulants. The references to these preparations are provided as source material for those not fully acquainted with the actions, dosage, and side-effects of some of the newer compounds. Occasions arise among hypersensitive patients, especially of the elderly type, when excess or even moderate dosage of a drug may lead to toxic reactions of confusion, delirium, and possibly visual and tactile hallucinations. These usually disappear within a day or two if use of the drug is discontinued. Similar symptoms, when produced by cerebrovascular disturbances in the aged, may take days or weeks to disappear, and there is a tendency toward recurrence of the episodes. In such events, the advice of a neurologist should be sought.

Medication is one of the essentials of therapy. Physiotherapy is another, and it should be strongly recommended to every patient suffering from rigidity. The patient must be made to realize not only its value but also the reason he must use it early and continuously, since once contractures develop to an irreversible degree it becomes useless.[13] Exercise by the patient is the third component of the three essentials of therapy, and it should be stressed both as a means of prevention of later contractures and as a means of correction of those already acquired. The doctor must also be reasonably well prepared to discuss with the patient and family the advantages and disadvantages of neurosurgery.[14]

Lending a Sympathetic Ear.—During the long course of the illness, the patient may be harrassed, not only by the symptoms but by endless complications that older people fall heir to—such as memory impairment, otosclerosis, vertigo, tinnitus, headaches, cardiac problems, mental depression, nervousness, fear of the future, insomnia, fatigue, weakness, loss of weight, constipation, urinary problems, swollen ankles, dental problems, and visual disorders. He may suddenly develop a hernia, hemorrhoids, an ulcer, gallbladder disease, or diabetes, or he may fall and fracture a leg. He may also be confronted by problems relating to his work, retirement, rest, exercise, diet, travel, and family difficulties. For such situations the patient requires frequent audiences with his doctor. Not all his problems are subject to successful solutions, but he needs a sympathetic ear in order to make it possible for him to carry on and hurdle his difficulties. No one is better equipped to comfort the patient than the family doctor, who knows his background, temperament, and failings and has repeatedly helped him in the past.

Reassurance to Patient and Family.—Every chronic illness that cripples the body but spares the mind is bound to bring about a certain amount of discouragement and depression, and paralysis agitans is no exception. Some people bear hardships with greater fortitude than others because of greater strength of personality or because background experiences have better prepared them to face life's reverses. Others have secure family members to fall back on for emotional and physical support, and, hence, can withstand their plight with greater equanimity than widows, for example, who live alone despite much suffering and privation because they do not wish to burden their children.

Generally, the mild and ambulatory patients have ample automatic and free activity of the trunk and uninvolved limbs and possess speech and all mental faculties; hence they continue to perform successfully their usual duties of home and shop. Such patients require but little reassurance because they are well equipped by emotional reserve, physical adequacy, and buoyancy of spirit to carry on for many years with a minimum of help from the doctor. They maintain a hopeful attitude that better things will come and are grateful that they are no worse than some patients they see about them.

They do not deviate into frank depressions unless the effects of medication wear off and there is a progression in the symptoms, as when they suddenly find they cannot get out of a chair without assistance. Fears of future invalidism enter, accompanied by alarm, anxiety, and apprehension, which can aggravate tremor, muscle spasm, and physical inadequacy. Other events that may suddenly set them back emotionally and physically include a death in the family, loss of weight, or a fall and injury. Since fears of this nature are usually groundless, the doctor can call into service the most appropriate items listed previously. They should be used with emphasis and reassurance as often as needed to erase all traces of fear and uncertainty of the future. Visits at this time should be made more frequently and medication and physiotherapy fortified, as required.

There are isolated instances when even a mild tremor, as in a barber, may bring loss of employment, economic hardships, and mental depression, which do not readily respond to psychotherapy. They are likely to be remedied by programs of trade retraining to be undertaken by the National Parkinson Foundation.

Patients with late and advanced symptoms of bilateral rigidity, akinesia, impairments of gait, and limitations in self-care can likewise be successfully treated by the family physician, provided a secure home environment and proper facilities for physiotherapy are available. Even disabled patients, under suitable home conditions, will respond favorably to kind words of emotional support and encouragement. Among the latter, however, a more frequent occasion arises for the doctor to obtain the help of a psychiatrist, because of a greater tendency toward depression and agitation. Even so, most patients who are depressed by advanced physical deficits have become more or less acclimated to their status over the years; hence, there is very little risk of attempts at self-destruction.

Aside from active psychotherapy, the doctor's personal interest, enthusiasm, and willingness to see the patient frequently may operate as powerful indirect forces to bolster the patient's morale. The family doctor is often the patient's last recourse for psychotherapeutic help. Many patients dread the prospect of having to go to a psychiatrist because of the inescapable implication that there is something wrong with their minds or that they are "insane." This alone can nullify all the benefits that might be derived from such a referral. It is different with the family physician, whom they know and trust; hence, he is in a position to accomplish more for them and without the alarm and unnecessary expense of consulting a specialist. Second, if the million or so patients with paralysis agitans were to be suddenly thrust on psychiatrists, there would hardly be enough phychiatrists available for the purpose in the entire country.

The means by which a general practitioner could provide better psychotherapy to 98% of patients with paralysis agitans have been presented. Such psychotherapy is within the training and province of every general practitioner. Probably no more than 2% of these patients who are violently disturbed, agitated, and depressed require the services of a psychiatrist or the use of shock therapy, special tranquilization, or mental hospital programs. The fact that the general practitioner cannot always do as well as he would like to is due to forces beyond his control.

Current Limitations to Better Therapy

Because of the absence of suitable community facilities for physiotherapy and rehabilitation, many of today's patients with advanced symptoms of disease become the disabled, dependent, and helpless patients of tomorrow. It is universally recognized that care and treatment of these patients are beyond the resources of the average family. In some sections of our country, physiotherapy treatment is either nonexistent or, if available, is above the means of the patient and family. Some patients are unable to reach a clinic or doctor's office because of gait impairments and lack of transportation; hence they give up all thought of treatment and deteriorate. General hospitals are usually not available to patients with paralysis agitans because the patients do not constitute material for interesting research or teaching and because they require much nursing and other care. Nursing and convalescent homes do not welcome them because of the extra attention they require. For similar reasons, city and chronic hospitals often reject them. The effect on the morale of the patient is bad and is still worse on the morale of members of the family, who are frequently forced to struggle with the care of such patients under adverse conditions until one or the other breaks under strain. The following instance will illustrate:

A patient, 68 years of age, was in an advanced stage of paralysis agitans and had been treated in my office for the past 15 years. Because of lack of physiotherapy facilities in her area and other neglect she became disabled to a point where it was a severe trial for her husband to bring her, even once in several months. He was a hypertensive cardiac patient who struggled to bring his wife from far away Staten Island, at times exerting himself strenuously to even get her out of the automobile and into the office. More recently, he had to bring her in a wheel chair. The strain was far too much for him, with the result that six months prior to this writing he died. Now the responsibility of the patient's care has fallen to her daughter, who has three children to look after. Thus, every two months, with the help of her husband, she undergoes the ordeal of bringing her badly disabled mother to my office. The patient would gladly have spared her family all this hardship if a suitable place were available for her to go to for care and treatment.

Under existing conditions of community neglect, it is not surprising that some patients, realizing that they are to be an endless burden to their families, with nothing to look forward to in terms of treatment, threaten or attempt suicide and are placed for the remainder of their lives in state hospitals, where they do not belong. These people are not insane but are frustrated by real and unfortunate circumstances.

The treatment of disabled patients and those with advanced disease poses a challenge not only to the patient and family but to the doctor from whom the impossible is expected at times. The solution to the problem rests in a twofold broad approach: (1) early and intensive treatment to prevent the later onset of contractures and deformities and (2) a community program to provide proper rehabilitation for patients with advanced cases and special *facilities for the care of totally disabled ones.*

The Outlook

Within the past year the federal government, the American Medical Association, and other agencies have been awakened to the pressing needs of the rapidly growing numbers of the aged and infirm. This newly aroused interest cannot fail to be ultimately translated into better conditions for care and treatment of patients with paralysis agitans.

When the recently created foundations achieve active support from the public for their programs of better treatment for the afflicted and when vigorous research is directed toward the cause and prevention of the disease, the outlook for the patients will materially improve.

It has been pointed out that the ambulatory patients and those in early stages of the disease afford highly favorable prospects for medical and psychotherapeutic care by the family physician. When better community facilities become available for the care of patients with advanced cases, the current greatest challenge to the successful treatment of paralysis agitans will be removed.

USE OF TOLBUTAMIDE IN PARALYSIS AGITANS

PRELIMINARY REPORT

Edwin W. Gates, M.D., Niagara Falls, N. Y.
and
Irving Hyman, M.D., Buffalo

Because a marked diminution of tremor of hands and fingers was noticed in a diabetic receiving tolbutamide, the authors began to use tolbutamide in patients with paralysis agitans. The studies have been continued for a year and a half, and the results have been observed in 15 patients. Eleven of the patients showed considerable reduction of tremor or rigidity or both. In several there was a marked improvement in the mask-like facies, with return of a more normal smile. In several patients, improvement of speech was noted. Care was taken to minimize the psychic effect of a new drug. It was determined that the improvements were not related to hypoglycemia. The significance of these findings is not clearly understood, but the results are consistent and indicate the need for further research on man and animals.

Since the introduction of tolbutamide into the United States in 1955, a vast amount of literature has accumulated on its use in the treatment of diabetes mellitus. However, we have been unable to find any reference describing the effect of tolbutamide on tremor or rigidity of paralysis agitans (Parkinson's disease). In May, 1958, one of us noted a marked diminution in the tremor of the hands and fingers of a 57-year-old diabetic who had been given 1 Gm. of tolbutamide three times a day. We began to use tolbutamide in patients with paralysis agitans and observed the effect on tremor and rigidity. Care was taken to minimize the psychic effect of a new drug. The studies have continued for a year and a half, and we have observed the effects of this drug on 15 patients. In 12 of these patients there was noted either reduction of tremor or rigidity or both. In several patients there was a marked change in the mask-like facies with return of a nearly normal facial expression.

Report of Cases

Case 1.—A 57-year-old man with diabetes had a coarse tremor of the hands and fingers. He was unable to hold a cup of coffee without spilling it, and he was not able to write legibly. He was given 1 Gm. of tolbutamide three times a day before meals. After the drug had been given for three days, it was noted that the patient could drink coffee without spilling it and that he could now write legibly. There was a marked diminution in the tremor. Therapy with tolbutamide was continued; 1 Gm. was given twice daily. Four months later tolbutamide therapy was discontinued, and at the end of 11 days the tremor returned. The patient was again given 1 Gm. of the drug three times daily, and in 48 hours there was marked decrease in the tremor. This patient was also on insulin therapy. Six weeks later, when placebo tablets were substituted for tolbutamide, the tremor returned and

---

From the Medical Service, Niagara Falls Memorial Hospital (Dr. Gates) and the Neurological Service, Buffalo General Hospital (Dr. Hyman).

again he could not hold a cup of coffee without spilling it. Tolbutamide was again given, after which improvement in the writing and a marked diminution in the tremor were noted. One month later tolbutamide was again replaced with placebo tablets. Once again the tremor returned and the patient was unable to write legibly. There was then an interval of five months during which he was not seen. He had taken tolbutamide intermittently during this time. The tremor had now returned and was the same as before tolbutamide was given. He was again given the drug in a dosage of 3 Gm. daily, but nausea resulted. However, on a dosage schedule of 1 Gm. twice daily, there was no nausea and the tremor improved though not as much as previously. There had been no hypoglycemia; blood sugar levels, determined repeatedly, were in the range of 200 mg. %.

CASE 2.—A 65-year-old woman had had paralysis agitans for 35 years. Examination showed marked rigidity of the arms, legs, and back. There was only slight voluntary motion in the arms with a little more in the right arm. The speech was a monotone, and the patient talked very little. There was constant pill-rolling motion of fingers, a mask-like facies, and salivation. There was considerable loss of motion in some of the joints. There was flexion of the head. The legs could not be fully extended because of rigidity. The patient was given tolbutamide in a dosage of 1 Gm. three times daily. At the end of 48 hours there was much less rigidity and much improvement in the speech. There was a change in the facial expression and the patient could now smile. The left arm showed much less rigidity and could be used slightly. There was more voluntary motion in the right arm. The legs could now be fully extended. The rigidity of the back was practically absent. Forty-eight hours later the patient had a cerebral thrombosis. Tolbutamide therapy was discontinued, and one week later the symptoms of paralysis agitans were the same as before administration of the drug. The signs of the cerebral thrombosis cleared rapidly, and three weeks after the incident the only residual was slight weakness of the left facial muscles. Tolbutamide was again given in a dosage of 1 Gm. twice daily. There was again diminution of the rigidity in the arms, legs, and back, diminution of the tremor of hands, and a return of more facial expression.

CASE 3.—A 78-year-old woman with a severe case of paralysis agitans had marked rigidity of the arms and legs and a coarse, pill-rolling, rhythmic tremor of the hands and fingers. An antispasmodic drug had been given for some months. This therapy was discontinued and resulted in an increase in rigidity; the patient was unable to get out of bed. Seventy-two hours after starting therapy with tolbutamide in a dosage of 1 Gm. three times a day, the patient was able to get out of bed and walk. The tremor was less marked, and there was considerable decrease in the rigidity. This improvement was greater than that resulting from any antispasmodic drugs.

CASE 4.—A 78-year-old woman had paralysis agitans for six years. In spite of antispasmotic medication she showed marked rigidity of legs and arms, more marked in the left arm. There was salivation, mask-like facies, and a coarse tremor of the hands with typical pill-rolling motion of the fingers. There was flexion of the head. Tolbutamide was given in a dosage of 1 Gm. three times daily for two days and then 1 Gm. twice daily. The antispasmotic drug therapy was continued. Three days after the start of therapy with tolbutamide, there was much less rigidity of the arms and legs, and shortly the patient was crossing her knees, which she had been unable to do for years. She was now able to aid in dressing her hair and could put her hands behind her head. It was noted that she was able to lift her feet better. There was considerable improvement in walking, and the fingers were not as stiff. There was a definite improvement in the facial expression. She has been able to walk up and down stairs with help, while formerly she had to be carried. She has been able to get out to visit an oculist and a dentist.

CASE 5.—A 56-year-old woman had a coarse tremor of the hands which became more marked with use of the hands or toward the end of the day when she was tired. Physical examination, including neurological examination, revealed no significant findings. She was given tolbutamide in a dosage of 1 Gm. three times daily before meals. There was no change in the tremor, and after 10 days the drug therapy was discontinued.

CASE 6.—An 83-year-old man had constant tremor of the hands, so marked that it was only with a great deal of difficulty and much time that he could unbutton his shirt. This had been observed frequently. He had generalized arteriosclerosis and arteriosclerotic heart disease. He was given tolbutamide in a dosage of 1 Gm. three times daily before meals. Three days later there was a marked diminution of the tremor. The patient was now able to unbutton and button his shirt nearly normally. The drug therapy was discontinued, with resulting return of tremor. The drug was again given, with resulting diminution of the tremor, but the results the second time were not as spectacular as the first time.

CASE 7.—A 63-year-old woman with paralysis agitans had rigidity of the extremities and a coarse tremor of the outstretched fingers in spite of antispasmodic medication. Her gait was unstable and she walked slowly. The facies were mask-like. She was given tolbutamide, 1 Gm. three times a day, and five days later she was walking much faster and with much less rigidity. The tremor was gone. There was also a change in the facial appearance with some diminution of the mask-like facies.

CASE 8.—A 74-year-old woman had a severe coarse tremor for several years. Her tremor was so violent that she was unable to care for herself. She also complained of abdominal pain and stiffness in her extremities. Examination showed a thin undernourished woman who had a coarse tremor of the outstretched hands. The tremor decreased on grasping. There was generalized rigidity, and she could not perform alternating movements nor do finger-to-nose or heel-to-shin tests. She had hyperactive tendon reflexes and bilateral Babinski response. Some decrease in position and vibration sense were noted in the feet. There were no masses in the abdomen to explain her complaints. She was unable to stand unaided. Tolbutamide was given in doses of 3 and 2 Gm. per day; there was only minimal, if any, improvement in tremor or rigidity.

Case 9.—A 76-year-old man was admitted to the hospital in a lethargic and confused condition and with evidence of pneumonia. The blood pressure was 100/60 mm. Hg and the pulse rate was 70 per minute. He cooperated poorly during the examination. The pupils were small and the arterioles were narrowed. There was paresis of the right upper and lower extremities from a prior cerebral infarct. Cogwheel rigidity could be demonstrated in all extremities, particularly the left. A coarse rhythmic tremor was noted in the outstretched arms. There was flexion of the head. The results of alternation movements and finger-to-nose tests were poor. He was unable to tie his pajamas. He was given insulin, 10 units before breakfast for three days, with no change. One gram of tolbutamide was given three times one day and then twice daily. By the third day there was considerable improvement. He was almost feeding himself and was assisting in his own care. The next morning he had a hypoglycemic reaction with a fasting blood glucose level of 57 mg.% and had a temporary increase in his right-sided paresis.

Case 10.—A 71-year-old woman had paralysis agitans for over 10 years. She was admitted to the hospital because she had fallen and injured her right shoulder. She was unable to get out of bed without assistance and could not feed herself. She had taken various antispasmodic drugs with only moderate relief of her symptoms. On admission to the hospital she demonstrated marked rigidity in all four extremities. There was a coarse tremor of the right hand. There was a right hemiparesis with increased deep tendon reflexes and, on the right, a Babinski response was noted. No sensory deficit was present. The fundi showed considerable arteriovenous nicking. Her speech was rather monotonous and at times difficult to comprehend. She was given tolbutamide, 1 Gm. three times a day for one day and then 1 Gm. twice daily. She became less rigid and the tremor decreased in intensity. After a few days she was able to feed herself and required much less assistance in daily living tasks, such as dressing and bathing. She could walk unaided after one week of therapy.

Case 11.—A 72-year-old woman was admitted for a fracture of the left femur. She had considerable difficulty with tremor and rigidity for several years. Prior treatment with antispasmodics was ineffective. Examination disclosed generalized arteriosclerosis. She had a coarse regular tremor of the hands and feet. There was generalized rigidity, mask-like facies, and salivation. She was given tolbutamide, 1 Gm. three times daily, but no effect was noted on the rigidity nor the tremor.

Case 12.—A 76-year-old woman had increasing stiffness for about six years. She became so immobile that she was unable to get out of bed. Examination disclosed that, aside from generalized arteriosclerosis, she had marked rigidity in all four extremities. The reflexes were equal and the plantars were normal. No sensory deficit was present. She was unable to feed herself because of the rigidity. A coarse alternating tremor was observed. Because of her lack of response to the usual antispasmodic drugs, she was given tolbutamide, 1 Gm. three times daily and then twice daily. She experienced considerable improvement and, with assistance, was able to feed herself. A definite lightening in her mood was observed, and she became more amenable to discussions of her problems.

Case 13.—A 72-year-old man was admitted to the orthopedic service with a fractured pelvis. He had a history of such increasing stiffness and difficulty in getting about that he became an invalid. When seen in the hospital he was thin and undernourished. His spine was flexed and his hands were in a clenched position. Alternations were poorly done and he was unable to feed himself, get out of bed, or walk. He could not tie his pajamas or put on his shirt. There was evidence of generalized arteriosclerosis. When tolbutamide was administered in the dosage of 1 Gm. three times daily and then twice daily, there was a remarkable improvement. He could get out of bed, take some steps unaided, and feed himself. His rigidity was notably less, and there was a diminution in the tremor. Use of the medicament was discontinued, and there was a prompt return of the rigidity and tremor. When tolbutamide was given again, less effect was noted.

Case 14.—A 78-year-old patient had severe paralysis agitans for several years. There was only mild relief from antispasmodic medications. She was able to get out of bed only with assistance and had difficulty in feeding herself. She could not dress herself nor take care of her personal hygiene. She had generalized arteriosclerosis and a pill-rolling tremor of the hands. The tremor decreased on grasping objects. There was generalized rigidity and the fingers were flexed. The spine had a flexed posture. The reflexes were active and equal with normal plantar responses. Some decrease in the peripheral sensation was noted in the feet. She was given tolbutamide, 1 Gm. three times a day and then twice daily. There was considerable improvement in her ability to get out of bed. She could rise to a standing position and was able to feed herself. She required much less nursing care.

Case 15.—A 57-year-old man was admitted for neurological examination to determine his eligibility for chemopallidectomy. He had shown symptoms of paralysis agitans for 15 years and had not shown any response to the antispasmodic medicaments. On examination he was depressed and had a mask-like expression. There was a flexion deformity of the hands and generalized rigidity. A coarse tremor was present in the outstretched hands. He could barely bring his finger to his nose. He was given tolbutamide, 1 Gm. three times daily, and had a marked decrease in rigidity and tremor but no change in mood.

Comment

We suggest that all patients who are given tolbutamide for paralysis agitans be fed six times daily, three meals and three lunches; or each lunch may be replaced with 6 oz. of orange juice. Only one of our patients had a hypoglycemic reaction; this man was undernourished and not taking food very well. In some patients there was a decrease in tremor, and in others the most marked effect was the lessening of the rigidity. Most of the patients given tolbutamide were benefited to the extent that they required less care and could perform many more daily living tasks. Discontinuing the medication and restarting it had varying results, some patients showing benefits and others demonstrating less effect. The effect was not related to hypoglycemia and was present whether or not the patient was given antispasmodic medicaments. In one patient placebos were given and there was prompt return of rigidity and tremor. Most of the patients were not told that the pills would help their symptoms, so the element of suggestion was reduced. We feel that an objective set of tests are in order and also contemplate producing parkinsonian states in animals and administering varying doses of tolbutamide by injection so that the dose and effect can be controlled.

Summary

Tolbutamide was administered to 15 patients with long-standing paralysis agitans (Parkinson's disease). Eleven showed considerable decrease in rigidity and tremor or both. Several showed marked improvement in the mask-like facies with return of a more normal smile. In several patients, improvement of speech was noted. These improvements were not related to hypoglycemia. The significance of these findings is not clearly understood. The results were consistent and indicate the need for further research on man and animals.

OBSERVATIONS ON LIVE INFLUENZA VACCINE

Gordon Meiklejohn, M.D., Denver

The influenza vaccines developed in the United States since 1940 have been inactivated virus vaccines given by subcutaneous, intradermal, or intramuscular injection. Protection of very high degree has been conferred on vaccinated persons, but no satisfactory solution of many of the problems involved in immunization against influenza has been found. Meanwhile, workers in Russia have concentrated their efforts on live vaccines, with use of attenuated virus strains administered by the respiratory route. Russian vaccines have not previously been tested in the United States. This report presents observations on the responses of 27 volunteers who received live vaccine in the fall of 1958.

Material and Methods

Vaccine.—The vaccine used in this study was prepared at the Metchnikov Institute in Moscow and was received through the good offices of the National Institutes of Health. It was a lyophilized suspension of the fourth allantoic passage of the Iksha (A_2) strain. When resuspended in distilled water and titrated by the allantoic route in chick embryos, it contained $10^{-4.5}$ embryo-infective doses (EID_{50}) per 0.1 ml.

Subjects.—Members of the staff and student body of the University of Colorado School of Medicine served as volunteers for the vaccination studies. Most of them were young adults, and all were symptom-free at the time of inoculation.

Administration of Vaccine.—Subjects lay on their backs on an examining table, with their heads hanging over the end of the table. One-quarter milliliter of vaccine was dropped into each nostril, and the subject was instructed to hold this position for at least one minute, sniffing vigorously.

Laboratory Methods.—Throat washings were collected in beef heart extract broth on the first and second days after inoculation from all subjects, and also on the third and fourth days from 13 subjects. These were frozen at −45 C and subsequently inoculated by both the amniotic and allantoic routes into

10-or-11-day-old chick embryos. Hemagglutination tests were carried out by means of the technique used by the World Health Organization (WHO),[1] both with the parent nonavid-Iksha strain and with the avid strain, Japan 305. The Japan-305 line used in this study had been passed through ferrets and mice before being propagated serially in chick embryo. Serums were periodate-treated.[2]

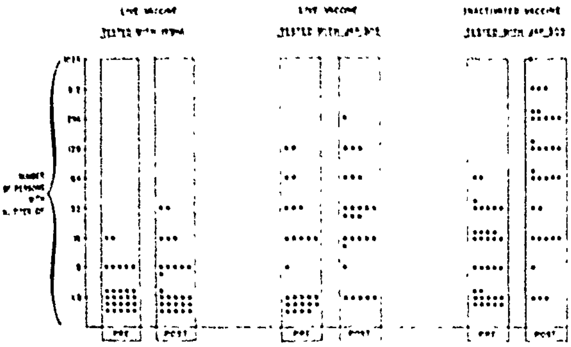

Fig. 1.—Hemagglutination-inhibiting (HI)-antibody titers before and two weeks after vaccination in tests with Iksha and Japan 305 strains.

Results

Clinical Observations.—All subjects reported at the laboratory daily for four days after vaccination. None showed significant elevation of body temperature, and none had symptoms referable to the vaccination.

Recovery of Virus.—Virus was recovered from the throat washings of 3 of the 27 vaccinated subjects. In one person the recovery was from the washing collected on the first day, but washings collected on the second and subsequent days were negative. With the other two subjects, virus was present in washings taken on the second day, but not in those of the first day. In each case virus was recovered in both allantoic and amniotic fluids. Each of these three subjects showed an increase in antibody titer from <1:8 to 1:32.

Hemagglutination-Inhibiting Antibody Response.—The distribution of hemagglutination-inhibiting (HI) antibody titer before and two weeks after vaccination is shown in figure 1. Fourteen of the 27 persons had titers of <1:8 prior to vaccination, while the remaining 13 had antibody in measurable amounts. After vaccination, there was a slight upward shift in the level of antibody titers. This resulted almost entirely from the development of antibody in these subjects who had shown none prior to vaccination (fig. 2). Nine of the 14 persons with titers of <1:8 showed increases in antibody titer of from 2-fold to 32-fold. Of the 13 subjects with titers of 1:8 or more, only 2 showed a fourfold rise, 3 showed a twofold rise, and the remaining 8 showed none. The nonavid character of the Iksha strain in the vaccine is also illustrated in figure 1, in which titers obtained in tests with both the Iksha strain and the avid Japan-305 strain are presented.

In figure 2 the antibody levels before and after vaccination of a similar group of 35 subjects who had received a subcutaneous injection of a polyvalent aqueous vaccine containing 100 chick cell-agglutination (CCA) units of Asian vaccine (Japan 305) are compared to those obtained with the live vaccine. The responses of persons who had titers of <1:8 were of the same order with both vaccines; however, the responses of subjects who had demonstrable levels of antibody differed. With the inactivated vaccine a sharp booster effect was observed, while with the live vaccine the change in antibody titer was relatively insignificant.

Comment

The vaccine used in this study met certain of the criteria set forth by Smorodintsev and Zhdanov in 1957.[3] The infectivity titer of $10^{-5.5}$ per milliliter was close to their recommended level of 10^{-6} per milliliter. Nine of the 14, or more than 50% of the subjects with titers of <1:8, were shown to have an increase in antibody titer after vaccination. However, virus was recovered from only 3 of 14 "susceptible" persons, a proportion which falls considerably short of Smorodintsev's and Zhdanov's criterion that virus should be recovered from 50% of "susceptible" vaccinated subjects. Hence it is possible that the vaccine was below optimal standards in terms of antigenicity, or that the method of administration was faulty. In terms of safety, there was no evidence that the vaccine caused illness.

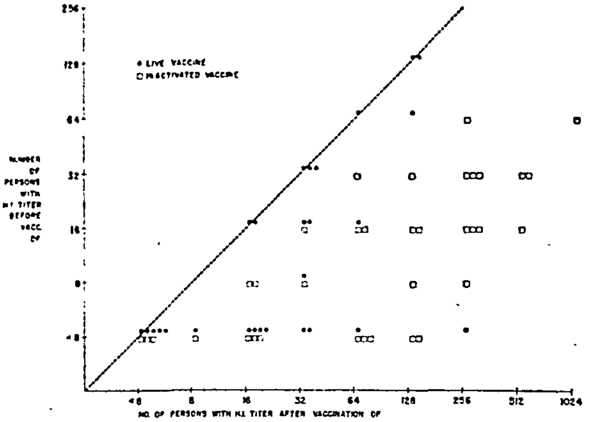

Fig. 2.—Distribution of prevaccination and postvaccination HI-antibody titers of recipients of live and inactivated vaccines.

With respect to effectiveness in evoking an antibody increase in subjects with titers of <1:8, the live vaccine was no better than an inactivated vaccine which was administered subcutaneously and contained only 100 CCA units. In producing a booster effect in persons who had antibody before vaccination, the live vaccine appeared to be inferior to the inactivated vaccine. While the data presented here tend to support the generally held toms of paralysis agitans for 15 years and had not shown any response to the antispasmodic medicaments. On examination he was depressed and had a mask-like expression. There was a flexion deformity of the hands and generalized rigidity. A coarse tremor was present in the outstretched hands. He could barely bring his finger to his nose. He was given tolbutamide, 1 Gm. three times daily, and had a marked decrease in rigidity and tremor but no change in mood.

Comment

We suggest that all patients who are given tolbutamide for paralysis agitans be fed six times daily, three meals and three lunches; or each lunch may be replaced with 6 oz. of orange juice. Only one of our patients had a hypoglycemic reaction; this man was undernourished and not taking food very well. In some patients there was a decrease in tremor, and in others the most marked effect was the lessening of the rigidity. Most of the patients given tolbutamide were benefited to the extent that they required less care and could perform many more daily living tasks. Discontinuing the medication and restarting it had varying results, some patients showing benefits and others demonstrating less effect. The effect was not related to hypoglycemia and was present whether or not the patient was given antispasmodic medicaments. In one patient placebos were given and there was prompt return of rigidity and tremor. Most of the patients were not told that the pills would help their symptoms, so the element of suggestion was reduced. We feel that an objective set of tests are in order and also contemplate producing parkinsonian states in animals and administering varying doses of tolbutamide by injection so that the dose and effect can be controlled.

Summary

Tolbutamide was administered to 15 patients with long-standing paralysis agitans (Parkinson's disease). Eleven showed considerable decrease in rigidity and tremor or both. Several showed marked improvement in the mask-like facies with return of a more normal smile. In several patients, improvement of speech was noted. These improvements were not related to hypoglycemia. The significance of these findings is not clearly understood. The results were consistent and indicate the need for further research on man and animals.

In terms of safety, there was no evidence that the vaccine caused illness.

With respect to effectiveness in evoking an antibody increase in subjects with titers of <1:8, the live vaccine was no better than an inactivated vaccine which was administered subcutaneously and contained only 100 CCA units. In producing a booster effect in persons who had antibody before vaccination, the live vaccine appeared to be inferior to the inactivated vaccine. While the data presented here tend to support the generally held

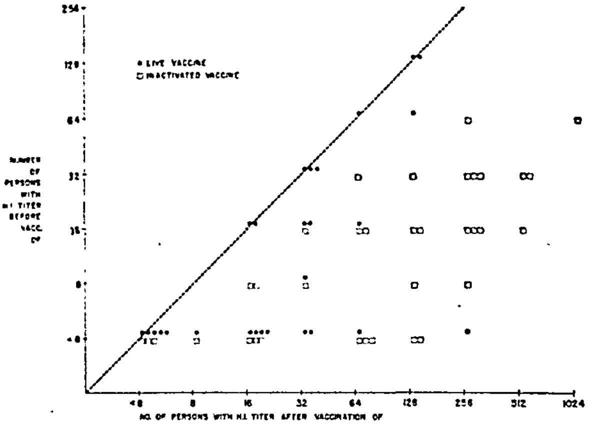

Fig. 2.—Distribution of prevaccination and postvaccination HI-antibody titers of recipients of live and inactivated vaccines.

opinion that inactivated vaccines are preferable to live vaccines, it seems advisable to conduct further comparative studies in laboratories in the United States.

Summary

Live Russian influenza A_2 vaccine, given intranasally, was moderately effective in raising hemagglutination-inhibiting (HI) antibody levels in persons who had no detectable antibody, but persons with antibody showed little booster effect. Inactivated vaccine given subcutaneously was far more effective than the live vaccine in raising antibody levels of persons who had antibody at the time of vaccination. No illness was observed in persons vaccinated with live vaccine.

OCCURRENCE OF ALLERGIC DISEASE IN PATIENTS WITH ADRENAL CORTICAL HYPOFUNCTION

Haddon M. Carryer, M.D., Donald W. Sherrick, M.D.
and
Clifford F. Gastineau, M.D., Rochester, Minn.

Data from 27 patients were analyzed in order to determine the relation of adrenal cortical hypofunction to the occurrence of allergic disorders. This group was selected on the basis of evidence of allergic disease, obtained either from the case record or from a personal interview, out of a total of 496 who had been found to have adrenal cortical hypofunction. Among the 496 there were 18 in whom the existing allergic disease showed no correlation with adrenal cortical function and 27 in whom there was (1) a definite time-relation between full development of the hypofunction and appearance or intensification of the allergic disorder or (2) improvement in the allergic disorder as treatment for adrenal cortical hypofunction was implemented. The latter most commonly were in the form of atopic reactions. In 8 of the 27 patients with adrenal cortical hypofunction the administration of cortisone or adrenal extracts ameliorated the atopic symptoms.

It has long been recognized that the adrenal cortex influences reactions of hypersensitivity. Depriving an animal of a functioning adrenal cortex by adrenalectomy or causing adrenal cortical atrophy by hypophysectomy measurably increases the sensitivity of the animal to anaphylactic shock.[1] More recently, hormones of the adrenal cortex, hormones similar to those elaborated by the adrenal cortex, and ACTH, which stimulates the outpouring of adrenal cortical hormones, have all been shown to influence favorably various allergic diseases.[2]

The occurrence of allergic disease was reviewed in a recent study of 101 patients who had adrenal cortical hyperfunction (Cushing's syndrome).[3] Patients with hay fever and bronchial asthma, as well as adrenal cortical hyperfunction, experienced an amelioration of allergic symptoms when adrenal cortical hyperfunction occurred. Conversely, with the surgical correction of adrenal cortical hyperfunction, the allergic disorder recurred.

Present Study

We reviewed data on the occurrence of allergic disorders among patients who had adrenal cortical hypofunction (Addison's disease). For this study we had access to the case records of 496 patients who were found to have adrenal cortical hypofunction at the Mayo Clinic from 1915 through 1957. We either reviewed the case records or interviewed and examined these patients to ascertain the presence or absence of allergic disease. If allergic disease was present, we also determined the pattern it assumed and whether it was associated with or influenced by adrenal cortical hypofunction. Because the patients included in the series were seen at the Mayo Clinic over many years, the majority of facts were elicited from a review of medical records.

Allergic Reaction	Related	Not Related
Atopic	17	10
Drug	8	8
Both	2	...
Total	27	18

At the beginning of this study it was recognized that certain problems would be encountered. Foremost among these was the fact that, in the era under consideration, striking changes in the management of adrenal cortical hypofunction were taking place. Patients who had the disease in earlier years under study were uniformly in a serious condition and soon died. The changing efficacy of treatment for this disease is of great importance to the present study. Treatment for adrenal cortical hypofunction progressed through an era of use of weak adrenal cortical extracts to one of use of substances more effective primarily in mineral metabolism and ultimately to use of cortisone and similar drugs. Current clinical and experimental data have demonstrated that the antiallergic influences of steroid drugs are more intimately linked with the anti-inflammatory steroid hormones than with those hormones that primarily induce effects on mineral metabolism.

The records of some patients with adrenal cortical hypofunction were brief and information concerning associated medical problems was limited. This was particularly true in the earlier years. Often the patients were first observed in a state of desperate illness, thereby limiting the opportunity for completion of their recorded medical histories. Information recorded was mainly concerned with the critical problem at hand, namely, adrenal cortical hypofunction. Inquiry about other medical problems including allergic disorders, therefore, was often incomplete. More recent records have served better in providing information as to allergic disorders.

Another problem encountered was the necessity for arbitrarily deciding the time of onset of adrenal cortical hypofunction. The onset of this disease usually is insidious. Before a diagnosis was established and before medical attention was sought, many patients experienced a period of gradual weakness, loss of weight, or other symptoms suggesting, in retrospect, that these were indeed early evidences of adrenal cortical hypofunction. Since it was our wish to correlate the occurrence of allergic disorders with adrenal cortical hypofunction, it became necessary to make, on occasion, assumptions that symptoms occurring before overt signs of adrenal cortical hypofunction were actually harbingers of that disease.

It was necessary to decide, at times rather arbitrarily, whether cortisone was being given only in physiological replacement amounts or in amounts so large as to implement a pharmacological suppression of allergic manifestations. The distinction is probably a quantitative one only, inasmuch as amounts of cortisone corresponding to the normal adrenal production of cortisone-like hormones are similarly capable of suppression to a degree of the allergic process.

The purpose of this study was to compare the degree of allergy exhibited by these persons with an allergic diathesis before and after the development of adrenal insufficiency. The effect of therapy for adrenal cortical hypofunction on the allergic state was also considered.

Results

Of 496 patients with adrenal cortical hypofunction, 451 had no recorded history or finding of associated allergic disease, and 45 had a history or findings suggesting one or another type of allergic disorder, such as asthma, hay fever, urticaria, angioedema, perennial allergic rhinitis, or drug allergy (table 1).

	Adrenal Cortical Hypofunction						Treatment for Adrenal Cortical Hypofunction	
	Onset		Initial Visit					
Case No.	Age	Sex	Yr.	Age	Allergic Disease	Time of Onset of Allergic Disease in Relation to Onset of Adrenal Cortical Hypofunction	At Time of Allergic Symptoms	Effect on Allergic Symptoms
1	31	F	1930	32	Perennial allergic rhinitis	Perennial allergic rhinitis 2 yr. before, moderately severe at onset of adrenal cortical hypofunction	Extract of adrenal cortex (Swingle's extract)	. . .
2	46	M	1931	49	Bronchial asthma; chronic urticaria	Bronchial asthma and chronic urticaria 2½ yr. after first pigmentation	Extract of adrenal cortex (Swingle's extract)	. . .
3	44	M	1932	44	Drug allergy, with beginning exfoliative dermatitis, to emetine or methenamine derivative of meta-amino para-oxyphenylarsonic acid (Treparsol) or both for parasitic infestation	Allergic reaction after fully developed adrenal cortical hypofunction	None until allergic reaction rapidly spread, extract of adrenal cortex (Eschatin), 10 cc. daily, after onset of skin eruption	What appeared to be rapidly developing exfoliative dermatitis subsided with stopping antiparastitic medications and/or use of extract of adrenal cortex
4	43	M	1934	45	Drug allergy to anterior pituitary extract; urticaria on 3rd injection	Allergic reaction after fully developed adrenal cortical hypofunction	10 cc. of adrenal cortical hormone by injection	. . .
5	32	F	1934	32	Drug allergy to sesame oil used as vehicle for desoxycorticosterone acetate; urticarial response; tolerated peanut oil as vehicle	Allergic reaction after fully developed adrenal cortical hypofunction	Desoxycorticosterone acetate, on preceding day 125 mg. of corticosterone by injection	. . .
6	28	M	1937	29	Chronic urticaria and angioedema	Allergic disease 6 mo. prior to early manifestations of adrenal cortical hypofunction	None	. . .
7	35	F	1939	40	Chronic urticaria	Urticaria briefly at age 11, chronic urticaria at time pigmentation developed at age 38, after 3 yr. of increasing weakness	None	. . .
8	31	F	1940	36	Perennial allergic rhinitis, onset at age 33; two isolated episodes of asthma at ages 33 and 36	Perennial allergic rhinitis after early manifestation of adrenal cortical hypofunction; two isolated episodes of asthma prior to and after diagnosis of adrenal cortical hypofunction	Desoxycorticosterone acetate by injection; sodium chloride orally	. . .
9	32	F	1940	33	Urticaria, cause undetermined (1 wk. duration)	Urticaria 2 yr. after onset of adrenal cortical hypofunction	Suprarenal preparation, cortin, 5 cc. daily, desoxycorticosterone acetate, 1 mg. daily, and sodium chloride	. . .
10	52	M	1940	52	Perennial allergic rhinitis 2 yr. before early manifestation of adrenal cortical hypofunction; nasal polypectomy required	Perennial allergic rhinitis with recurrent nasal polyps at time adrenal cortical hypofunction was diagnosed	Desoxycorticosterone acetate and sodium chloride	Nasal polypi present 6 mo. after treatment with desoxycorticosterone acetate and sodium chloride; nasal symptoms no longer a problem when seen at age 54 and age 58
11	52	M	1942	52	Bronchial asthma from 46 years of age	Mild bronchial asthma until age 52, moderately severe, with early manifestations of adrenal cortical hypofunction	Desoxycorticosterone acetate and sodium chloride. Adrenal cortical extract	Mild asthma persisted, congestive heart failure developed
12	30	F	1946	32	Drug allergy to penicillin, with skin eruption after its use for urinary tract infection	Allergic reaction 1 yr. after early symptoms of adrenal cortical hypofunction	None	. . .
13	40	M	1946	46	Drug allergy to concentrated liver extract for pernicious anemia at age of 36; urticarial drug reaction	Allergic reaction to liver extract at age 38, with desensitization, was tolerated several weeks; then not tolerated; recurred	Desoxycorticosterone acetate, 2 mg. daily by injection	Urticaria after injections of liver extract continued
14	49	F	1948	49	Drug allergy to penicillin and/or chlortetracycline, with edema and cheilitis after drugs for respiratory infection	Allergic reaction occurred after fully developed adrenal cortical hypofunction; reaction when control of adrenal cortical hypofunction was poor	Implants of desoxycorticosterone acetate	. . .
15	20	F	1948	21	Drug allergy with urticaria after intravenous injection of medium in excretory urography	Reaction a few weeks after early manifestation of adrenal cortical hypofunction	None	. . .
16	31	M	1948	32	Urticaria and angioedema; drug allergy after sulfadiazine and penicillin therapy; urticaria and angioedema 5 days after administration of sulfadiazine and 3 days after administration of "sulfa-penicillin" tablet	Urticaria and angioedema recurrently at age 20 to 27 prior to adrenal cortical hypofunction; drug allergy with urticaria during treatment for adrenal cortical hypofunction	Desoxycorticosterone acetate (Percorten) 0.4 cc. intramuscularly, daily	. . .
17	59	F	1948	60	Mild recurring bronchial asthma from age 44, mainly after upper respiratory infections	Asthma present 15 yr. before onset of adren [illegible] chang [illegible] time [illegible] developed	Lipoadrenal extract, 0.5 to 1 cc. daily + desoxycorticosterone acetate, 2 mg. daily	With treatment asthma virtually controlled. Recurrence on omitting treatment.
18	29	M	1948	30	Severe bronchial asthma requiring hospitalization for severe nightly attacks	Asthma 6 mo. after onset of adrenal cortical hypofunction	Desoxycorticosterone acetate + lipoadrenal extract, 0.5 cc. daily	In 2 weeks asthma virtually controlled
19	53	F	1949	54	Childhood asthma, onset of seasonal hay fever at age 33, gradually abating in several years thereafter	Mild recurrence of hay fever 4 yr. before and severe recurrence of hay fever 1 yr. before onset of adrenal cortical hypofunction	Desoxycorticosterone acetate (Cortate), 2 mg. daily	. . .

Case No.	Age	Sex	Yr.	Age	Allergic Disease	Time of Onset of Allergic Disease in Relation to Onset of Adrenal Cortical Hypofunction	At Time of Allergic Symptoms	Effect on Allergic Symptoms
20	37	F	1949	42	Bronchial asthma	Onset of chronic cough, age 39, 2 yr. after onset of adrenal cortical hypofunction; associated bronchial asthma at age 42	None	. . .
21	42	M	1950	42	Chronic urticaria, mainly nocturnal, 4 to 5 nights a week	Chronic urticaria 4 yr. after onset of adrenal cortical hypofunction	25 mg. of cortisone divided into 4 doses daily; buccal administration of desoxycorticosterone acetate 2 mg. daily; also buccal administration of testosterone, 10 mg. daily	. . .
22	39	F	1951	40	Perennial allergic rhinitis	Rhinitis 9 mo. after early manifestation of adrenal cortical hypofunction	None	. . .
23	37	F	1951	42	Chronic urticaria and angioedema; drug allergy to foreign serum, aspirin, aminopyrine and concentrated liver extract with urticaria and/or angioedema after their use	Urticaria and angioedema occasionally for 13 yr. prior to early symptoms (exhaustion); severe for 6 mo. before definite symptoms of adrenal cortical hypofunction	Cortisone, 37.5 mg. daily; later 30 mg. daily; 2 mg. of buccally administered desoxycorticosterone acetate added later; fludrocortisone acetate (Florinef), 0.2 mg., substituted for desoxycorticosterone acetate later	Chronic urticaria and angioedema controlled by controlling adrenal cortical hypofunction with this amount of cortisone. Only one recurrence (for 2 wk.) in ensuing 3 yr. No record of contact with drugs
24	27	F	1952	35	Bronchial asthma and perennial allergic rhinitis	Bronchial asthma and perennial allergic rhinitis at age 35 at time of deepening of previously mild pigmentation (present from age 27)	Cortisone 20 mg. daily; also buccally administered desoxycorticosterone acetate, 4 mg. daily	Bronchial asthma essentially controlled (one attack in 3 yr. after a respiratory infection)
25	36	M	1952	36	Drug allergy to penicillin (urticaria), nitrofurazone (dermatitis venenata), chloramphenicol (stomatitis)	No allergic symptoms until about 1 yr. after onset of adrenal cortical hypofunction	Cortisone, 15 mg. daily + fludrocortisone acetate, 0.2 mg. daily, or buccally administered desoxycorticosterone acetate, 2 mg. daily	
26	45	M	1953	47	Bronchial asthma	Bronchial asthma 1 mo. after early symptoms of adrenal cortical hypofunction	None at time asthma occurred for 18 mo; later cortisone, 20 mg. daily, and either buccally administered desoxycorticosterone acetate, 6 mg. daily, or 0.1 mg. of fludrocortisone daily	Bronchial asthma subsided to chronic cough after 18 mo.; with treatment for adrenal cortical hypofunction cough subsided; no respiratory complaints at examination at age 49, 50, and 52
27	60	F	1954	61	Bronchial asthma since age 15; mild after age 28; only 2 mild attacks a year after respiratory infection	Bronchial asthma more severe at age 60 with initial symptoms of adrenal cortical hypofunction	Cortisone, 30 mg. daily, and desoxycorticosterone acetate, 4 mg., sublingually daily (latter drug later supplanted by fludrocortisone)	Bronchial asthma improved

these 18 patients 8 had drug reactions and 10 had atopic disease. This group will not be considered further in this report.

In 27 of the 45 patients the allergic disorder (1) developed long before and was worse after the onset of adrenal cortical hypofunction, (2) developed so near the time of onset as to suggest that adrenal cortical hypofunction might have been present, (3) was first evident after adrenal cortical hypofunction was fully developed, or (4) appeared to be influenced by therapy for adrenal cortical hypofunction. In these 27 patients the allergic reaction was considered to be definitely related to the adrenal cortical hypofunction. In 17 of these patients, the reaction was atopic and assumed the form of asthma, hay fever, urticaria, angioedema, or perennial allergic rhinitis. In eight patients the reaction was a drug reaction. Two patients exhibited hypersensitivity of both types.

Of the patients who showed a correlation between the occurrence of adrenal cortical hypofunction and various reactions of hypersensitivity, 12 were male and 15 were female. Evidences of adrenal cortical hypofunction first developed at the average age of 40 years and 8 months. The allergic diseases encountered included drug allergy in 10 cases, bronchial asthma in 10, urticaria or angioedema in 7, perennial allergic rhinitis in 5, and hay fever in 1.

Among patients with atopic forms of hypersensitivity, seven had had allergic manifestations long before adrenal cortical hypofunction occurred. Twelve had atopic symptoms either shortly before, suggesting that adrenal disease may have been beginning, or soon after adrenal cortical hypofunction was fully developed. With one exception (case 23) all allergic reactions to drugs followed the onset of classic addisonian symptoms (table 2).

Among the seven patients who had atopic reactions antedating adrenal cortical hypofunction, there were five in whom the severity of allergic symptoms was accentuated coincidentally with the onset or intensification of the disease. The allergic status of the other two patients was improved after replacement therapy for adrenal cortical hypofunction.

The establishment of a correlation between the occurrence of drug allergy and adrenal cortical hypofunction posed many problems. In many instances there was little basis for a comparison of reactions under different circumstances, for such isolated reactions were frequently single. They had usually taken place prior to the institution of treatment for adrenal cortical hypofunction.

Observations concerning the effect of treatment for adrenal cortical hypofunction on an associated atopic disease were available primarily among patients seen later in the series. In all eight cases in which the effect of treatment with cortisone or adrenal extracts on atopic disease was documented, such treatment was associated with an amelioration of the atopic disorder. In one (case 10) an effect on the improvement of the allergic state is dubious inasmuch as desoxycorticosterone acetate was the agent employed.

A suggestion as to the possible influence of adrenal cortical hypofunction on drug allergy was noted in two patients (cases 3 and 13). In one patient a spreading dermatitis which was assuming exfoliative characteristics was rapidly halted by stopping use of offending drugs and by the administration of extract of adrenal cortex (Swingle's extract). Another patient who tolerated injections of concentrated liver extract poorly continued to do so despite improvement in the control of his adrenal cortical hypofunction. Desoxycorticosterone acetate, which exhibits mainly a mineral effect, was used in the management of that patient.

The study has pointed out a relationship between adrenal cortical hypofunction and various allergic disorders. No attempt has been made to designate that facet of the allergic reaction influenced by the occurrence of adrenal cortical hypofunction.

Details of these 27 cases are given in table 3.

Summary and Conclusions

A study of 496 patients with adrenal cortical hypofunction (Addison's disease) disclosed 45 with allergic disorders. The allergic disorder in 27 of these 45 patients was chronologically associated with Addison's disease or improved after replacement therapy for adrenal cortical hypofunction. Eight of these 27 patients had drug allergy alone, and 17 had atopic disorders such as asthma, hay fever, perennial allergic rhinitis, urticaria, and angioedema. Two patients had both drug allergy and atopic disorders.

Patients with atopic disorders of long standing often experienced an accentuation in the severity of those disorders at the time adrenal cortical hypofunction developed or as it progressed. In each of the eight patients with atopic disorders on whom an appraisal of the influence of replacement therapy for adrenal cortical hypofunction was possible, an amelioration of the atopic disorder occurred. The information was less conclusive concerning an accentuating influence on the occurrence or severity of drug allergy. This study again suggests the role of the adrenal cortex in influencing the course of an allergic diathesis.

RELIEF OF PREOPERATIVE ANXIETY.—The relief so clearly verbalized by the patients after the sharing of anxieties, ridding themselves of misconceptions and getting the needed concrete information (unassimilated in the examining room), would indicate that the contact alone, with its grant of freedom to talk, has had important meaning for them. Presumably any hospitalization for surgery would have its own patterns of meaning for any given individual, including the psychosomatic implications of each particular illness. A few patients sail through operations with smooth mastery. It is the average patient who needs reassurance and a chance to balance her fears against reality, and the seriously disturbed patients who vitally need support for anxieties only indirectly related to the operation itself. A consideration of such needs should be incorporated in any goal of comprehensive medical care.—S. H. Sturgis, M.D., and H. S. BACTERIOPHAGE TYPING OF STAPHYLOCOCCI FROM ASTHMATIC PATIENTS

SEVENTH OF A SERIES ON BACTERIOLOGICAL AND EPIDEMIOLOGIC APPROACH TO TREATMENT OF SINORESPIRATORY INFECTIONS

Samuel J. Prigal, M.D., New York

The techniques of bacteriophage typing were applied in a study of staphylococci cultured from 115 persons in an effort to detect a possible role that the hemolytic staphylococcus might play in infectious asthma. Ninety-five of the subjects were members of 27 families. A family was classified as "colonized" if two or more of its members yielded staphylococci of the same bacteriophage pattern. Among 12 colonized families the number of persons harboring hemolytic staphylococci, the number of patients with asthma, and the severity of the asthma were all greater than in an equal number of noncolonized families. However, the distribution of staphylococci according to their reaction to bacteriophage typing was the same as that usually seen in the general population, and no one type of staphylococcus could be etiologically related to infectious asthma.

The hemolytic staphylococcus was found, in earlier studies, to be frequently encountered in sinorespiratory infections associated with asthma.[1] Further studies of individual persons and members of families suggested the possibility that sinorespiratory infections, recurrent or chronic, or both, resulted from intrafamilial contagion.[2] A study was undertaken, therefore, to identify more specifically the staphylococci encountered by the method of bacteriophage typing. The use of this procedure, it was hoped, would (1) confirm the earlier evidence suggestive of intrafamilial contagion and of self-reinfection from other infected sites of the body (e. g., skin, eye, and ear), (2) determine whether any special type or types of staphylococci were dominant in these persons and whether they were in any way causally related to infective asthma, (3) demonstrate the manner of spread of the staphylococcic infection, and (4) determine the persistence of the staphylococcus in infections encountered in individual persons and families.

Material and Methods

The procedures involved in bacteriophage typing have been described elsewhere in detail by Blair and Carr [3] and were used by them in this investigation. Twenty-four bacteriophages, classified into five groups and recommended by the International Committee on Bacteriophage Typing of Staphylococci, were used.

In view of the specificity of the lytic action of the bacteriophages, it is possible to identify and "fingerprint" staphylococci, thereby making it an important tool in epidemiologic studies.

Results

Table 1 summarizes the proportion of typable cultures obtained from 27 families and 20 individual subjects in whom sinorespiratory infections were a problem. Altogether, 115 persons were examined and subjected to bacterial culture. The families were selected for bacteriological studies because of the frequency of sinorespiratory infections (often associated with asthma) in one or more members. Many subjects presented no obvious signs of infection. Despite negative physical findings, some of these persons yielded coagulase-positive hemolytic staphylococci and presumably were carriers. Some of the staphylococci, it should be indicated, were also isolated from the eyes or skin of a limited number of patients with pyogenic infections in these areas. In contrast to the families studied, all the individual patients presented positive evidence of infection, usually in several sites.

Of a total of 198 staphylococci available for typing, 164 (82.8%) were found typable, while the 34 others (17.2%) were not. The high degree of typability is accounted for by the repeated cultures taken from the same subject on different occasions or by multiple cultures taken from several sites of infection.

It should be noted that most often the staphylococci were lysed by more than one bacteriophage, in one instance by as many as eight and more frequently by a combination of two or three. When grouped, they fell into a basic pattern as previously described, with a distribution of about 50% in group 3.[3]

The bacteriophage-type pattern of reaction was specially analyzed in 16 patients with asthma, some of whom were asymptomatic at the time of examination but were included in family surveys. In five of these patients, hemolytic staphylococci were encountered which reacted to bacteriophages 52A

BACTERIOPHAGE TYPING OF STAPHYLOCOCCI FROM ASTHMATIC PATIENTS

SEVENTH OF A SERIES ON BACTERIOLOGICAL AND EPIDEMIOLOGIC APPROACH TO TREATMENT OF SINORESPIRATORY INFECTIONS

Samuel J. Prigal, M.D., New York

The techniques of bacteriophage typing were applied in a study of staphylococci cultured from 115 persons in an effort to detect a possible role that the hemolytic staphylococcus might play in infectious asthma. Ninety-five of the subjects were members of 27 families. A family was classified as "colonized" if two or more of its members yielded staphylococci of the same bacteriophage pattern. Among 12 colonized families the number of persons harboring hemolytic staphylococci, the number of patients with asthma, and the severity of the asthma were all greater than in an equal number of noncolonized families. However, the distribution of staphylococci according to their reaction to bacteriophage typing was the same as that usually seen in the general population, and no one type of staphylococcus could be etiologically related to infectious asthma.

The hemolytic staphylococcus was found, in earlier studies, to be frequently encountered in sinorespiratory infections associated with asthma.[1] Further studies of individual persons and members of families suggested the possibility that sinorespiratory infections, recurrent or chronic, or both, resulted from intrafamilial contagion.[2] A study was undertaken, therefore, to identify more specifically the staphylococci encountered by the method of bacteriophage typing. The use of this procedure, it was hoped, would (1) confirm the earlier evidence suggestive of intrafamilial contagion and of self-reinfection from other infected sites of the body (e. g., skin, eye, and ear), (2) determine whether any special type or types of staphylococci were dominant in these persons and whether they were in any way causally related to infective asthma, (3) demonstrate the manner of spread of the staphylococcic infection, and (4) determine the persistence of the staphylococcus in infections encountered in individual persons and families.

Material and Methods

The procedures involved in bacteriophage typing have been described elsewhere in detail by Blair and Carr[3] and were used by them in this investigation. Twenty-four bacteriophages, classified into five groups and recommended by the International Committee on Bacteriophage Typing of Staphylococci, were used.

In view of the specificity of the lytic action of the bacteriophages, it is possible to identify and "fingerprint" staphylococci, thereby making it an important tool in epidemiologic studies.

Results

Table 1 summarizes the proportion of typable cultures obtained from 27 families and 20 individual subjects in whom sinorespiratory infections were a problem. Altogether, 115 persons were examined and subjected to bacterial culture. The families were selected for bacteriological studies because of the frequency of sinorespiratory infections (often associated with asthma) in one or more members. Many subjects presented no obvious signs of infection. Despite negative physical findings, some of these persons yielded coagulase-positive hemolytic staphylococci and presumably were carriers. Some of the staphylococci, it should be indicated, were also isolated from the eyes or skin of a limited number of patients with pyogenic infections in these areas. In contrast to the families studied, all the individual patients presented positive evidence of infection, usually in several sites.

Of a total of 198 staphylococci available for typing, 164 (82.8%) were found typable, while the 34 others (17.2%) were not. The high degree of typability is accounted for by the repeated cultures taken from the same subject on different occasions or by multiple cultures taken from several sites of infection.

It should be noted that most often the staphylococci were lysed by more than one bacteriophage, in one instance by as many as eight and more frequently by a combination of two or three. When grouped, they fell into a basic pattern as previously described, with a distribution of about 50% in group 3.[3]

The bacteriophage-type pattern of reaction was specially analyzed in 16 patients with asthma, some of whom were asymptomatic at the time of examination but were included in family surveys. In five of these patients, hemolytic staphylococci were encountered which reacted to bacteriophages 52A

to the mother's side of the family, but the identical staphylococcus was not obtained in any other member.

Case 4.—This case deals with a child with severe asthma and eczema, in whom, for seven years, a coagulase-positive hemolytic staphylococcus was repeatedly cultured from the nose, throat, eye, or skin. Continued use of a variety of antibiotics ultimately led to resistance to each one and to the emergence of a staphylococcus of type 80/81, which was also isolated from an infected ear of the mother. The asthma was further complicated by unusual pulmonary manifestations, presumably due to staphylococcic infection.

A female infant was first seen in December, 1951, at the age of 19 months, because of a generalized ezcema and asthma. From the beginning infection was considered a primary cause of her asthma. A coagulase-positive Staphylococcus aureus was repeatedly obtained from the nose and throat, at times in pure culture but frequently in association with streptococci.

In 1955, the entire family was studied because of repeated infections both in the patient and in other members. Clinically, there was evidence of intrafamilial contagion. Bacteriophage typing, however, revealed that the staphylococci responsible for the symptoms were of unrelated types.

Because of the persistence of the infection in the patient, despite antibiotic therapy, the asthma continued to be moderately severe and cortisone was resorted to for therapy. A high degree of allergy was present in the patient, as shown first by passive transfer test and subsequently by direct testing as well as by clinical observation of sensitivity to many foods, pollens, and inhalants. The asthma became severe with each new

and would impro

another, from the nose and throat, the eczematous skin area, a purulent conjunctivitis, and a gluteal abscess.

In November, 1958, there was an unusual complaint of severe abdominal pain which had followed an acute upper respiratory infection with fever. The pain was, at times, so severe as to make the attending physician suspect an attack of gallbladder disease. The erythrocyte sedimentation rate (Wintrobe) was increased to 51 mm. per hour, and the white blood cell count was 24,000 per cubic millimeter, with an eosinophilia of 10%. The child was hospitalized for study.

Although the asthma was under control and there were no overt chest symptoms, an x-ray of the chest revealed a large emphysematous cyst in the right upper pulmonary lobe (fig. 1, *center, right*). Roentgenographic examination of the sinuses showed bilateral maxillary sinusitis (fig. 2, *right*). (Similar studies performed five months earlier had revealed no pathological findings [fig. 1, *left*, and 2, *left*]). Studies of cultures from the pharynx again revealed coagulase-positive hemolytic staphylococcus.

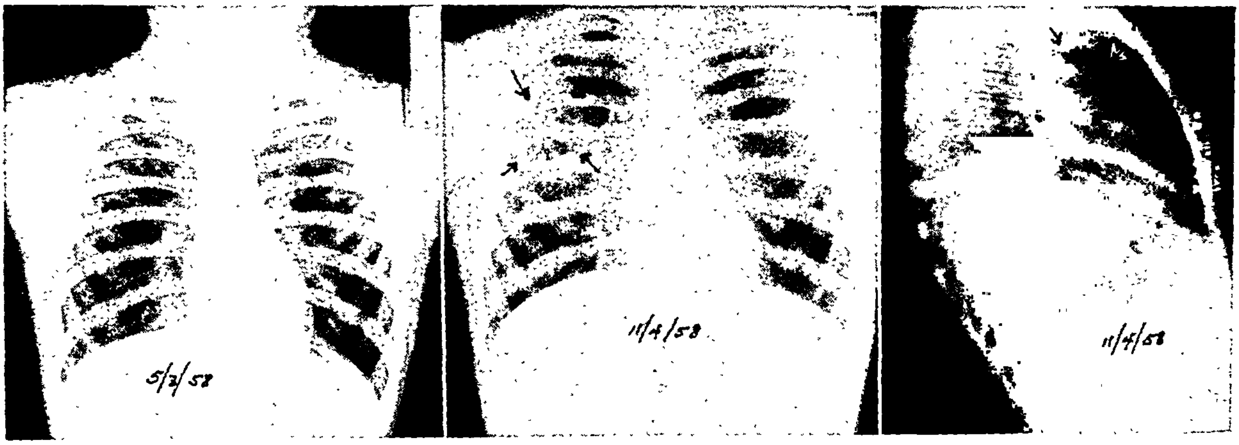

Fig. 1 (case 4).—Chest roentgenograms of asthmatic patient with staphylococcic infection. *Left*, routine chest roentgenogram, May 3, 1958, without abnormalities. *Center*, large emphysematous cyst in right upper pulmonary lobe. *Right*, lateral view of same (Nov. 4, 1958).

Subsequent follow-up studies show a gradual reduction in the cyst to approximately one-third of the original size. In March, 1959, there was a recurrence of the abdominal pain which again could not be accounted for clinically, and an x-ray of the chest once more revealed a small area of consolidation, this time in the left lower lobe (fig. 3). Pharyngeal culture again showed a hemolytic staphylococcus which, on bacteriophage typing, was revealed to be 80/81 and was completely unresponsive to any of the common antibiotics. (The bacteriophage typing pattern in 1954 had been 7/42E/42B/42D/44A and in 1955 39/44A.) New cultures were

of all the members of the family, now in-

five, and this time hemolytic staphylotion were noted, nor was there any evidence of asthma. However, a slight purulent discharge was visible in the inner canthus of the right eye, without any obvious conjunctivitis.

Laboratory examination showed a slight elevation in the number of leukocytes, without eosinophilia; a nasal smear was unrevealing. Roentgenographic studies of the chest showed an increase of the hilar markings, while those of the sinuses revealed a thickening of the mucosa of the right maxillary antrum, without evidence of any fluid.

The first cultures from the boy's nose, throat, and right eye yielded no pathogens. While under observation, a series of respiratory infections occurred within the family group, including the patient whose asthma was worse and who developed a purulent conjunctivitis from which a hemolytic staphylococcus was cultured. Cultures taken simultaneously from the rest of the family yielded hemolytic staphylococci from the nose, throat, and eye of the mother who had a history of sinusitis, frequent styes, and acneiform skin infections. These organisms, when typed (53/70), were identical with that obtained simultaneously from the patient's eye and were also identical with that cultured from the father's nose. Culture from the father's throat swab yielded a staphylococcus with bacteriophage pattern 75/VA4, while from the younger son, who was also subject to frequent respiratory infections without asthma, a nontypable hemolytic staphylococcus was cultured.

Intradermal skin tests on the patient showed many positive reactions. Only house dust, apple, and white potato were considered clinically important allergens.

Aerosol therapy, in which neomycin sulfate, polymyxin B sulfate, and bacitracin were used in combination, was administered to both the patient and his mother, while the doses of cortisone and orally given antibiotics were simultaneously reduced and then eliminated. Both responded to this treatment; the boy's asthma became less troublesome, while the mother's skin and eye infections improved.

To improve the immunity of both the mother, who presumably was the carrier, and the patient, a vaccine was made of the staphylococcus obtained from the three members of the family, to which was added a stock-mixed catarrhal vaccine. Soon it was noted that minute doses of the vaccine resulted in exacerbations of the boy's asthma. The vaccine was therefore diluted further and the amount given increased cautiously.

At reexamination of the patient in June, 1956, one year after the initial examination, it was disclosed that the incidence of respiratory infections within the household had been reduced, and that the patient had virtually no asthma.

CASE 3.—This case demontsrates the use of bacteriophage typing in the identification of a hemolytic staphylococcus which had colonized a family, three of whose members had asthma, and the transfer of the organism in the process of moving from one apartment to another. This case, described in detail elsewhere,[10] will be reviewed briefly.

A father and his two children, all with asthma in which infection was a factor, had been under observation; on culture, a hemolytic staphylococcus was obtained from them and from one other member of the family. Bacteriophage typing proved all the organisms to be identical, exhibiting the phage pattern 52A/79. The same organism ultimately was cultured from a kitchen plate during an investigation of the dissemination of the staphylococcus within the household. Simultaneously, the new and uninhabited apartment into which the family was moving was investigated, and no hemolytic staphylococci were encountered. Three months after habitation of the new apartment, agar plates were exposed again; the results revealed that the organism had now been transported into the new environment, staphylococci of the same bacteriophage pattern (52A/79) being isolated.

As in the earlier studies of intrafamilial contagion, an investigation was made of the father's six brothers and sisters and their children, as well as of his parents. Many members of the family were subject to frequent colds, sinusitis, bronchitis, asthma, boils, styes, and conjunctivitis. Of 13 cultures obtained from the 22 members of the family, 5 yielded coagulase-positive staphylococci which, however, on bacteriophage typing, differed from the one found in the members of the originally tested family. Bacteriological studies of this family continued over one year, during which time the staphylococcus type 52A/79 persisted in most members.

During one of these examinations, a nephew from the mother's side, who was helping with the children, was at once recognized as a former patient with asthma due to ragweed sensitivity and infection, who had been successfully treated and had remained asthma-free for the past five years. On culture, he yielded a hemolytic staphylococcus of type 52A/79. The investigation then was [illegible] from

TABLE 2.—*Incidence of Hemolytic Staphylococci in Relation to Infectious Asthma in Colonized and Noncolonized Families*

Type of Family*	No. of Families	No. of Individual Members	No. of Persons Showing Hemolytic Staphylococcus	No. of Patients with Asthma	No. of Families with Asthma	Status of Patients with Asthma: Symptomatic	Status of Patients with Asthma: Asymptomatic
Colonized	12	42	36(85.7%)	11(26.2%)	8(66.6%)	9	2
Noncolonized	12	41	21(58.5%)	5(12.2%)	4(33.3%)	1	4

* Colonized families are those in which more than one member in the immediate family showed hemolytic staphylococci of identical bacteriophage pattern. The noncolonized families also showed hemolytic staphylococci, although to a lesser degree, but these were not identical when they occurred in more than one member in the family. At least one member showed a hemolytic staphylococcus, most often the patient.

and 79. No significance can be attached to this, however, since it occurred three times in a single family, once in a close relative, and once in an unrelated subject. This merely reflected colonization of a family by a specific hemolytic staphylococcus. It would seem, therefore, that no specific type of hemolytic staphylococcus may be associated with asthma based on infection, although this organism is frequently encountered in this condition.

The possible role that the hemolytic staphylococcus may play in infectious asthma is shown in the family studies. If one groups them into "colonized" and "noncolonized" families on the basis of the isolation of identical (according to bacteriophage reaction) staphylococci which are present in more than one member of the family, it is apparent that asthma associated with infection occurs more often in colonized families. Table 2 shows that, in a comparison of equal numbers of families and individual subjects who are classified into the aforementioned groups, the colonized group contains twice as many families and patients with asthma as the noncolonized group. Furthermore, the colonized group contained the patients with the worst asthmatic condition; 9 of 11 were symptomatic at the time of culture, whereas only one of five was symptomatic in the noncolonized group.

Table 1.—*Source and Bacteriophage Typing of Hemolytic Staphylococci Isolated from Persons and Families with Sinorespiratory Infections*

Totals		115	164(82.8%)	34(17.2%)	198

Report of Cases

The following case histories illustrate the various applications of bacteriophage typing used in this study:

Case 1.—This case demonstrates the role of a father as the carrier for a child with infectious asthma. A 4-year-old boy was first seen in June, 1954, because of asthma after a series of acute upper respiratory infections which had begun in the first weeks of his life when he developed croup. Thereafter he had frequent sore throats and bronchitis through most of the winter. At the age of 2 years he began to wheeze with each of the colds, and in the past year shortness of breath became a prominent symptom to a degree that required an injection of epinephrine for relief. The child's family history disclosed no allergic background. The father had been subject to sinusitis for many years, as well as to bronchopneumonia and croup in childhood.

At examination of the patient, no evidence of asthma was noted. There were, however, findings indicative of a low-grade upper respiratory infection. The membranes of the nose were hyperemic, and the concha nasalis media on the right side was swollen. Stringy mucus was seen bridging the nose on that side. The tonsils were enlarged, the throat was granular, and a postnasal drip was noted. Cervical nodes were palpable bilaterally.

A diagnosis of bronchial asthma based primarily on an infection was made. Results of skin tests with inhalants were negative. Food tests were deferred, since each episode, as observed over a period of several months, was definitely associated with respiratory infection.

A culture taken from the throat at the first examination yielded Staphylococcus citreus, which was nonhemolytic but coagulase-positive. The patient continued to have respiratory infections, and, while they responded to antibiotic therapy, they recurred subsequently. It was decided, therefore, to take cultures from the noses and throats of all members of his family.

On July 27, 1954, a coagulase-negative hemolytic staphylococcus was cultured from the nose and Pseudomonas aeruginosa from the throat of the patient. His sister's culture specimen yielded a hemolytic staphylococcus of bacteriophage type VA4 in association with a nonhemolytic streptococcus. The mother's specimen yielded a staphylococcus of bacteriophage type 29 from the nose. A coagulase-positive hemolytic Staphylococcus aureus, of bacteriophage pattern 52/52A/44A, was isolated from the father's nose. Two months later, after the boy had had several respiratory infections associated with asthma, new cultures were taken; the specimens from the noses of both father and son contained staphylococci which exhibited the bacteriophage pattern 55/52A/44A, identical to that originally obtained from the father.

By adherence to instructions on personal hygiene to prevent cross infection (it was common for the father to use his handkerchief on the boy's nose and for the child occasionally to sleep with the parents) the incidence of infections was reduced and the boy has had no asthma for two years despite incomplete investigation and lack of immunotherapy for allergy.

Case 2.—In this case of severe asthma, primarily due to a respiratory infection associated with conjunctivitis, a hemolytic staphylococcus which had been cultured from the mother's nose, throat, and eye had colonized the family and produced a variety of infections in most of its members.

A 6-year-old boy was seen on March 19, 1955, because of persistent asthma he had had since August, 1954, which had been controllable only by administration of cortisone, 100 mg. per day, given over a six-month period. To guard against superinfection, in view of the boy's frequent respiratory infections, the family physician prescribed also 300 mg. of tetracycline (Achromycin) daily during this period.

On examination, the boy showed typical moon facies due to excessive doses of cortisone (reduced dosage, when attempted, resulted in return of symptoms). No obvious signs of respiratory infection were noted, nor was there any evidence of asthma. However, a slight purulent discharge was visible in the inner canthus of the right eye, without any obvious conjunctivitis.

Laboratory examination showed a slight elevation in the number of leukocytes, without eosinophilia; a nasal smear was unrevealing. Roentgenographic studies of the chest showed an increase of the hilar markings, while those of the sinuses revealed a thickening of the mucosa of the right maxillary antrum, without evidence of any fluid.

The first cultures from the boy's nose, throat, and right eye yielded no pathogens. While under observation, a series of respiratory infections occurred within the family group, including the patient whose asthma was worse and who developed a purulent conjunctivitis from which a hemolytic staphylococcus was cultured. Cultures taken simultaneously from the rest of the family yielded hemolytic staphylococci from the nose, throat, and eye of the mother who had a history of sinusitis, frequent styes, and acneiform skin infections. These organisms, when typed (53/70), were identical with that obtained simultaneously from the patient's eye and were also identical with that cultured from the father's nose. Culture from the father's throat swab yielded a staphylococcus with bacteriophage pattern 75/VA4, while from the younger son, who was also subject to frequent respiratory infections without asthma, a nontypable hemolytic staphylococcus was cultured.

Intradermal skin tests on the patient showed many positive reactions. Only house dust, apple, and white potato were considered clinically important allergens.

Aerosol therapy, in which neomycin sulfate, polymyxin B sulfate, and bacitracin were used in combination, was administered to both the patient and his mother, while the doses of cortisone and orally given antibiotics were simultaneously reduced and then eliminated. Both responded to this treatment; the boy's asthma became less troublesome, while the mother's skin and eye infections improved.

To improve the immunity of both the mother, who presumably was the carrier, and the patient, a vaccine was made of the staphylococcus obtained from the three members of the family, to which was added a stock-mixed catarrhal vaccine. Soon it was noted that minute doses of the vaccine resulted in exacerbations of the boy's asthma. The vaccine was therefore diluted further and the amount given increased cautiously.

At reexamination of the patient in June, 1956, one year after the initial examination, it was disclosed that the incidence of respiratory infections within the household had been reduced, and that the patient had virtually no asthma.

Case 3.—This case demontsrates the use of bacteriophage typing in the identification of a hemolytic staphylococcus which had colonized a family, three of whose members had asthma, and the transfer of the organism in the process of moving from one apartment to another. This case, described in detail elsewhere,[10] will be reviewed briefly.

A father and his two children, all with asthma in which infection was a factor, had been under observation; on culture, a hemolytic staphylococcus was obtained from them and from one other member of the family. Bacteriophage typing proved all the organisms to be identical, exhibiting the phage pattern 52A/79. The same organism ultimately was cultured from a kitchen plate during an investigation of the dissemination of the staphylococcus within the household. Simultaneously, the new and uninhabited apartment into which the family was moving was investigated, and no hemolytic staphylococci were encountered. Three months after habitation of the new apartment, agar plates were exposed again; the results revealed that the organism had now been transported into the new environment, staphylococci of the same bacteriophage pattern (52A/79) being isolated.

As in the earlier studies of intrafamilial contagion, an investigation was made of the father's six brothers and sisters and their children, as well as of his parents. Many members of the family were subject to frequent colds, sinusitis, bronchitis, asthma, boils, styes, and conjunctivitis. Of 13 cultures obtained from the 22 members of the family, 5 yielded coagulase-positive staphylococci which, however, on bacteriophage typing, differed from the one found in the members of the originally tested family. Bacteriological studies of this family continued over one year, during which time the staphylococcus type 52A/79 persisted in most members.

During one of these examinations, a nephew from the mother's side, who was helping with the children, was at once recognized as a former patient with asthma due to ragweed sensitivity and infection, who had been successfully treated and had remained asthma-free for the past five years. On culture, he yielded a hemolytic staphylococcus of type 52A/79. The investigation then was ext from

Table 2.—*Incidence of Hemolytic Staphylococci in Relation to Infectious Asthma in Colonized and Noncolonized Families*

Type of Family*	No. of Families	No. of Individual Members	No. of Persons Showing Hemolytic Staphylococcus	No. of Patients with Asthma	No. of Families with Asthma	Status of Patients with Asthma	
						Symptomatic	Asymptomatic
Colonized	12	42	36(85.7%)	11(26.2%)	8(66.8%)	9	2
Noncolonized	12	41	21(58.5%)	5(12.2%)	4(33.3%)	1	4

* Colonized families are those in which more than one member in the immediate family showed hemolytic staphylococci of identical bacteriophage pattern. The noncolonized families also showed hemolytic staphylococci, although to a lesser degree, but these were not identical when they occurred in more than one member in the family. At least one member showed a hemolytic staphylococcus, most often the patient.

to the mother's side of the family, but the identical staphylococcus was not obtained in any other member.

Case 4.—This case deals with a child with severe asthma and eczema, in whom, for seven years, a coagulase-positive hemolytic staphylococcus was repeatedly cultured from the nose, throat, eye, or skin. Continued use of a variety of antibiotics ultimately led to resistance to each one and to the emergence of a staphylococcus of type 80/81, which was also isolated from an infected ear of the mother. The asthma was further complicated by unusual pulmonary manifestations, presumably due to staphylococcic infection.

A female infant was first seen in December, 1951, at the age of 19 months, because of a generalized ezcema and asthma. From the beginning infection was considered a primary cause of her asthma. A coagulase-positive Staphylococcus aureus was repeatedly obtained from the nose and throat, at times in pure culture but frequently in association with streptococci.

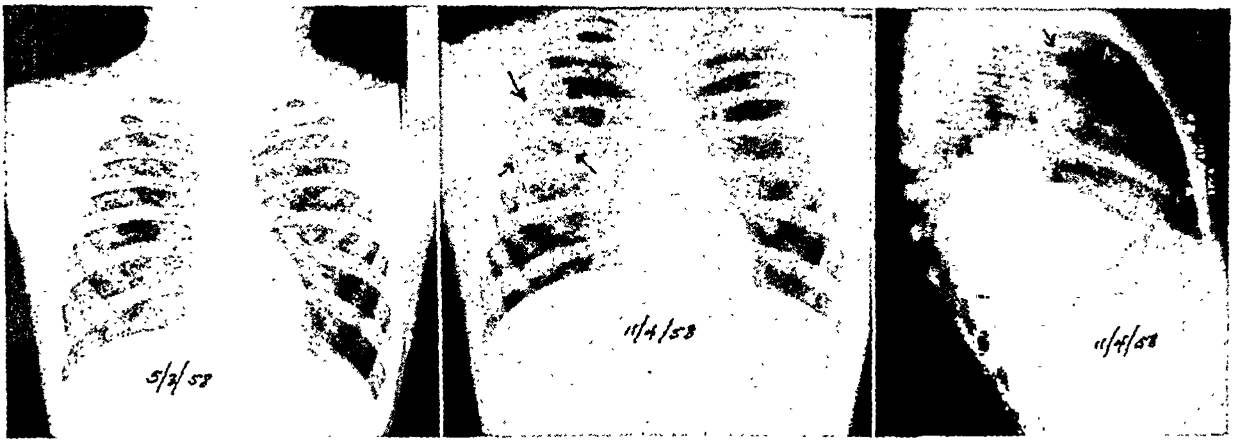

Fig. 1 (case 4).—Chest roentgenograms of asthmatic patient with staphylococcic infection. *Left,* routine chest roentgenogram, May 3, 1958, without abnormalities. *Center,* large emphysematous cyst in right upper pulmonary lobe. *Right,* lateral view of same (Nov. 4, 1958).

In 1955, the entire family was studied because of repeated infections both in the patient and in other members. Clinically, there was evidence of intrafamilial contagion. Bacteriophage typing, however, revealed that the staphylococci responsible for the symptoms were of unrelated types.

Because of the persistence of the infection in the patient, despite antibiotic therapy, the asthma continued to be moderately severe and cortisone was resorted to for therapy. A high degree of allergy was present in the patient, as shown first by passive transfer test and subsequently by direct testing as well as by clinical observation of sensitivity to many foods, pollens, and inhalants. The asthma became severe with each new upper respiratory infection and would improve for short periods only, with use of an antibiotic that was most often selected on the basis of sensitivity tests. Staphylococci were obtained from this child, at one time or

and the co

another, from the nose and throat, the eczematous skin area, a purulent conjunctivitis, and a gluteal abscess.

In November, 1958, there was an unusual complaint of severe abdominal pain which had followed an acute upper respiratory infection with fever. The pain was, at times, so severe as to make the attending physician suspect an attack of gallbladder disease. The erythrocyte sedimentation rate (Wintrobe) was increased to 51 mm. per hour, and the white blood cell count was 24,000 per cubic millimeter, with an eosinophilia of 10%. The child was hospitalized for study.

Although the asthma was under control and there were no overt chest symptoms, an x-ray of the chest revealed a large emphysematous cyst in the right upper pulmonary lobe (fig. 1, *center, right*). Roentgenographic examination of the sinuses showed bilateral maxillary sinusitis (fig. 2, *right*). (Similar studies performed five months earlier had revealed no pathological findings [fig. 1, *left,* and 2, *left*]). Studies of cultures from the pharynx again revealed coagulase-positive hemolytic staphylococcus.

Subsequent follow-up studies show a gradual reduction in the cyst to approximately one-third of the original size. In March, 1959, there was a recurrence of the abdominal pain which again could not be accounted for clinically, and an x-ray of the chest once more revealed a small area of consolidation, this time in the left lower lobe (fig. 3). Pharyngeal culture again showed a hemolytic staphylococcus which, on bacteriophage typing, was revealed to be 80/81 and was completely unresponsive to any of the common antibiotics. (The bacteriophage typing pattern in 1954 had been 7/42E/42B/42D/44A and in 1955 39/44A.) New cultures were taken of all the members of the family, now increased to five, and this time hemolytic staphylococcus of the same type (80/81) was isolated from a draining infected ear of the mother.

In retrospect, the pulmonary findings were interpreted as being secondary to a staphylococcic infection of the lung which was probably not recognized because its symptoms were obscured by therapy with both steroids and antibiotics. It was of special interest that these infections occurred despite the continued use of an antibiotic of the tetracycline group, namely, glucosamine-potentiated tetracycline hydrochloride plus one part of oleandomycin (Cosa-Signemycin).

Comment

Although bacteriophage typing of staphylococci is a relatively new technique, it has already proved its usefulness in epidemiologic studies. It has been found helpful in tracing the dissemination of penicillin-resistant strains by hospital personnel, in food poisoning, and in epidemics of infantile diarrhea due to staphylococci.[3]

Since we had frequently found the ubiquitous hemolytic staphylococcus in studies of both individual persons and families who suffered from chronic or recurrent sinorespiratory infections, often associated with asthma, it was imperative to identify these organisms further to answer the questions raised in the introduction to this paper.

The data assembled here indicate that some families, particularly those in which asthma occurs frequently, are infected by specific hemolytic staphylococci. Other families, however, which presented the same clinical evidence suggestive of intrafamilial contagion showed no infection with hemolytic staphylococci and less asthma. The failure to demonstrate bacteriological colonization in families in which it was suspected clinically may have arisen from errors in the taking of a single culture, such as overgrowth by contaminants and failure to reach the site of infection. Other possible factors include the isolation of staphylococci which were not typable and which might have been identical had additional bacteriophages for typing been available. In some instances, by the time the staphylococci were transferred for bacteriophage typing, contamination had occurred. These failures can be resolved by study of a larger series of families, preferably in those in whom no antibiotic therapy has been used prior to bacteriological investigation.

Why some families become colonized by staphylococci is an intriguing question. Perhaps colonization results from a particularly active carrier, as in case 2, in which the mother had the staphylococcus in the nose, throat, and eye and dissemination, therefore, presumably was widespread. It is also possible that an allergic background may play some role. Suggestive evidence of this is presented by the correlation between asthma and the colonized families (table 2). Furthermore, experimental studies by myself and Dubos[4] indicate that prior sensitization of mice made them vulnerable to infection with the staphylococcus.

What is the significance of the higher incidence of asthma in the families colonized by pathogenic staphylococci? It is difficult to implicate the staphylococcus, even when hemolytic and coagulase-positive, since this organism is so frequently encountered in the nose and skin of persons in the general population without clinical disease. One cannot dismiss, however, the following observation previously reported: In a comparative study of seven related families in which asthma and pyogenic infections were frequently encountered, the hemolytic staphylococcus was encountered in 60% of the members.[1] On the other hand, control studies of 15 nonrelated families without asthma and relatively free from

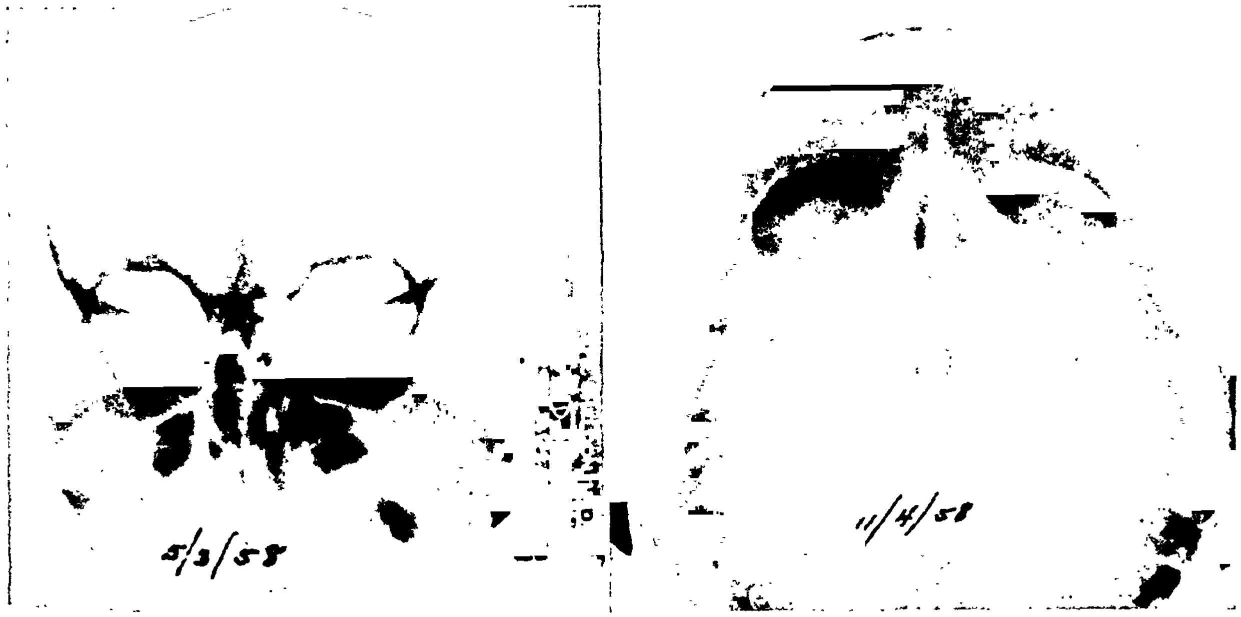

Fig. 2 (case 4).—Roentgenograms of sinuses. *Left*, May 3, 1958, normal. *Right*, Nov. 4, 1958, bilateral maxillary sinusitis.

respiratory infections yielded an incidence of staphylococci of only 16%. The percentage of streptococci, however, was the same in both groups (36%). Here too, further comparative study of a larger group of asthmatics and their families and an adequate number of control families is indicated.

What role, if any, does the hemolytic staphylococcus play in infectious asthma? The question cannot yet be answered definitively, since this micro-organism is so ubiquitous and may be a merely innocent bystander. We know,[1d] however, that this hardy organism can remain latent for long periods and then produce disease; that its toxin can enhance sensitivity and even produce autosensitivity[5]; and that its extract possesses pharmacological properties capable of producing smooth muscle contraction.[6] Although we cannot yet define the role of the hemolytic staphylococcus in asthma, we cannot dismiss it as an insignificant finding.

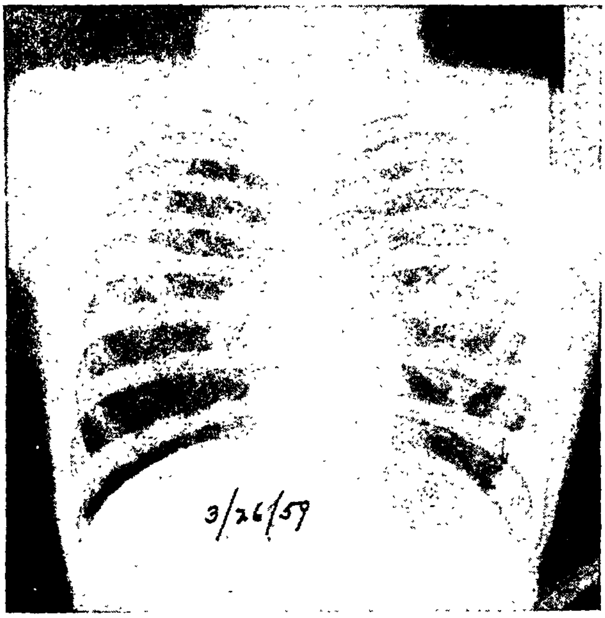

Fig. 3 (case 4).—Chest roentgenogram, April 26, 1959, small area of consolidation after marked reduction in emphysematous cyst in left lower lobe.

Assuming some ill-defined role for the staphylococcus in some cases of asthma, is a type-specific organism involved? The available evidence indicates that no one type of staphylococcus can be etiologically related to asthma. Although the staphylococcus of bacteriophage type 52A/79 was encountered most often, this was due to repeated study of the same family. Furthermore, the organisms encountered in these studies followed the general pattern of distribution of staphylococci in the population at large.

How does the staphylococcus colonize a family? One family study presented (case 3) indicates that, like most bacterial infections, the staphylococcus contaminates the environment so that infection may be transmitted not only by direct contact but indirectly as well by droplet or dust contamination. In case 3, it was shown that, as the family moved from a contaminated apartment into an uncontaminated one, contamination of the environment had occurred within three months or less. In this family the organism continued to be isolated from most members while they were under observation over one year.

This raises the question of the persistence of staphylococcic infection. Blair[7] had witnessed a case of recurring osteomyelitis in which a type-specific staphylococcus was encountered during three episodes of osteomyelitis over a 13-year period. The most persistent case studied in my series lasted only 18 months; moreover, a type-specific staphylococcus (previously isolated from the patient's husband) which had been present in the nose and eye of the patient for nine months, gave way to another type of staphylococcus which had only recently been recovered from the husband. He apparently was the carrier for the wife, and this helped to maintain in her a blepharitis of many years' duration. Here, too, continued study over several years would be helpful in determining the persistence of the staphylococcus, the mode of its transmission and its relation to the patient's asthma. That it plays some role in the asthma of this person is convincing, since the findings of skin tests with extracts of staphylococcus are positive and since she develops constitutional reactions from injections with staphylococcic vaccine. This is evidence of bacterial allergy, although it is possible that the staphylococcus may cause asthma for other reasons.

In view of the finding that contagion plays such an important role in recurrent or chronic sinorespiratory infections, with or without associated asthma, it is not enough to investigate the patient's allergies; it is also necessary to reduce infection by eliminating carriers, where possible, and by improving the patient's immunity.

Summary

Hemolytic staphylococci are frequently encountered in patients with recurrent or chronic sinorespiratory infections, with or without associated asthma. Bacteriophage typing of these coagulase-positive staphylococci indicates that some families with sinorespiratory problems become colonized with staphylococci. Persons in these families are more apt to have asthma. Other families in which clinically intrafamilial contagion seems to be a factor were not colonized; members of these had less asthma.

The distribution of staphylococci according to their reaction to bacteriophage typing was the same as that generally encountered in the population at large. No one type of staphylococcus could be etiologically related to infectious asthma.

Bacteriophage typing of staphylococci is of value in the epidemiologic study of chronic sinorespiratory infection and infectious asthma. It reveals foci of infections from which the respiratory tract may become reinfected, and it may reveal the presence of a carrier within the household.

MONITORING OF VENTILATION BY INTEGRATED DIAPHRAGMATIC ELECTROMYOGRAM

DETERMINATION OF CARBON DIOXIDE (CO_2) THRESHOLD IN ANESTHETIZED MAN

B. Raymond Fink, M.D., Edgar C. Hanks, M.D., Duncan A. Holaday, M.D.
and
Shih Hsuh Ngai, M.D., New York

A direct determination of the threshold level of the respiratory center under conditions of anesthesia has been made, apparently for the first time, by use of the integrated diaphragmatic electromyogram (EMG). The disappearance of electrical activity of the diaphragm was used to determine the apneic carbon dioxide pressure (pCO_2) in anesthetized man. Controlled increases and decreases of ventilation in 11 anesthetized patients were correlated with the end-tidal carbon dioxide pressures. The onset of apnea occurred at an average pCO_2 of 38 mm. Hg, 10 mm. Hg below the mean level of unassisted respiration. Recovery from apnea occurred at an average pCO_2 that was 5 mm. Hg higher than at the onset. The discrepancy probably results from the slow equilibration of carbon dioxide between the blood and nerve cells of the respiratory center.

In clinical anesthesia, controlled hyperventilation is often used to produce apnea by reducing the arterial carbon-dioxide pressure or tension (pCO_2) below the respiratory-center threshold. Estimates of the respiratory-center threshold have been published for unanesthetized man,[1] but a direct determination of the threshold level under conditions of anesthesia does not appear to have been made. An approach to this problem is offered by the diaphragmatic electromyogram (EMG) since, in the presence of normal myoneural transmission, the electromyogram is a direct expression of activity in the respiratory center. After Rossier and co-authors[2] showed the feasibility of recording the electrical activity of the human diaphragm, it was decided to use the disappearance of this activity to determine the apneic carbon dioxide (CO_2) tension in anesthetized man.

MONITORING OF VENTILATION BY INTEGRATED DIAPHRAGMATIC ELECTROMYOGRAM

DETERMINATION OF CARBON DIOXIDE (CO_2) THRESHOLD IN ANESTHETIZED MAN

B. Raymond Fink, M.D., Edgar C. Hanks, M.D., Duncan A. Holaday, M.D.
and
Shih Hsuh Ngai, M.D., New York

In clinical anesthesia, controlled hyperventilation is often used to produce apnea by reducing the arterial carbon-dioxide pressure or tension (pCO_2) below the respiratory-center threshold. Estimates of the respiratory-center threshold have been published for unanesthetized man,[1] but a direct determination of the threshold level under conditions of anesthesia does not appear to have been made. An approach to this problem is offered by the diaphragmatic electromyogram (EMG) since, in the presence of normal myoneural transmission, the electromyogram is a direct expression of activity in the respiratory center. After Rossier and co-authors[2] showed the feasibility of recording the electrical activity of the human diaphragm, it was decided to use the disappearance of this activity to determine the apneic carbon dioxide (CO_2) tension in anesthetized man.

A direct determination of the threshold level of the respiratory center under conditions of anesthesia has been made, apparently for the first time, by use of the integrated diaphragmatic electromyogram (EMG). The disappearance of electrical activity of the diaphragm was used to determine the apneic carbon dioxide pressure (pCO_2) in anesthetized man. Controlled increases and decreases of ventilation in 11 anesthetized patients were correlated with the end-tidal carbon dioxide pressures. The onset of apnea occurred at an average pCO_2 of 38 mm. Hg, 10 mm. Hg below the mean level of unassisted respiration. Recovery from apnea occurred at an average pCO_2 that was 5 mm. Hg higher than at the onset. The discrepancy probably results from the slow equilibration of carbon dioxide between the blood and nerve cells of the respiratory center.

Materials and Method

The subjects were 11 patients who were observed before or after minor operations and were anesthetized with a mixture of 70% nitrous oxide and 30% oxygen, and thiopental sodium, administered by intermittent or slow continuous intravenous injection. The patients breathed through a cuffed endotracheal tube and a nonreturn valve. Respiration was either unassisted or controlled by a ventilator whose frequency and tidal volume could be regulated independently. Inspiratory flow was recorded through a pneumotachograph and a Statham strain gauge (resistive transducer) and integrated electronically for volume measurements. The diaphragmatic EMG was obtained with insertion of two insulated monopolar needles, 5 mm. apart, through the left 8th, 9th, or 10th intercostal space respectively. The needles were advanced until a characteristic crescendo inspiratory discharge was heard in a monitoring loudspeaker. The EMG and the rectified EMG integral were recorded, together with inspiratory flow and volume, on a multichannel cathode ray oscillograph. The slopes of the integral, i. e., the average diaphragmatic activity, in successive breaths, were compared by returning the trace to the base line at the end of each inspiration (fig. 1). The endotracheal carbon dioxide concentration was recorded continuously with a Liston-Becker infrared carbon dioxide analyzer, which absorbs infrared energy in proportion to the carbon dioxide concentration of the sample.

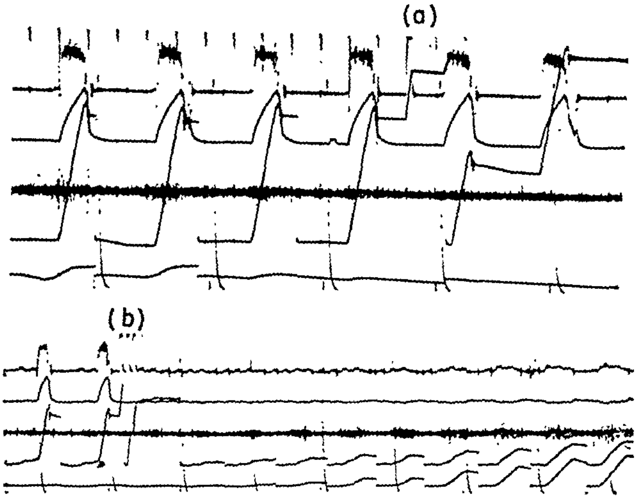

Fig. 1 (case 8).—Electromyographic monitoring of ventilation: (*a*) disappearance of diaphragmatic activity; (*b*) recovery of diaphragmatic activity during controlled ventilation. Traces from above down: time lines (seconds), inspiratory flow, airway pressure, diaphragmatic EMG, integral of inspiratory flow, integral of diaphragmatic EMG. Stroke volume of ventilator is observable in flow integral. At (*a*): large stroke volume, phasic activity in diaphragm became inaudible, end-tidal carbon dioxide tension (pCO_2) 42.5 mm. Hg (see fig. 2). At (*b*): after reduction of stroke volume and reappearance of phasic diaphragmatic activity at pCO_2 46.5 ventilator was turned off and patient breathed spontaneously and unassisted. Note parallel increase in diaphragmatic activity and inspiratory flow, observable in EMG and flow integrals. End-tidal pCO_2 rose to 51 mm. Hg and settled at 49 mm. Hg.

Procedure

The patients' unassisted respiration was observed for about 30 minutes to determine the existence of a stable minute volume and a stable end-tidal carbon dioxide tension (pCO_2). The patients were then connected to a mechanical ventilator which delivered a minute volume that approximated the spontaneous minute volume. Phasic diaphragmatic activity continued during this period, although not always synchronously with the inflation phase of the respirator. After five minutes, at this basal level of ventilation, the stroke volume of the ventilator was increased in steps of about 50 ml. The frequency of the ventilator remained constant. Each successive increase was accompanied by a decline in phasic diaphragmatic activity and a parallel fall of the end-tidal pCO_2. The pCO_2 at which phasic diaphragmatic activity disappeared altogether was noted (fig. 1 and 2). The stroke volume of the ventilator was then restored to the initial maintenance volume, and the pCO_2 at which phasic activity returned was observed. Finally, as soon as phasic diaphragmatic activity reappeared, the ventilator was turned off and respiratory exchange left to settle down at the level dictated by the patient's respiratory center.

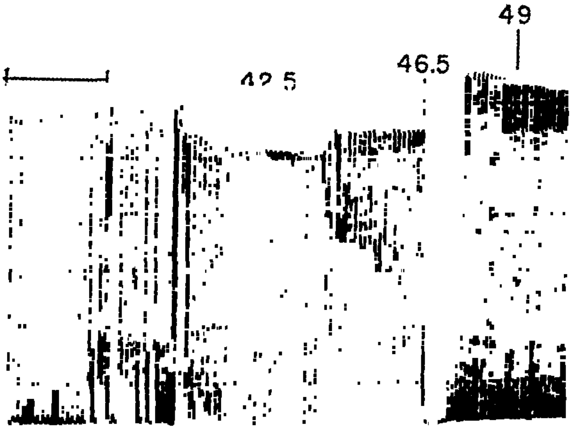

Fig. 2.—Infra red-analyzer record of expiratory CO_2 tensions. Same experiment as fig. 1. Top of each line represents end-expiratory value. Time mark at upper left: 1 minute. Numbers indicate end-expiratory CO_2 tension at time of disappearance (42.5) and of recovery (46.5) of phasic diaphragm activity, and pCO_2 level during unassisted spontaneous respiration (49).

Results

The results of 45 determinations in 11 consecutive studies are summarized in the table. Records from a typical experiment are presented in figures 1 and 2.

In the upper half of fig. 1 the patient was ventilated mechanically, with a stroke volume of 800 ml. at a frequency of 18 strokes per minute. The diaphragmatic EMG shows some continuous background activity and a burst of increased activity in phase with the inflation imposed by the ventilator. The inflation phase coincides with the period of positive pressure in the airway-pressure trace. In association with the high volume of ventilation, the diaphragmatic EMG shows decreasing activity with each successive stroke, as is evidenced quantitatively by the decline of the EMG integral of successive contractions. The signal at (*a*) marks the time at which phasic inspiratory increase of activity became inaudible. This point was regarded as the onset of apnea and was marked simultaneously on the carbon dioxide–analyzer record (fig. 2, at point 42.5).

The stroke volume of the ventilator was then reduced to 250 ml. at a frequency of 18 strokes per minute, and the return of phasic activity in the diaphragm was observed. In the bottom half of figure 1, point (*b*) shows the beginning of such a return, corresponding to the pCO_2 level marked 46.5 in figure 2. At (*b*) the ventilator was turned off and the patient allowed to breathe unassisted. The diaphragmatic activity increased slowly at first and then more rapidly, and there was a parallel increase in the inspiratory flow and tidal volume. In the carbon dioxide–analyzer record (fig. 2) there is a gap corresponding to the six breaths in which the inspiratory flow was very small. At this time, the carbon dioxide–analyzer sampled atmospheric air sucked in through the nonrebreathing valve, since little or no expired gas was flowing past the sampling site in the endotracheal tube.

End-Expiratory Carbon-Dioxide Tensions in Patients with Apnea During Nitrous Oxide-Thiopental Sodium Anesthesia

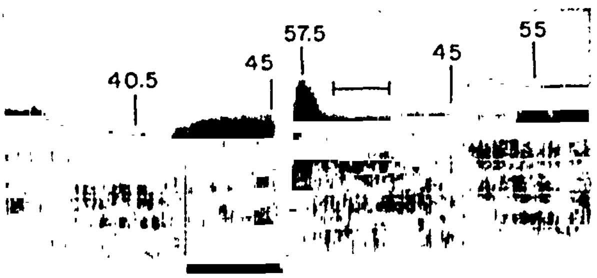

Fig. 3 (case 8).—End-tidal carbon dioxide (pCO_2) tensions in controlled apnea and recovery, 20 minutes after recording in fig. 2. Onset of apnea at 40.5 mm. Hg, recovery of phasic diaphragmatic activity at 45 mm. Hg. After turning off ventilator, indicated by gap signalling low expiratory volume, pCO_2 rose to 57.5 mm. Hg. Ventilator was then restarted at same stroke volume; pCO_2 returned to 45 mm. Hg, but vigorous phasic diaphragmatic activity continued. On turning off ventilator a second time (45), pCO_2 rapidly rose to 57.5 mm. Hg and settled to steady spontaneous ventilation level of 55 mm. Hg (time mark: 1 minute).

As alveolar carbon dioxide accumulated, the end-tidal pCO_2 rose to 51 and then settled down to a level of 49 mm. Hg. The overshoot is seen more clearly in another determination in the same patient, presented in figure 3. Here, apnea set in at a carbon dioxide tension of 40.5 mm. Hg, and recovery occurred at 45 mm. Hg, at which point the ventilator was turned off and the pCO_2 began to rise. In this experiment, the ventilator was turned on again at the peak of the carbon dioxide rise. The carbon dioxide tension was again depressed to 45 mm. Hg, but diaphragmatic contractions continued. Finally, the ventilator was turned off again, and the tension rose rapidly to the same level as the previous peak and then settled back to the equilibrium spontaneous-ventilation level of 55 mm. Hg.

It is evident from the data in the table that the recovery of diaphragmatic activity invariably occurred at a higher end-tidal pCO_2 than the onset of apnea. The difference ranged from 1.5 to 9.5 mm. Hg, with a mean of 5 mm. Hg (fig. 4). The pCO_2 at the onset of apnea averaged 38 mm. Hg, or 10 mm. Hg below the mean end-tidal pCO_2 maintained in spontaneous ventilation. When spontaneous ventilation resumed, there was a transient overshoot of 2 to 3 mm. Hg lasting one-half to one minute, sometimes followed by several smaller oscillations, after which the expiratory pCO_2 settled down to a steady resting level that averaged 48 mm. Hg.

Comment

These results establish, apparently for the first time in anesthetized patients, to what extent the end-expiratory carbon dioxide tension must be lowered to abolish spontaneous respiration and establish apnea. The reduction of 10 mm. Hg below the spontaneous ventilation level is surprisingly large in view of estimates of the so-called apnea point for unanesthetized man. Lindhard [1a] obtained this point by extrapolating backward the curve of ventilation volume during inhalation of carbon dioxide mixtures. The extrapolation indicated that the apnea alveolar carbon dioxide tension was about 2.5 mm. Hg below the spontaneous respiratory level. However, the ventilation-alveolar pCO_2 curves published by Eckenhoff and coauthors,[3] who used a more sensitive technique, indicate clearly that a linear extrapolation such as that made by Lindhard is invalid. Tenney [4] criticized the extrapolation on the ground that experimentally determined values were always higher than predicted. However, few such experimental determinations are available in the literature. Douglas and Haldane [5] determined the alveolar pCO_2 when the subject's breathing resumed after a two-minute apnea induced by voluntary hyperventilation. Recovery of respiration occurred at a tension of 37 mm. Hg, 3 mm. below his normal resting level of 40 mm. Hg. Nielsen's [1b] subject was hyperventilated and then paused until the urge to breathe returned, at which time an alveolar sample was obtained. The carbon dioxide tension in this sample was 41.5 mm. Hg, 1 mm. lower than the resting value.

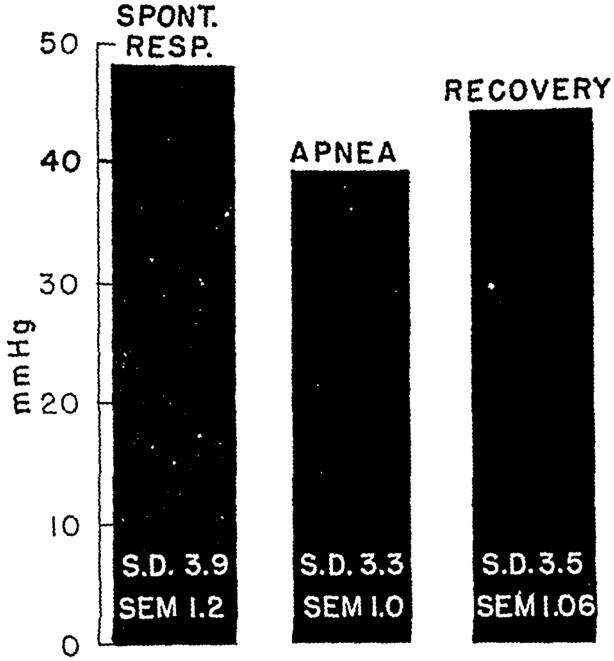

Fig. 4.—End-tidal carbon dioxide tensions (pCO_2) in anesthetised patients: bar graph of averages calculated from table 1. Spont. resp.: unassisted spontaneous respiration. S. D.: standard deviation. S. E. M.: standard error of mean.

The finding that the diaphragm does not recover immediately when the end-tidal pCO_2 rises above the apneic level was at first sight surprising. A difference between the apnea and recovery tensions was observed, regardless of whether hyperventilation was achieved by increased stroke frequency or by increased stroke volume of the ventilator. However, the discrepancy between the apnea and recovery tensions was smallest when the alveolar ventilation and the pCO_2 changed most slowly. Kety [6] suggested that the difference is due to slow equilibration between the carbon dioxide tensions in the blood and in the respiratory center. The true respiratory-center threshold to carbon dioxide must be intermediate between the "apnea" and "recovery" carbon dioxide tensions that were determined in these experiments. It also seems likely that the determinations by Douglas and Haldane [5] and by Nielsen,[1b] as well as Lindhard's [1a] extrapolation, do not represent the "apnea point" or respiratory center threshold but correspond to the "recovery" level of our own experiments. However, comparison with our data is limited by the fact that these were obtained during anesthesia and in the absence of such hypoxia as occurs in apnea after hyperventilation with air.

The overshoot of the end-expiratory carbon dioxide tension when spontaneous respirations was resumed is of some interest. It is believed that this reflects the circulatory time lag between the alveoli and the respiratory center. The reasoning on which this conclusion is based is represented diagrammatically in figure 5. As the tidal ventilation is progressively reduced, the pCO_2 in the blood climbs slowly to a level sufficient to stimulate the respiratory center and produce activity in the diaphragm. At this point (fig. 5, time line A) the ventilator is turned off. Since the stimulus to breathing is barely above threshold, the patient's breathing remains initially shallow. Therefore, when the ventilator is turned off the alveolar carbon dioxide tension rises rapidly, as seen in the carbon dioxide–analyzer

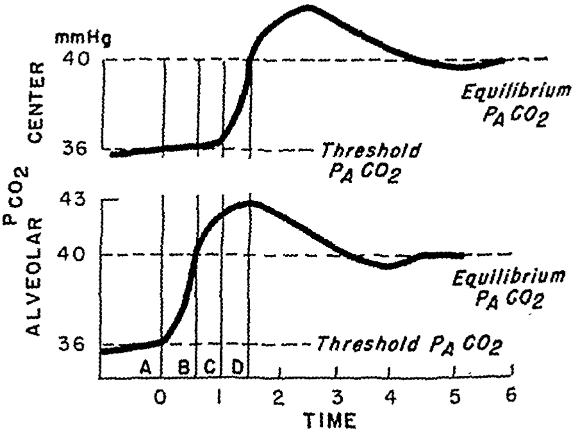

Fig. 5.—Diagrammatic analysis of alveolar and respiratory center carbon dioxide tensions during recovery from apnea.

curve of figure 3. However, at the respiratory center the rapid rise in pCO_2 begins later than at the alveoli (fig. 5, time line C), the lag being equal to the lung-brain circulation time. Similarly, when the carbon dioxide equilibrium tension is reached in the alveoli (time B), this tension has not yet been reached in the center. The patient, therefore, continues to have hypoventilation and the alveolar pCO_2 climbs above equilibrium level. When this above-equilibrium concentration reaches the center, the patient begins to have hyperventilation and the alveolar tension begins to drop. The interval B-D from the alveolar pCO_2 rise above equilibrium level to the peak-alveolar pCO_2—between 7 and 11 seconds in these studies—represents the lung-medulla circulation time. The presence of smaller oscillations after the first large overswing (fig. 3) is readily explained on the same basis.

Continuous low-grade "background" activity was observed in the diaphragm at the onset of apnea and continued for one or more minutes thereafter. This background activity was found in all cases and invariably disappeared if the pCO_2 fell more than 2 mm. Hg below the apneic tension. Recovery of phasic activity was preceded by return of the continuous discharge. The presence of background activity in the diaphragm is in agreement with the observations of Nieporent.[7]

Summary

The integrated diaphragmatic electromyogram (EMG) gives a measure of the inspiratory activity of the respiratory center. Disappearance and recovery of diaphragmatic activity, produced by controlled increases and decreases of ventilation in 11 anesthetized patients, were correlated with the end-tidal carbon dioxide pressures (tensions) (pCO_2). The onset of apnea occurred at an average pCO_2 of 38 mm. Hg, 10 mm. Hg below the mean level of unassisted respiration. Recovery from apnea occurred at an average pCO_2 that was 5 mm. Hg higher than the onset. The discrepancy probably results from slow equilibration of carbon dioxide between the blood and nerve cells of the respiratory center.

THE TRANSMISSION OF HATRED.—Thorne has charted the "epidemiology of hostility" through family studies. Thorne has pointed out the contagious quality of hostility, its tendency toward chain reactions, and its extreme potency when the recipient is in an inescapable position. The application of his thesis to institutions is apparent and appears borne out by the present observations of a penal institution. The sentries, our youngest siblings of the brig family, feel subject to inescapable frustration and hostility. The sentry is often young, inexperienced, lacks mature outlets, and is hard pressed to deal with his "chronic anger state." Standards within his peer group sanction downward acting-out, and he readily translates pressures from his superiors as well as neurotic hostility into aggression toward the prisoners. Of course, the cycle does not end there. Although severely restricted, the prisoners retaliate with negativism, accidents, sluggishness, and malingering. A further result, pointed out by Thorne, is the build up of mutually suspicious and paranoid attitudes. Although not striking in the present study, marked paranoid attitudes on the part of prison personnel have been described in other studies. Thorne's epidemiologic framework is a useful approach to the subject. An interesting sidelight in the epidemiology of hostility is the practice of mass punishment in the brig. Implicit in this device is the wish that the group will become enraged and turn on the one, enforcing the discipline of the authority. Thus, mass punishment is the planned use of the retaliation motif to maintain control.—Lieut. L. D. EFFECT OF DEXTRO PROPOXYPHENE, MEPERIDINE, AND CODEINE ON POSTOPERATIVE PAIN

William S. Van Bergen, M.D., William C. North, M.D., Ph.D.
and
Mary Karp, M.D., Chicago

An investigation to determine the comparative value of pain-relieving drugs conducted on 94 private patients who had undergone orthopedic surgery was started 48 hours postoperatively and continued for three days. Four substances were used: dextro propoxyphene hydrochloride, 100 mg.; codeine phosphate, 65 mg.; meperidine hydrochloride, 100 mg.; and placebo. Capsules were administered at four-hour intervals. Intensity of pain was scored and interrogation of patients was done by a physician. The drugs were found to be significantly more pain-relieving than was the placebo. The analgesic effectiveness of the drugs in the doses used was indistinguishable. The over-all analgesic effectiveness of drugs and placebo was similar to that found by other workers. A separate study on placebo effect showed that the patients discriminated more accurately between analgesics and placebos on the first day of study than on subsequent days.

The management of postoperative pain is generally based on a "clinical impression" that, immediately after performance of an operation, there is severe pain, which gradually wanes until the fourth to sixth postoperative day when it ceases. On the basis of this assumption, medication is ordered: first, potent narcotic analgesics are given by injection in the immediate postoperative period; next, less potent narcotics are used; and, finally, non-narcotic analgesics of the salicylate type are given.

Several analyses of the severity of postoperative pain have appeared in the literature; the results have been conflicting. Papper and associates[1] reported that 38% of 110 patients did not complain of pain in the 24-hour period after operation. Jaggard and associates[2] studied 1,005 patients and found that only 64% required narcotic analgesics after having undergone various types of surgery. On the other hand, our experience with private patients indicates that only 6.6% of 167 patients who had undergone various orthopedic operations did not require potent analgesic medication, and 10% of 100 patients who had had rectal surgery did not have sufficient pain to warrant the postoperative administration of a narcotic. Of 100 patients undergoing thoracotomy, 7 required no narcotic throughout the postoperative period and 17 required none in the first 24 hours.

A number of objections may be raised to this means of determining the existence of pain, and they probably account for the discrepancy in the results. However, the curves in the figure were constructed from data of this type that are available for analysis, relating the intensity of pain, expressed as the average number of doses of a narcotic administered per patient, to the length of time after surgery. It will be noted that, although the number of doses of any one drug given on any postoperative day varied with the type of surgical procedure performed, the rate of decline was similar.

The use of narcotic drugs is fraught with the possibilities of addiction or sufficient central nervous system depression to retard the rate of recovery from the trauma of surgery, or both. The development of a new analgesic, dextro propoxyphene hydrochloride (Darvon), which was claimed to be about equivalent in effectiveness to meperidine (Demerol) hydrochloride or codeine but to be devoid of addictive liability and central nervous system depression if given in analgesic doses, suggested the possibility that adequate relief of pain might be accomplished more safely than was possible previously. To that end, the study reported below was undertaken.

Materials and Method

Ninety-four private patients who had undergone various types of orthopedic operations served as subjects. The only selective requirement was that the patients chosen were likely to be in the hospital for at least five postoperative days. They were housed on the same floor and cared for by the same group of nurses. The distribution of patients with respect to areas of surgical procedure is given in table 1.

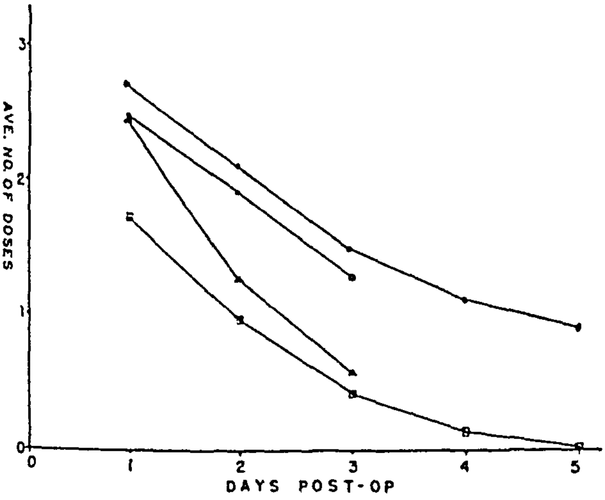
Four medicaments were used: dextro propoxyphene hydrochloride, 100 mg.; codeine phosphate, 65 mg.; meperidine hydrochloride, 100 mg.; and placebo.

From the Department of Pharmacology, Northwestern University Medical School, and the Department of Anesthesiology, Chicago Wesley Memorial Hospital.

Read before the Section on Anesthesiology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 12, 1959.

The experiment was started 48 hours postoperatively and continued for three days, if possible. No other analgesics were given. All medicaments were given orally in identical capsules. The capsules were individually packaged and coded so that neither the observers, nurses, nor patients knew the identity of individual medicaments. The capsules were given by the nurses every four hours on a 2-6-10-o'clock schedule. The order of administration was systematically randomized. All patients received all four medicaments, with the exception of 20 who did not receive the placebo. The 2 a. m.-capsule was given if asked for by the patient, but observations on the effect on pain with this dose were not included in the results.

The patients were questioned three or four times per day about premedication pain, postmedication pain, duration of relief obtained, and side-effects experienced during each four-hour period. The pain was scored as follows: 1 = no pain; 2 = mild pain; 3 = moderate pain; and 4 = severe pain.



Incidence of postoperative administration of narotics: solid circles, orthopedic surgery; open circles, thoracic surgery; triangles, abdominal surgery (Keats[44]); open squares, rectal surgery.

No attempt was made to determine hourly pain scores. The interrogation of all patients was carried out by a physician. Observations were recorded numerically on a special chart, together with the code number of the drug.

Relief from pain is defined as the difference between the predrug score and the lowest score reported in the four hours after taking a capsule. The mean pain-relief scores were determined for each medicament on each postoperative day. The percentage of administrations of each drug giving relief was also determined. The degree of relief afforded by only the first dose given each patient was evaluated. Data concerning constant reactors, inconstant reactors, and constant nonreactors to placebo were separated and analyzed. Only those patients who had received two or more doses of placebo while they had pain were included in these groups.

Results

All patients were caucasoid. Thirty-eight (40.4%) were men and 56 (59.6%) were women. The mean age was 45.3 ± 1.9 years. Sixty-three (67%) of the patients completed the entire three-day study.

TABLE 1.—*Orthopedic Operations by Location in Ninety-four Patients Given Postoperative Analgesics*

	Operations Performed	
Location of Operation	No.	%
Foot	19	20.2
Ankle	2	2.1
Lower leg	3	3.2
Knee	10	10.7
Femur and hip	25	26.6
Back	13	13.8
Shoulder	10	10.7
Humerus	4	4.3
Forearm	4	4.3
Hand	4	4.3
Total	94	100(+)

Thirty-two per cent of the patients had severe pain (grade four) sometime during the study, and only 7.5% reported no pain at any time during the study. Of the 1,132 medicaments administered (about 300 doses of each), 68% were given at times when definite pain was present, namely, of 229 placebo capsules, 71.6% (164); of 305 codeine capsules, 67.3% (205); of 302 dextro propoxyphene capsules, 70.2% (212); and of 296 meperidine capsules, 63.5% (188).

Only the 769 administrations of the four medicaments which were given while pain was present were used to analyze pain-relief scores (table 2). Relief afforded by the active agents was significantly greater than that afforded by placebo on the first day and for the three-day period.

Meperidine and dextro propoxyphene significantly lowered the mean pain score on postoperative day number four, but there was no difference between the effects of any of the agents on the last day of the study. None of the active agents differed significantly from each other. A progressive daily decline in relief was provided by all agents except placebo.

TABLE 2.—*Mean Pain Relief Scores Obtained from Four Drugs Given Postoperatively*

	Drug Given				
Postoperative Day	Placebo	Codeine	Dextro Propoxyphene	Meperidine	Total
3*	0.43	0.76†	0.79†	0.95†	0.75
4	0.34	0.58	0.76†	0.71†	0.62
5	0.49	0.60	0.49	0.44	0.51
Total	0.41	0.67†	0.72†	0.77†	0.66

* Postoperative day 3 includes time between 48 and 72 hours after completion of surgery.
† $P = < 0.01$ compared with placebo responses.

The enumerative data on the medicaments whose administration gave relief are as follows: Pain was relieved to some extent about 42% of the time by placebo and about 58% of the time by the active agents, namely, 56.5% of the time by codeine, 60.5% of the time by dextro propoxyphene, and 65.4% of the time by meperidine ($p<0.01$ compared with placebo response).

TABLE 3.—*Pain Relief Scores with Use of Only First Dose of Four Medicaments Given*

Drug Given		Relief of Pain	
Type	Doses, No.	Mean Score	%
Placebo	14	0.57	57
Codeine	21	0.85	62
D-Propoxyphene	30	0.97	73
Meperidine	18	1.00*	83

* P = <0.05 compared with placebo response.

There were no differences in the duration of relief afforded by any of the capsules including placebo, the mean duration in hours having been, respectively, 3.26 for placebo, 3.28 for codeine, 3.17 for dextro propoxyphene, and 3.20 for meperidine. The maximum possible duration of relief was four hours, because another medicament was given at that time.

The responses to and the first dose of the medicaments administered are summarized in table 3. The results give a wide spread, but, because of the small size of the sample, these data are not significant.

The number of patients reporting various side-effects from any of the four medicaments is given in table 4. Drowsiness was the most frequently reported side-effect. The total reported side-effects from use of placebo and dextro propoxyphene were considerably lower than those reported from meperidine and codeine.

A summary of placebo effects is given in table 5. The placebo reactors had less pain and got more relief from all medicaments administered than did the other patients.

TABLE 4.—*Incidence of Side-Effects with Use of Four Medicaments*

	Medicament Given

Total doses administered	229	305	302	296	1,132

Comment

The results reported here are in agreement with the work of others.[3] That is, about 40% of the time administration of a placebo was followed by a reduction in the severity of pain. Administration of any one of the analgesic drugs resulted in a decrease in pain in a significantly larger percentage of the patients, although none of the agents could be distinguished from another. No agent provided relief all the time.

From the figure it can be seen that 48 hours after operation there is still pain severe enough to require the use of frequent doses of narcotic agents. Orthopedic patients, particularly, seem to require more frequent doses of narcotics.[4] The incidence of administration of narcotics is not a quantitative measure of severity of pain but reflects the frequency with which pain occurs.

Oral administration of narcotics does not provide dependable analgesia comparable to that obtained by injection of the same agent.[3a] However, meperidine and codeine are absorbed from the intestine in quantities sufficient to provide analgesic blood levels.[5] Oral medication has obvious advantages from the standpoint of nursing care. In the period studied here, the orally given medicaments were therapeutically effective.

TABLE 5.—*Analysis of Postoperative Placebo Effect in Fifty-three Patients*

	Type of Response		
	Constant Reactors	Constant Nonreactors	Inconstant Reactors
Number	12	20	21
Sex			
Male	4	10	10
Female	8	10	11
Mean Age, Yr.	50	42	41
% reporting placebo side-effects	17	10	19
% of time pain present	70	83	80
Mean pain score before use of drugs	2.16	2.34	2.19
% relieved by use of placebos	100	...	42.4
% relieved by use of analgesics	74.5	40.6	61.8

This study was primarily one of relief of pain. The technique of grading pain intensity numerically and measuring relief thereby is, in actual practice, difficult and insensitive; yet with this crude device significant drug effects could be demonstrated on the first and second days of the study and for the entire three-day period (table 3). The failure to detect drug effects on the third day might result from the existence of less severe pain, so that the placebo effect became more important in providing relief.

For that reason we were interested in examining the patients with respect to their reaction to placebos (table 5). Surprisingly, the so-called placebo reactors, that is, those patients who always obtained relief from pain when given a placebo, had significantly less frequent pain than the others. The active analgesics relieved pain in a significantly higher percentage of administrations to the placebo reactors than to the nonreactors. The patients discriminated between the effect of placebos and analgesics best on the first day of the study when the pain was most severe, and this ability to identify the placebos waned as the pain declined. This agrees with the findings of Free and Peeters[6] and is contrary to the results reported by the Harvard group.[3c]

Evaluation of the duration of analgesia is difficult in a situation in which pain is intermittent. No data are available to indicate the natural course of postoperative pain. The values obtained for duration of pain relief are not significantly different and reflect two disadvantages of this study if used to determine the duration of the analgesic effect of medicaments—namely, no value can be greater than four hours, and apparent analgesic duration may merely be a reflection of the absence of a painful stimulus.

Free and Peeters[6] reported that analgesic effectiveness in postoperative pain could be most readily evaluated by means of the first postoperative dose of an analgesic. Analysis of our results failed to demonstrate a significant difference between any one analgesic and the placebo in ability to relieve pain, measured by either pain score or incidence of relief (table 3); this may be a reflection of the necessarily small number of doses administered. With use of the results of all administrations of medicaments on the first day of this study, the differences between any one analgesic and the placebo were highly significant.

The benefit of the experimental design used here to evaluate the side-effects of the drugs administered is limited. Only those untoward reactions which would be expected to occur promptly after administration could be attributed to the drugs used. Furthermore, postoperatively, patients have many disturbances in their physiology which need not be related to analgesic therapy. The over-all incidence of side-effects of the medicaments used (table 5) is low and corroborates more meaningful data on these drugs already reported in the literature.[7]

Summary

Postoperative pain is a variable entity and difficult to assess. In the 94 postoperative orthopedic patients studied here, 92.5% had pain of at least moderate severity sometime in the three-day period beginning 48 hours after the end of operation. In these patients, orally administered dextro propoxyphene (Darvon) hydrochloride, meperidine (Demerol) hydrochloride, and codeine were significantly more effective than a placebo in relieving pain. The over-all response to the medicaments given, active or placebo, was similar to that found by other workers. Oral medication with moderately potent analgesics is effective in relieving pain in this period and probably interferes less with the physiological processes of the body than do more potent narcotics. The analgesic effectiveness of dextro propoxyphene, meperidine, and codeine, in the doses used, was indistinguishable.

RETURN TO WORK AFTER SURGERY.—I make one plea to surgeons. When you are satisfied concerning the surgical recovery of a patient, leave the decision as to return to work to the plant physician, if the patient's company has one. A well-trained and experienced industrial physician knows the nature of the employee's job and is better able to judge whether the employee should go back to full-time, or part-time work, or be assigned temporarily to another job. The addition of another two-week period of convalescence merely for the sake of safety can often be avoided by so doing.—A. J. Fleming, M.D., Return to Work After Surgery—An Industrial Study, *Journal of Occupational Medicine,* October, 1959.

ACUTE GASTRIC DILATATION

Ted F. Leigh, M.D., Atlanta, Ga.

In cases of acute gastric dilatation the progression of symptoms is rapid and prompt relief is necessary. Since the pathogenesis of the condition is poorly understood, however, treatment is still empirical. The most effective measure is to intubate the stomach and to remove the accumulated secretions and gases by continuous suction. Dilatation of the stomach has frequently followed abdominal surgery in the past, but three case histories here presented show that it sometimes follows other trauma, especially in patients immobilized for various reasons. In the fourth case, that of a 69-year-old woman, no obvious cause was found, but the condition progressed rapidly to a fatal termination. Acute dilatation of the stomach is a serious condition that is easily diagnosed and should be treated promptly.

Acute gastric dilatation is a condition characterized by clinical findings of vomiting, abdominal distention, and collapse. Radiographically, it is characterized by the identification on abdominal films of a large gastric shadow whose contents are air and fluid in varying proportions. The importance of a radiographic examination in suspected cases of gastric dilatation rests in the fact that the diagnosis can be quickly established by proper examinations of the abdomen and the condition can be differentiated from a host of others which show the same clinical features of vomiting, distention, and collapse. These other conditions include generalized dilatation of the large or small intestine caused by obstruction; localized dilatation of these same structures, as in volvulus of the small intestine, the cecum, or sigmoid; ascites; pneumoperitoneum; cyst or tumor; and distention of the urinary bladder.

Pathogenesis

The pathogenesis of acute gastric dilatation is of interest and in its consideration the following factors must be taken into account: (1) etiology of the gastric dilatation, (2) origin of the fluid contained within the stomach and duodenum, (3) origin of the air in the distended stomach (and duodenum), and (4) causative factors in the associated gastric or duodenal obstruction which is sometimes present.

Cause of Gastric Dilatation.—The most widely accepted theory of acute gastric dilatation is that it is caused by paralysis of the stomach, which has been described as being analogous to intestinal paralysis, such as occurs with peritonitis. Dragstedt and others [1] attribute this paralysis to a reflex inhibition of the peripheral gastric motor mechanism through efferent impulses which reach the stomach by way of the vagi and splanchnics. Their experimental evidence is adequate to show that the stimulation of either visceral or somatic central nerves may produce such reflex gastric inhibition, allowing the stomach to distend abnormally as fluid and air are progressively accumulated within it. These authors also believe that the principal contributing cause of death in these cases is failure of reabsorption of the gastric and pancreatic juices and more particularly of the inorganic elements, sodium and chloride, within these juices.

Origin of Fluid Contained Within the Stomach.—The fluid in the stomach is derived from several sources—gastric juice secreted by the stomach wall; pancreatic juice, bile, and secretions of the duodenal mucosa which reflux into the stomach; ingested material, including both fluids and food; and secretions, notably saliva, derived from the alimentary tract proximal to the stomach.

Origin of Air in the Distended Stomach.—It is generally agreed that all air seen in the stomach during acute gastric dilatation is derived from outside the body.[2] Morris and others [2c] after experimenting on animals and human beings, reached the conclusion that the air which is present in the stomach in acute gastric dilatation comes from sucking air or swallowing air. They state, "What keeps everyone from sucking air is the resistance offered by the superior esophageal sphincter, and one might postulate that general debilitation, anesthesia, or some reflex may decrease the tone of this structure, and allow significant volumes of air to enter the upper part of the gastro-intestinal tract."

Cause of Obstruction.—There are several factors which may contribute toward an associated obstruction in the distal end of the stomach or duodenum. It is postulated that an enlarging stomach in itself may so angulate the distal end of the stomach or proximal duodenum that obstruction results. In many instances, the enlarging stomach displaces much of the small intestine into the pelvic area, putting such traction on the mesentery and mesenteric vessels that they compress the transverse part of the duodenal loop against the lumbar vertebra,

Chairman's address, read before the Section on Radiology at the 108th Annual Meeting of the American Medical Association, Atlantic City, June 11, 1959.

which results in a partial or complete midline obstruction. In the presence of a body cast, there is sufficient hyperextension of the spine and reduced mobility of the abdominal musculature to cause a similar obstruction by the mesentery and mesenteric vessels in the transverse arm of the duodenum.[3]

Clinical Findings

The clinical features of acute gastric dilatation are classic. The chief symptoms are vomiting, abdominal distention, and collapse. Lesser symptoms include pain over the stomach, insufferable thirst, and scanty urine. The vomiting occurs at short intervals and once begun becomes the most prominent feature. It is not as debilitating as it would seem and does not give the patient a feeling of relief. The vomitus is usually thin watery material and is small in amount compared to the total fluid present in the stomach.

The degree of abdominal distention is varied, depending to a large extent on the size and shape of the abdomen and the degree of gastric distention in the individual case. More than likely the gastric distention causes the epigastric and periumbilical pain which is often present. Before complete gastric paralysis develops, there may be visible peristalsis on the abdominal wall.

The stomach fluid in the earlier stages is yellow or green and odorless. Later it becomes brown or black because of admixture with blood, usually contains biles, and has an offensive odor. The fluid volume varies from one to several liters. In one reported case, the stomach was estimated to contain 7,500 cc. of fluid; in another case, the distention was so great that the body could not be placed in a casket. Esophageal obstruction is sometimes present and is due to a deformity at the cardia initiated by the enlarging stomach.[23] The development of acute gastric dilatation can be exceedingly rapid. Within 24 to 48 hours, a normal stomach can expand into a cyanotic and hyperemic sac, filling almost the entire abdomen and extending caudad to reach the pelvic floor.

The treatment for acute gastric dilatation is not entirely satisfactory. In postoperative cases, dilatation may be prevented by suction applied to a stomach tube. Operative results for the dilatation itself have been discouraging. The principal types of procedures which have been performed include gastroenterostomy, gastrostomy, gastrotomy, and gastrectomy. The poor results of surgery are attributed to the condition of the patient and to the severe irreversible damage in the gastric wall.

Radiographic Characteristics

In the diagnosis of acute gastric dilatation, radiographic examination can be of help in establishing the diagnosis and in differentiating it from other conditions. An examination of the abdomen, made with the patient in recumbent position, will usually reveal the stomach as a large mass filling the upper and middle part of the abdomen and displacing the intestines laterally and caudad. When the stomach lumen contains large amounts of fluid and only small amounts of air, the gastric shadow may be poorly defined because it is of the same density as the surrounding abdominal structures. Air in the gastric lumen, on the other hand, is easily recognizable. When present in relatively small quantities, it is seen as a translucent shadow superimposed on the fluid (fig. 1*A*). In larger quantities, it may actually outline the stomach itself (fig. 2). Air may also outline the duodenum if sufficient amounts are located in that area.

An examination made with the patient in upright position will show an air-fluid level in the left upper quadrant of the abdomen, with the air mass corresponding to the contour of the fundus of the stomach and located immediately beneath the left diaphragm leaf (fig. 3*A*). In addition, a second air-fluid level is sometimes seen in the right middle or upper part of the abdomen, situated more caudad than the one on the left and shorter in length (fig. 3*C*); this level is due to the presence of small amounts of air trapped in the prepyloric region of the stomach or in the duodenal cap. Again the fluid in the stomach appears as a homogeneous shadow in the middle part of the abdomen but may be difficult to identify because of its density in relation to the surrounding structures (fig. 3*C*).

Other types of abdominal films can be made to aid in the diagnosis of acute gastric dilatation, particularly if the patient's condition is such that a film of the patient in an upright position is contraindicated; these include left and right lateral decubitus films and transabdominal films. These, in all instances, will show air fluid levels, with the air pocket outlining the portion of the distended stomach in which it is located.

Abdominal examinations after the oral administration of contrast medium may at times be indicated, particularly for delineating the size of the stomach (fig. 3*C*), and for determining the patency of the lower part of the esophagus at the cardia (fig. 1*B* and 4*B*). In these cases, the water soluble mediums are to be preferred over barium sulfate mixtures and iodized oils.

Predisposing Factors

There are certain predisposing factors in the development of acute gastric dilatation. These can be divided into surgical procedures in the abdomen, acute illness or convalescence, chronic illness, disorder or deformity of the spine, overloading of the stomach, abdominal trauma and intra-abdominal accidents, confinement, and vagotomy, induced either surgically or medically. To these may be-added those cases of acute gastric dilatation in which there is no obvious cause; these might be classed as idiopathic cases, although it is probable that a predisposing factor exists which defies detection.

Dilatation attributed to overloading of the stomach is of particular interest. In a report by Markowski[4] four cases of acute gastric dilatation attributed to overloading the stomach with food are cited. All patients were prisoners-of-war and were emaciated. Two of these patients developed the dilatation although they had eaten a meal no larger than one eaten by a normal healthy person. The author postulated that the acute dilatation was superimposed on a chronic one caused by malnutrition and that the sudden intake of food caused paralysis of an already weakened wall. He stated that chronic dilatation of the stomach, due to the prolonged intake of large amounts of food of poor caloric intake, was so common that they used to call it the occupational disease of the prisoners-of-war.

The following cases will serve to illustrate some of the clinical and radiographic characteristics in this entity of acute gastric dilatation.

Report of Cases

Case 1.—A 43-year-old woman had a long history of urinary calculi. A cystoscopy was performed on Sept. 15, 1955, with removal of calculi from the left ureter. An indwelling catheter was placed in the lower half of the left ureter. On this same day laboratory examinations disclosed an imbalance of the electrolytes. On the next day, because of abdominal distention, a radiographic examination of the abdomen was carried out (fig. 2), which disclosed an acute gastric and duodenal dilatation with a predominant amount of air. The dilatation was relieved by intubation and suction. After tl there was no further distention. About this san time the electrolyte disturbance had been correcte

Case 2.—A 17-year-old man was admitted to tl hospital in an unconscious state, having sustaine a simple fracture of the right femur in an aut mobile accident. He was initially placed in tractio but two weeks later, because of a disturbed ment state, he was placed in a plaster hip spica. H mental state cleared slowly, and he was discharge from the hospital. Seven weeks later persister vomiting developed and he was readmitted. Afte

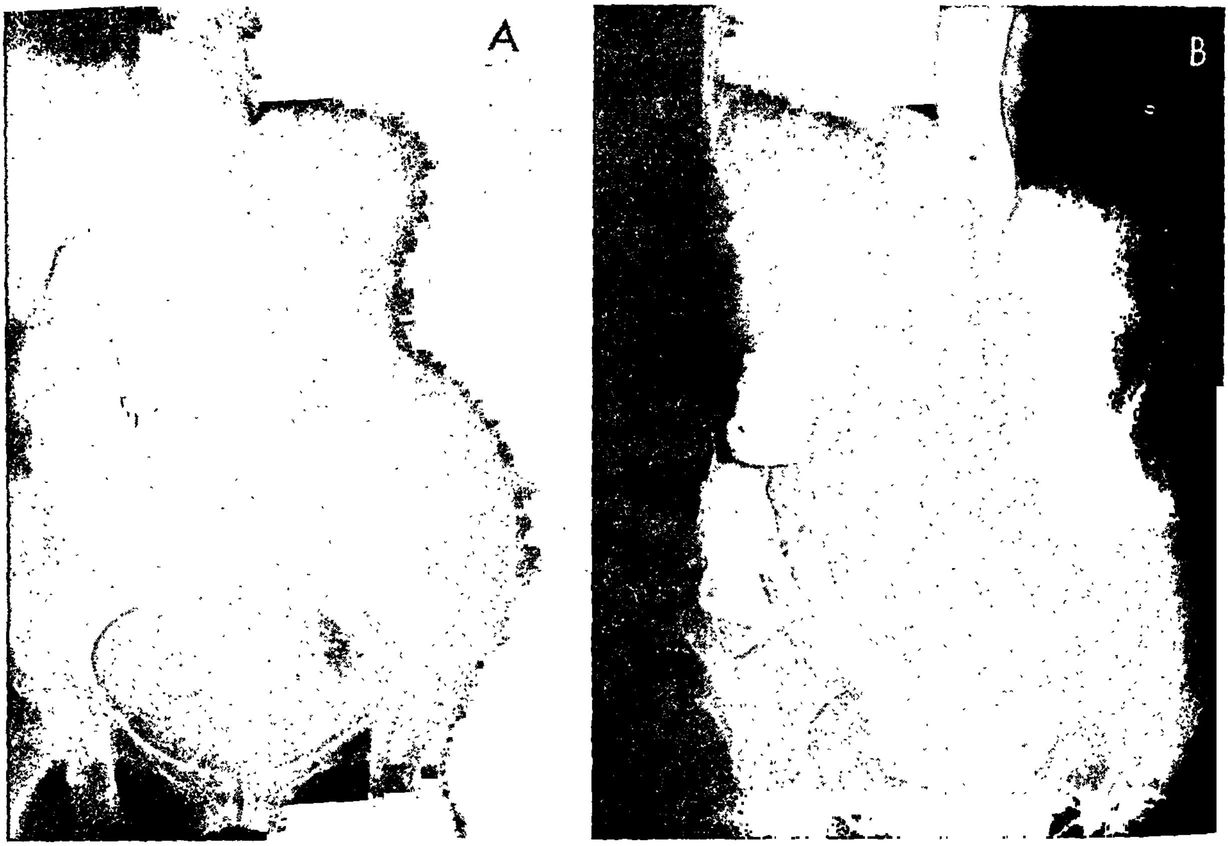

Fig. 1 (case 4).—Acute gastric dilatation of unknown cause. Abdominal film made with patient in recumbent position (shows the enlarged stomach, outlined in part by air in displaced intestines. Vague translucent shadow over lumbosacral area caused by air in stomach. Contrast medium studies (*B*) disclose compression and displacement of colon and obstruction esophagus.

the removal of the cast a physical examination of the abdomen disclosed generalized abdominal distention without tenderness. Radiographic examinations at this time (fig. 3*A*, *B*, and *C*) showed a gastric dilatation with a predominant amount of fluid. Intubation was carried out immediately, and 3,000 cc. of bile stained fluid were withdrawn. Continuous gastric suction was applied for 24 hours and then discontinued. The next day an examination again disclosed gastric distention. Suction was reinstituted. Four days later, a second gastrointestinal examination showed normal findings (fig. 3*D*). Gastric suction was continued for several more days and then the patient was placed on a liquid diet and finally on a solid diet. He was discharged from the hospital without a reapplication of the cast.

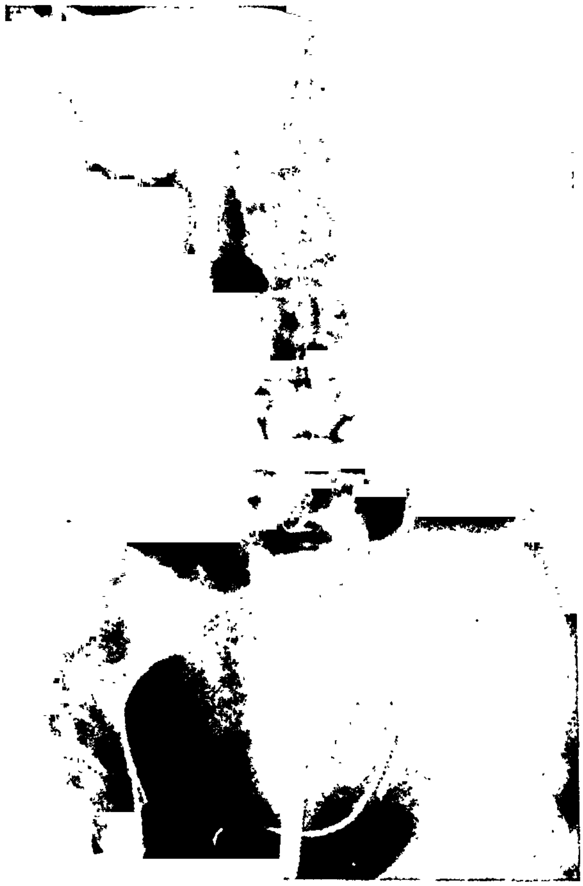

Fig. 2. (case 1).—Acute gastric dilatation after cystoscopy. mach and duodenal cap are markedly distended, princi- lly with air. Rectal tube can be seen. Calculus in left kid- y is well visualized because of superimposed air.

CASE 3.—A 59-year-old man sustained multiple juries to the chest, upper abdomen, and right etabulum in an automobile accident on May 31, 59. The chest injuries were the result of a blow the steering wheel of the automobile. An emergency electrocardiogram showed evidence of myocardial damage. A chest examination disclosed multiple rib fractures and acute pulmonary edema. The upper part of the abdomen was visible on this chest film and showed a mild amount of air in the stomach and a moderate distention of the transverse colon. Bilateral leg casts were applied, but no body cast was placed on the patient. On June 6 the patient complained of abdominal distention and vomiting. An abdominal film at this time (fig. 4*A*) disclosed marked distention of the stomach, predominantly with air, moderate distention of the entire colon, and mild distention of multiple loops of small intestine. An esophageal examination showed a partial obstruction at the cardia, presumably related to the enlarging stomach (fig. 4*B*). After this gastric suction removed 2,000 cc. of fluid, plus large quantities of air. The next day 800 cc. of fluid were removed. The patient experienced no further gastric distention after this.

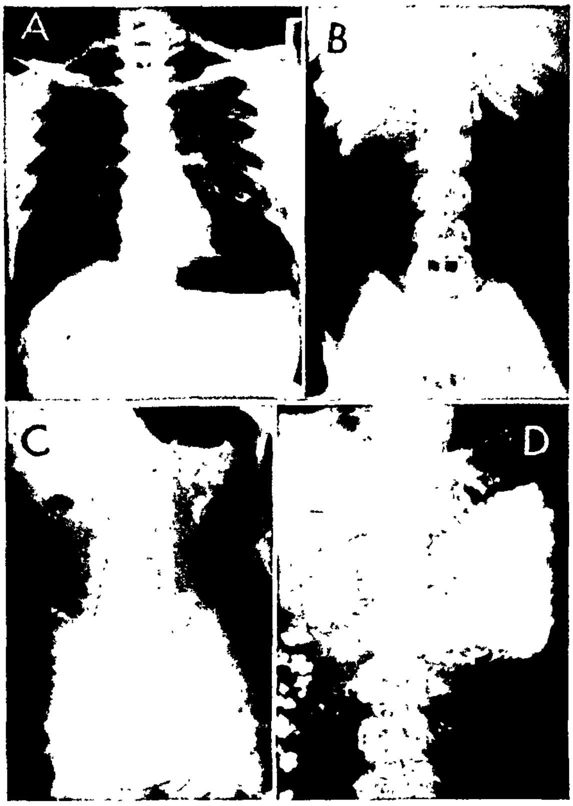

Fig. 3 (case 2).—Acute gastric dilatation after application of body cast for fracture of right femur. Upright chest film (*A*) and recumbent abdomen film (*B*) disclose the gastric dilatation, which predominates in fluid. After oral administration of contrast material (*C*), extent of dilatation can be appreciated. After treatment, second gastrointestinal examination six days later (*D*) discloses normal findings.

CASE 4.—A 69-year-old woman suffered from nausea and vomiting of four days' duration and after that from progressive abdominal distention and cramping pain. For two days she could retain no ingested food or fluid. There was no previous history of abdominal complaints of any type except constipation, for which she frequently took laxatives. Physical examination disclosed an acutely ill patient with marked distention of the abdomen. There was no visible or audible peristalsis in the abdomen and no obvious cause for her illness.

An abdominal radiographic examination, made with the patient in recumbent position, revealed the presence of a large mass filling the middle part of the abdomen (fig. 1*A*). On the same day, a barium enema and an upper gastrointestinal examination were made (fig. 1*B*) and showed the colon to be intrinsically normal but displaced by the abdominal mass. The lower esophagus was obstructed, and on the film several linear streaks of barium could be seen at the distal end of the esophagus, suggesting a volvulus of this structure. No barium entered the stomach. The radiographic impression from these studies was that the patient had gastric distention and esophageal obstruction resulting from the distention. Gastric intubation was unsuccessful. Esophagoscopy was performed, but the esophagoscope could not be passed into the stomach and no fluid could be withdrawn. Since the patient's admission her condition had become steadily worse; the morning after admission her pulse became imperceptible and within a short time she died.

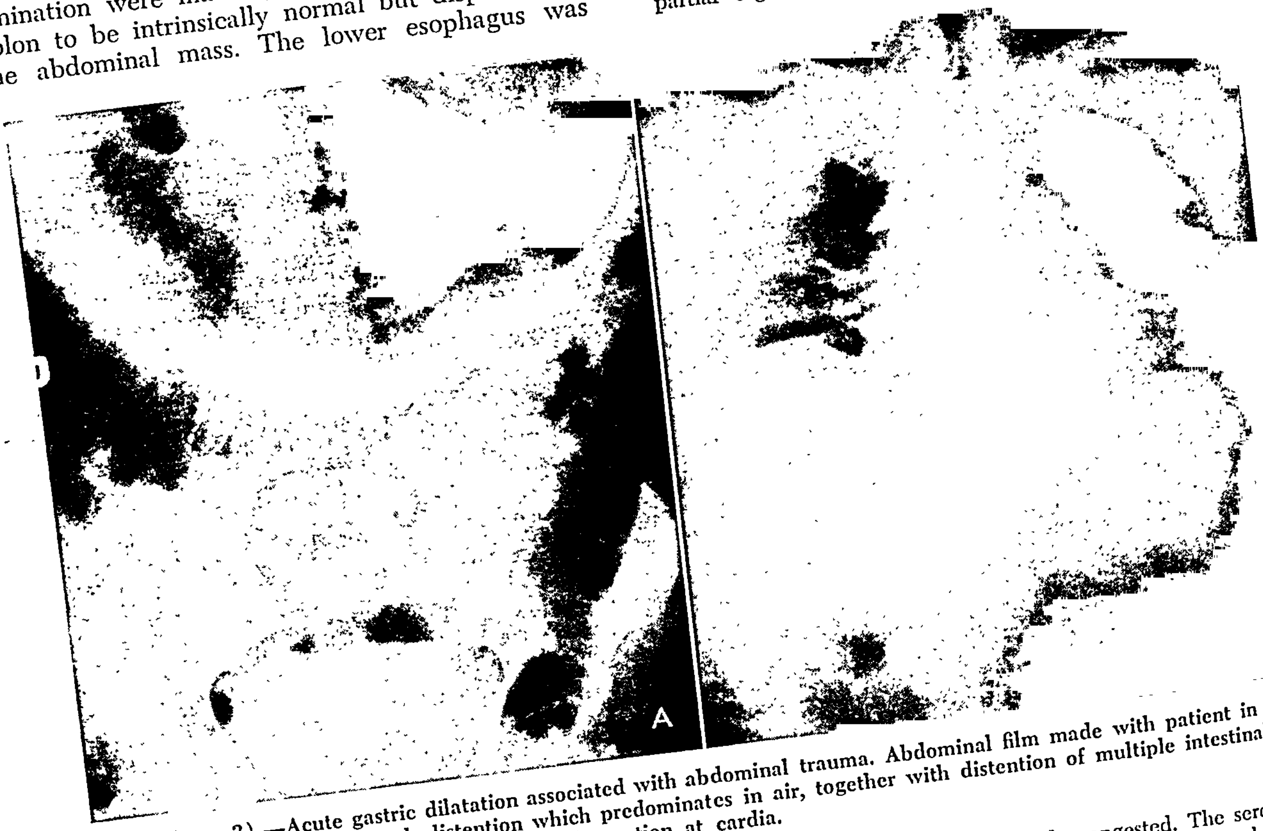

Fig. 4 (case 3).—Acute gastric dilatation associated with abdominal trauma. Abdominal film made with patient in recumbent position (*A*) shows stomach distention which predominates in air, together with distention of multiple intestinal loops. Esophageal examination (*B*) discloses partial obstruction at cardia.

A postmortem examination was performed, and part of the report read as follows:

> The peritoneal cavity contains approximately 3,000 cc. of rather foul smelling, brownish, watery fluid. Upon opening the cavity, a large amount of air also escapes. Upon examining the stomach, this entire organ is markedly discolored, and greenish-black in color. The stomach contains a large perforation measuring 4 to 5 cm. in diameter on its anterior surface near the lesser curvature. This perforation is located 6 cm. below the esophago-gastric juncture. The entire wall of the stomach is markedly thinned and falls apart very rapidly upon manipulation. The marked discoloration and thinning of the gastric wall ends abruptly at the pylorus. The duodenal mucosa appears essentially normal. There is no obstruction present at the pylorus. There is early acute peritonitis present. Microscopic examination of the stomach shows complete autolysis of the mucosa and partial digestion of the remainder of the stomach wall. The blood vessels are intensely congested. The serosal surface of the stomach shows an early polymorphonuclear leukocytic infiltration.

Summary

Acute gastric dilatation is a condition characterized by clinical findings of vomiting, abdominal distention, and collapse. The gravity of this condition in most instances makes mandatory its prompt recognition and treatment. The diagnosis can be quickly and easily established by proper radiographic examination of the abdomen. The necessary examination can be carried out at the bedside as well as in the radiology department.

The radiographic examination further aids in the differentiation of this condition from other abdominal conditions which show similar clinical findings.

LONG-TERM MANAGEMENT OF OBESITY IN A UNION HEALTH CENTER

ANALYSIS OF SUCCESSES AND FAILURES

Donald Berkowitz, M.D.
and
Nathaniel Beck, M.D., Philadelphia

Seven men and 93 women, each overweight by at least 20% of their calculated ideal weight, started a reduction program. The general plan of management included education, caloric restriction, anorectics, exercise, and psychotherapy. The results were appraised at the end of one year for the participant's success or failure to attain and then to stay at a normal weight. Twenty-six patients discontinued the program although they had lost some weight. Twelve were discharged because they failed to adhere to the program. Most of these people had regained weight during the year. Of the 62 continuing to the end of the year, 42 had lost 20 or more pounds, and 20 had not. Six succeeded in attaining normal weight levels. Three factors which apparently influenced those who failed were lack of motivation, lack of intelligence, and severe emotional difficulties.

Much has been spoken and written in recent years on the subject of obesity. A clearer understanding of the multiple etiological and psychological factors has been obtained [1] as well as more precise data concerning the various pathophysiological and metabolic disturbances frequently associated with the obese state.[2] More anorectic agents are being recommended for appetite suppression, and even hypnosis has its advocates.[3] However, the management of the overweight patient over the long term is rarely mentioned, and careful follow-up studies are lacking in otherwise prolific literature.

We have had the opportunity to observe a large number of obese patients for a prolonged period of time during their course of attempted weight reduction. This report describes our experiences in this endeavor.

Material

One hundred consecutive patients who were referred to the obesity clinic of a union health center were selected for study. There were 93 women and 7 men in the group. The ages ranged from 18 to 72 years, and most were in the 30-to-60-year age category. The initial weights varied from 151 to 320 lb. (68.5 to 145.5 kg.), each patient weighing at least 20% more than his ideal weight as calculated from standard height-age-weight tables.

Method of Treatment

The general plan of management included education, caloric restriction, anorectics, analeptics in some cases, exercise, and psychotherapy. Prior to initiation of therapy, a complete record of the patient's history was made and a physical examination

---

From the Sidney Hillman Medical Center of the Male Apparel Industry of Philadelphia, the Einstein Medical Center, and the Hahnemann Medical College.

was performed. A blood cell count, urinalysis, determination of blood sugar and cholesterol levels, and measurement of basal metabolic rate were performed routinely. An electrocardiogram and chest x-ray were taken. In a selected number of cases more elaborate metabolic studies, including a glucose and radioactive fat tolerance test plus liver function evaluations, were done initially and after a significant amount of weight had been lost. These results will be reported separately.

The basic essentials of good nutrition were discussed with each patient, and an attempt was made to distinguish between the many facts and fancies which are so commonly held to by obese persons. The methods for calculating caloric restricted menus were demonstrated by means of the various visual aids furnished by the American Diabetes Association and the American Medical Association. The word "diet" was carefully avoided because it connotes starvation to the average overweight patient.

An anorectic agent, levoamphetamine alginate (Levonor) was administered three times daily either before meals or during the middle of the morning, late afternoon, and at 8:00 p. m. In a certain number of cases levoamphetamine alginate and also methamphetamine alginate were prescribed. Posture control and moderate exercises were demonstrated and encouraged to be followed daily. Each patient was seen at two to four week intervals. The program was continued for one year.

Number of Patients Who Had Lost or Gained Weight One Year After Starting Treatment

	Weight Loss, Lb.						Weight Gain, Lb.	
Period of Treatment	0-9	10-19	20-29	30-39	40-49	50	1-9	10-19
One year	3	17	22	7	3	4	..	..
Less than one year								
Discharged*	..	..	3	3	..	..	..	..
Failed to continue	19	..	..	..	..	..	16	3

* Discharged because of adequate weight reduction.

Results

Fifty-six of the 100 patients were still attending the clinic after one year. Six had been discharged previously because their weight had been restored to normal. An analysis of the individual weight losses in this group of 62 patients revealed extreme variability (see table). Greater reduction usually occurred in those who weighed the most prior to therapy. Forty-two of this group lost more than 20 lb. (9.1 kg.) during the year, 17 lost from 10 to 19 lb. (4.5 to 8.6 kg.), and 3 lost less than 10 lb. (4.5 kg.). The maximum weight loss was 70 lb. (31.8 kg.) in a 45-year-old woman who originally weighed 320 lb.

Twenty-six persons who initially lost some weight failed to return after several visits to the clinic. Twelve others were discharged because they failed to adhere to the program. Follow-up examination of this group of 38 patients revealed that in practically every case an increase in weight occurred after treatment was discontinued. In 19 of the 38 persons the weight was actually greater one year after they had started the program.

Comment

Stunkard[4] has recently reviewed the literature dealing with the results of treatment for obesity. In his critical analysis he has emphasized two important points—the inadequacy and misleading aspects of most published papers and the generally poor results obtained in most of the studies in which adequate data and follow-up statistics are available.

The usual report deals with the management of small groups of persons for short periods of time, usually 4 to 12 weeks, with one of any number of anorectic agents currently available.[5] The results usually indicate that weight reduction was satisfactory in most of the subjects treated. Individual responses, however, are frequently obscured by the reporting of data in terms of averages for the entire group. The fact that most short-term weight reduction studies are favorable regardless of the type of diet or drug used is usually neglected.

Long-term treatment of the obese patient has invariably given poor results, with the finding that most of the patients were unable to lose even 20 lb.[6] In Stunkard's group of 100 obese persons only 12 succeeded in losing this amount.[4]

In our study, 38% of the patients who started on the weight reduction program did not continue. Moreover, an additional 20 who did continue failed to lose 20 lb. even after one year. However, on a more optimistic note, 42 of the original group were successful in losing this amount. This corresponded to 68% of those who persevered through the year's treatment.

Analysis of Successes and Failures

We have tried to analyze our successes and failures to see if there were any common denominators which would enable us to predict in which patients weight reduction would be successful. No objective criteria which could be used to prognosticate were forthcoming, however. Failure or success of the reducing program was not dependent in any way on age, sex, duration of obesity, family history, hypertension, carbohydrate metabolism, or cholesterol levels. This is unfortunate, for if such a scheme were possible it would certainly avoid much "wear and tear," frustration, and disappointment on the part of the physician as well as the patient.

In our experience three factors considered important reasons for failure were lack of motivation, lack of intelligence, and a severe emotional overlay.

Lack of Motivation.—No patient can hope to lose weight successfully if a genuine desire to do so is lacking, because inevitably the program involves self-deprivation and restriction to a point that is often unpleasant, if not uncomfortable. Fifty per cent of our failures belonged in this category.

Lack of Intelligence.—We considered lack of intelligence to be the basis for failure in 20% of our patients. A basic understanding of the aims of dietotherapy is a prerequisite before treatment can be undertaken. Where the lack of intelligence is great, or where language difficulties preclude the patient from comprehending, failure is inevitable. Blind obedience to a specifically prescribed menu for any prolonged period of time has been impractical. Each patient must be re-educated in his eating habits and encouraged to learn as much about the science of nutrition as possible. We have found the use of the exchange system of food values to be of great help in this respect.

Emotional Overlay.—In another 20% of our failures emotional overlay was considered to be of prime importance. The role of the psyche in obesity has been well established. To many people, eating is a compulsive act—a substitute for satisfaction which should be obtained by other means. In this group, headache, nervousness, irritability, dizziness, and depression were noted and were relieved only by the ingestion of food. These side-effects of dieting have also been emphasized by others.[7]

Other Factors.—Other factors which contributed to the ultimate inability of the patient to lose weight included specific intolerances to certain prescribed drugs and concomitant diseases such as severe arthritis which prevented any major degree of ambulation.

Successful Results.—Success, on the other hand, was more difficult to predict. Many patients who on initial impression were considered likely to succeed subsequently failed to continue with their treatment and did not lose weight. The results of previous attempts were of no value prognostically. Several patients who had been able to reduce satisfactorily on other occasions were unsuccessful during this course. Conversely, over 50% of the successful group had failed in each previous try. This was probably a reflection of the interest and vigor with which the present obesity clinic was maintained.

An over-all appraisal, therefore, of our experiences confirms that, as has been found many times before, the treatment of the obese patient is a tremendously difficult task. Success in this respect over the long term may be anticipated in less than half of those who come under our care.

As dismal as the outlook may appear, it should serve as a stimulus and challenge. Certainly, continued treatment is better than no treatment, as is evidenced by the follow-up weights of those who failed to continue with their prescribed regimen. As long as the physician continues to be interested in his patients, sympathetic, kind, and understanding and applies whatever new techniques become available, the future may hold some promise of greater success than is presently obtainable.

Summary

The results of treatment of 100 obese patients in a union health center were analyzed after a one-year period of follow-up. Fifty-six patients were still under treatment after this time. An additional six had been discharged previously because of a satisfactory weight loss. Forty-two of this group lost more than 20 lb. (9.1 kg.) during the year. Thirty-eight per cent failed to continue with the reducing program, although many lost weight initially. The three factors that appeared to be important reasons for failure were lack of motivation, lack of intelligence, and a severe emotional overlay.

101 S. 20th St. (Dr. Berkowitz).

The levoamphetamine alginate used in this study was supplied as Levonor by Nordson Pharmaceutical Laboratories, Irvington, N. J.

CLINICAL NOTES

CORONARY ARTERIOVENOUS FISTULA INTO MAIN PULMONARY ARTERY

PREOPERATIVE DIAGNOSIS BY SELECTIVE AORTOGRAPHY

Kurt Amplatz, M.D., Jeorge Aguirre, M.D.
and
C. Walton Lillehei, M.D., Minneapolis

Abnormal communications between the coronary arteries and the coronary veins, right atrium, right ventricle, or pulmonary arteries are usually referred to as coronary arteriovenous fistulas. Steinberg and associates,[1] in an excellent review of this subject, found 22 reported cases and added one case diagnosed by forward angiography.[1A] It is the purpose of this article to present an unusual case which was accurately diagnosed by selective aortography and successfully treated by surgical excision.

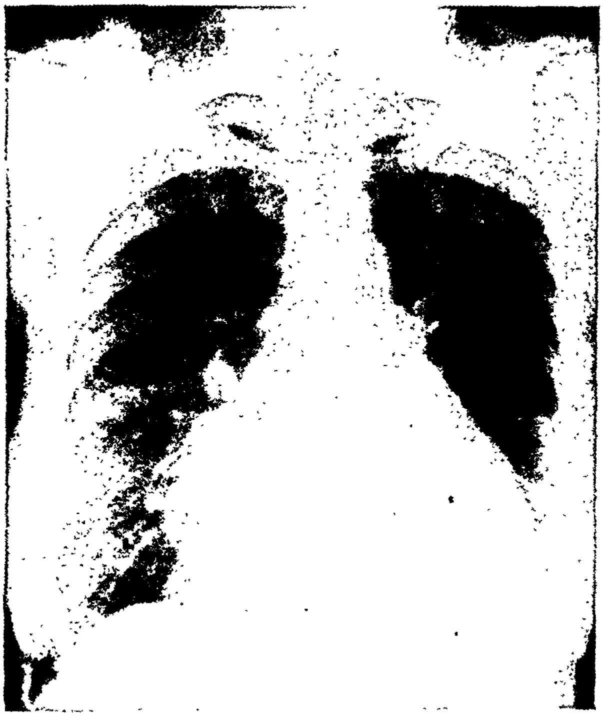

Fig. 1.—Marked, generalized, unspecific cardiac enlargement, without roentgenographic evidence of left-to-right shunt.

Report of a Case

A 53-year-old woman was admitted to the University Heart Hospital on Feb. 22, 1959, complaining of shortness of breath. She had always been in good health until October, 1958, when she noticed the onset of exertional dyspnea and increasing fatigue. In December, 1958, she was hospitalized for acute heart failure and given treatment with digitalis, diuretics, and sedatives. In 1953, when she had a hysterectomy, results of an examination of her heart had been recorded as normal. On admission, physical examination revealed the heart to be generally enlarged. No thrill was palpable. A loud continuous murmur was heard over the pulmonic area, with maximal intensity over the second and third left intercostal spaces. The murmur was not transmitted to the back. Blood pressure was 160/100 mm. Hg in the upper and lower extremities. The electrocardiogram showed left ventricular hypertrophy with left ventricular strain. The possibilities of aortic valvular disease, patent ductus arteriosus, or ruptured sinus of Valsalva were considered.

Cardiac fluoroscopy and heart films indicated a generally enlarged heart, without roentgenographic evidence of a left-to-right shunt, (fig. 1). A retrograde aortogram, with the catheter in the ascending aorta, was performed[2] and showed the presence of an arteriovenous malformation obviously being fed by the left coronary artery (fig. 2 and 3). Opacification of the pulmonary artery without staining of the right ventricle indicated a direct shunt from the coronary artery fistula into the pulmonary artery. During right heart catheterization radioactive methyl iodide curves were obtained from the pulmonary artery and right atrium.[3] A typical but delayed left-to-right shunt curve was obtained from the pulmonary artery which was consistent with a 1.7 vol. per cent oxygen increase at this level. Early appearance of radioactivity in the blood samples from the right atrium suggested an additional smaller arteriovenous communication from the coronary artery fistula to the coronary sinus or directly to the right atrium (fig. 4).

On March 6, 1959, a thoracotomy was performed on the left side. Just as the pleura was entered, the anesthesiologist reported that he was unable to obtain a blood pressure reading; therefore, the pericardium was rapidly opened. The heart was

---

Instructor of Radiology (Dr. Amplatz); Medical Fellow of Surgery, (Dr. Aguirre); and Professor of Surgery, (Dr. Lillehei); University of Minnesota Hospitals.

seen to be still feebly beating and the visible myocardium was of a deep cyanotic color. Immediately a small serrefine clamp was applied, occluding the main parent artery feeding the fistula, and the heart responded at once with contractions of increasing vigor. The blood pressure returned to the preanesthetic level and remained stable for the rest of the operation. A large cavernous mass of vessels was present between the left atrial appendage, base of the pulmonary artery, and origin of the left anterior descending coronary artery. This conglomerate of twisted vessels was fed by the left main coronary artery, which measured 1 cm. in diameter. The anterior descending and circumflex branches were of normal size. The arteriovenous malformation communicated with the main pulmonary artery just distal to the pulmonic valve through three openings. The parent artery (8 mm. in diameter) was divided at its origin from the very large left main coronary artery, and the fistulous mass was excised. Proceeding toward the communication into the main pulmonary artery, five or six smaller feeding arteries and veins were encountered descending directly into the underlying myocardium. These direct communications with the coronary veins probably accounted for the suggested left-to-right shunt at the atrial level on the radioactive methyl iodide curves. After the excision of the fistula, the initially present thrill disappeared; the patient made a rapid recovery and was discharged 14 days after operation. A recent follow-up examination disclosed the absence of cardiac murmurs and a continued dramatic improvement in the patient's exercise tolerance.

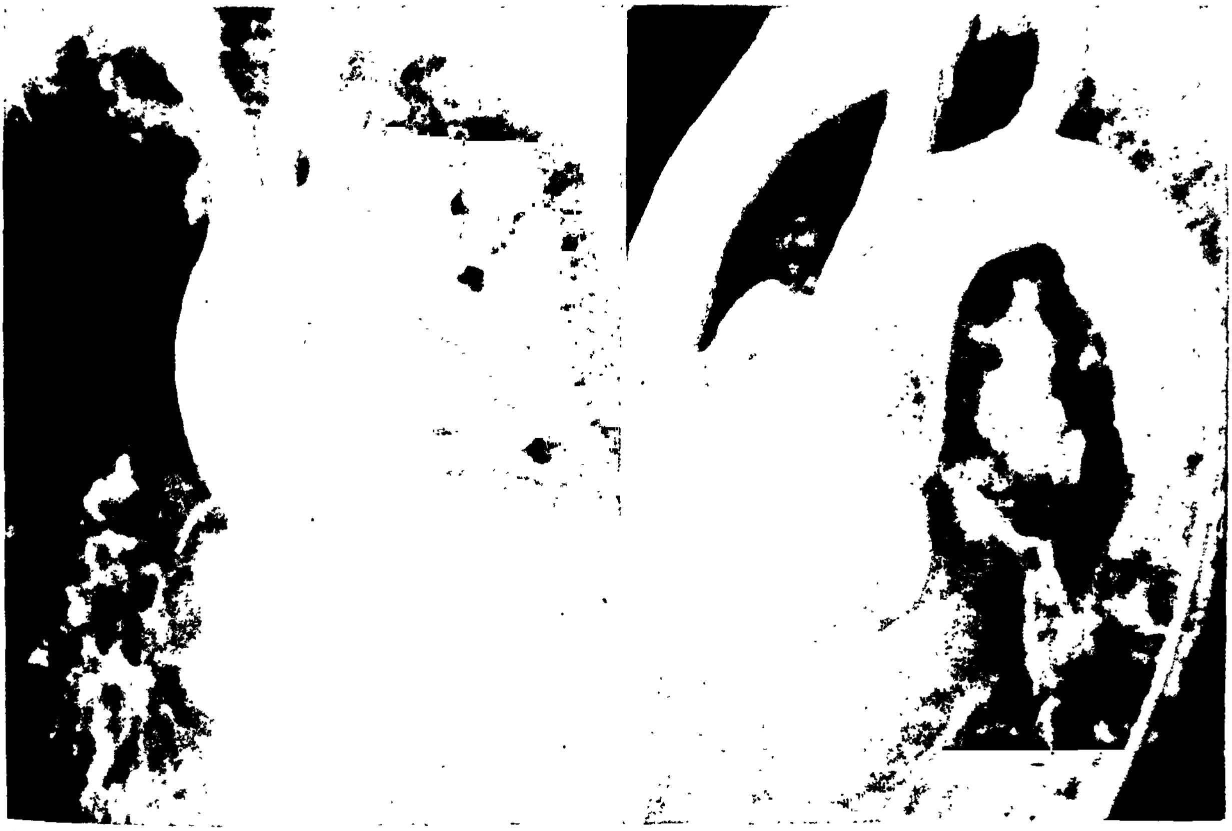

Fig. 2.—*Left,* selective aortography demonstrating coronary artery fistula feeding main pulmonary artery. *Right,* lateral view showing aortic cusps being opened during systole, with coronary artery fistula and opacified pulmonary artery well visualized.

Comment

During the past 12 months at the University of Minnesota Heart Hospital four patients ranging in age from 17 months to 53 years have been correctly diagnosed preoperatively as having a coronary arteriovenous fistula (two into the right ventricle, one into the right atrium, and one [the present patient] into the pulmonary artery). Three operations have been performed to the time of writing, all resulting in successful excision of the shunt with murmurs absent postoperatively. In three of these patients selective aortography was performed by means of a catheter placed into the ascending aorta, and in each the precise site of the fistula was clearly demonstrated. Selective aortography is considered to be the best method of diagnosis in patients with this type of heart lesion.

The immediate favorable response to clamping off the main feeding branch of the arteriovenous malformation showed the unique physiological burden of coronary arteriovenous fistulas on the myocardium. The specific hemodynamic effect of an arteriovenous communication is the loss of capillary resistance in the particular vascular bed. This decrease results in compensatory factors such as increased cardiac output, increased blood volume, and generalized vasoconstriction.

The normal heart may compensate well in large left-to-right shunts for long periods of time by virtue of an increased output. In arteriovenous fistulas involving the coronary circulation, the ability of the heart to compensate for these abnormal shunts is greatly reduced by direct effect on the myocardial blood supply. The fact that interarterial communications between the right and left coronary artery beds in man are limited further aggravates the effects of the fistula.[4]

Since these patients also are more susceptible to bloodstream infections and cardiac decompensation, diagnosis is sufficient indication for surgical intervention. Excision is the preferred method of treatment, since mere ligation is likely to lead to recurrence.

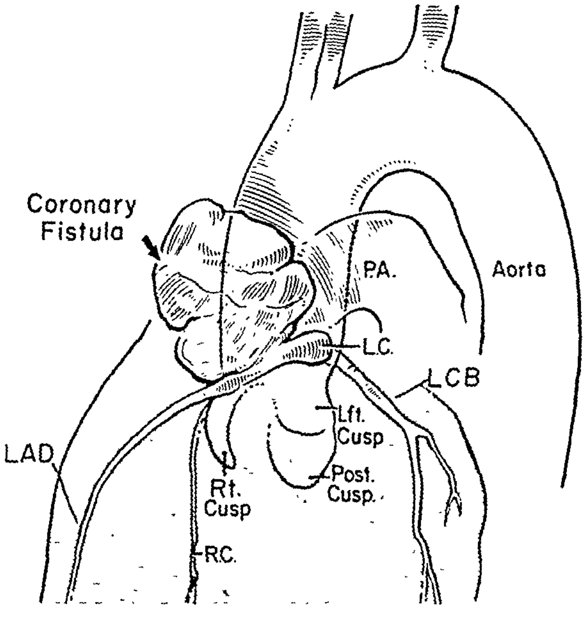

Fig. 3.—*L.C.:* left main coronary artery. *R.C.:* right coronary artery. *LCB.:* left circumflex coronary artery. *P.A.:* pulmonary artery (branch).

Summary

Coronary artery fistulas are 10 times less common than left heart tumors[1] but are now being more frequently identified.[5] Coronary artery fistulas cause progressive cardiac complications and should be surgically excised when diagnosed. Selective aortography has proved to be the preferred method for diagnostic purposes.

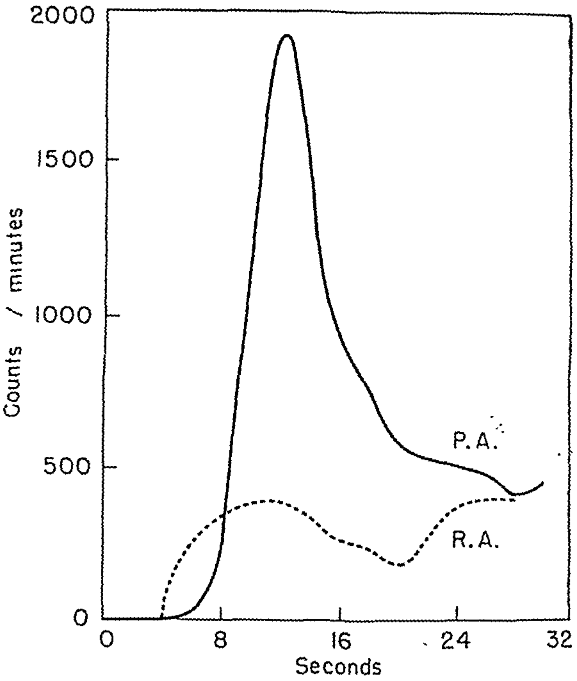

Fig. 4.—Radioactive methyl iodide curves obtained by sampling from pulmonary artery and right atrium. Note typical but delayed left-to-right shunt curve at pulmonary artery level, probable smaller left-to-right shunt at right atrial level.

A 53-year-old woman with a fistula between the left-main coronary artery and the pulmonary artery underwent operation and made a complete recovery after diagnosis had been established by selective aortography.

PALATABLE VEGETABLE-OIL MILK

Theodore W. Houk, M.D., Seattle

Because of the widespread use of diets low in saturated fats, many patients are restricted to the use of skim milk as a substitute for whole milk. Many of these same patients are instructed to take vegetable oil as a substitute for animal fat. The following recipe for a vegetable-oil milk was devised to meet the foregoing requirements and to provide the satiety value of a palatable whole milk.

Materials and Method

Five and one-half cups of cold water, 2 cups of powdered skim milk, 2⅓ oz. of vegetable oil, e. g., corn oil, cottonseed oil, or peanut oil, and between 4 and 13 drops of butter flavor, depending on individual preference, will make 1½ qt. of "milk." Place the cold water in a 2-qt., narrow-mouthed fruit jar. Stir in the powdered skim milk. Add the oil and butter flavor. Attach the beater head of a high-speed electric blender to the 2-qt. jar. Blend at high speed for seven minutes. The mixture should be stored in the refrigerator.

After several hours most of the foam will have settled. In pouring the milk the remaining foam may be held back with a tablespoon. Sometimes a little cream-like material will rise to the top of the jar, but this can be readily dispersed by shaking.

When varying the total quantity of the recipe, the blending time as well as the individual ingredients must be varied in direct proportion to the total quantity of the recipe. Individual ingredients may be varied slightly to suit the taste. The preparation contains about 23 calories per ounce.

A palatable 20% cream-like material for use in coffee can be prepared by blending 1 cup of cold water, ⅓ cup of skim milk powder, 2 oz. of vegetable oil, and 4 to 12 drops of butter flavor for two minutes in a pint jar.

PRELIMINARY COMMUNICATION

COMPARATIVE CLINICAL EVALUATION OF TWO ALKYLATING AGENTS

MANNITOL MUSTARD AND CYCLOPHOSPHAMIDE (CYTOXAN)

Rose Papac, M.D., Nicholas L. Petrakis, M.D., Fari Amini, M.D.
and
David A. Wood, M.D., San Francisco

An intensive search for agents of increased therapeutic benefit in the treatment of neoplastic disease has prompted the development of newer alkylating agents. To meet the requirement of increased clinical efficacy, it is necessary that such compounds exert more selective action and fewer side-effects and have dimished toxic properties.

On the basis of animal testing, numerous alkylating compounds demonstrate tumor-inhibiting properties which exceed that of mechlorethamin hydrochloride (nitrogen mustard). Clinical trials with two such agents form the basis of this report.

Mannitol mustard (Degranol), also called mannomustine (British Pharmacopeia) and with a chemical structure of 1-6-(dibetachloroethylamino)-1, 6-deoxy-D-mannitol dihydrochloride (fig. 1) was synthesized by Vargha and co-workers.[1] This modification of the alkylating group was introduced with the supposition that cell membranes could be readily permeated by substances, namely the sugars, which take part in cell metabolism.

Cyclophosphamide or N-N-di (beta-chlorethyl)N' O-propylenephosphoric acid ester diamide (Cytoxan, Endoxan, [fig. 1]), synthesized by Arnold and co-workers,[2] was also developed in an attempt to increase the selectivity of cytotoxic action. It was postulated that the phosphamide group might well be attacked by enzymes (e.g., phosphatases, phosphamidases) which are present in large amounts in tumor tissue, and that this group would then liberate the active betachloroethyl group at the desired site of action.

Materials and Methods

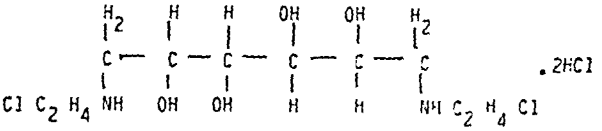
Thirty-two patients with advanced carcinomas and lymphomas have been treated with mannitol mustard since August, 1958. Thirty-one patients

---

From the Cancer Research Institute and the Department of Medicine, University of California Medical Center.

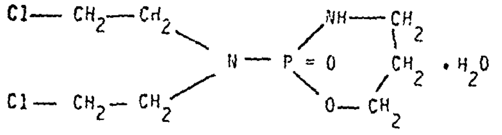
with these diseases have been treated with cyclophosphamide since January, 1959. In each group lymphomas constituted about one-half of the cases.

The clinical and hematological evaluations were carried out at weekly intervals for 6 to 10 weeks and, in most instances, monthly thereafter.



$$\underset{ClC_2H_4NH}{\overset{H_2}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{NHC_2H_4Cl}{\overset{H_2}{C}}\cdot 2HCl$$

Mannitol Mustard



Cyclophosphamide

Fig. 1.—Chemical structure of mannitol mustard (Degranol) and cyclophosphamide (Cytoxan, Endoxan).

Mannitol Mustard

Administration and Dosage.—Mannitol mustard is supplied as a white powder readily soluble in isotonic sodium chloride solution. It is administered intravenously. In some instances it was given as a single injection but more frequently in divided doses of 5 mg. per kilogram of body weight. The injections did not damage the veins. Extravasation occurred in three instances; only once did superficial ulceration develop, but it healed completely in eight weeks. Intrapleural and intraperitoneal administration of mannitol mustard were each carried out on one occasion. While the drug was well tolerated when administered in this manner, no benefit resulted in either instance.

The dose-response relationship with mannitol mustard, expressed as that dose which produced a leukopenia of 2,000-3,000 cells per cubic millimeter, is shown in figure 2. Each point on the graph represents the cumulative percentage of the total number of persons who, having received a given dose, showed such a response. These data are derived from the solid tumor and lymphoma groups combined. The median effective dose which induced such a response in 50% of the patients is 12.8 mg. per kilogram of body weight.

Side-Effects.—The most prominent side-effects of therapy with mannitol mustard were nausea and vomiting, which developed in all but six patients. In most instances this was related to the dose given; with administration of a divided dosage and the use of phenothiazine drugs, however, these effects were controlled. Total doses of 10 mg. per kilogram of body weight or less were seldom associated with gastrointestinal side-effects.

Cyclophospamide (Cytoxan)

Administration and Dosage.—Cyclophosphamide is available as a water-soluble white powder, 5 cc. of distilled water being added to 100 mg. of the powder. It is also supplied in 50-mg. tablets for oral use. Intravenous administration did not result in damage to veins. Intrapleural and intraperitoneal use were similarly well tolerated.

In three instances the drug was given as a single dose; usually it was administered in divided doses for a total dose range of from 20 to 40 mg. per kilogram of body weight, intravenously. The orally given dose ranged from 56 to 126 mg. per kilogram of body weight.

The dose-response relationship of cyclophosphamide which induced a leukopenia of 2,000-3,000 cells per cubic millimeter is shown in figure 3. With the orally administered preparation, each dose level was represented by a single patient, but with the intravenously given preparation each dose level was studied in from 1 to 12 persons. The straight-line character of this response indicates in this figure, as in the preceding one, that a normal distribution is present. The median effective dose of cyclophosphamide is 70 mg. per kilogram of body weight for the orally given preparation and 25 mg. per kilogram of body weight if given intravenously.

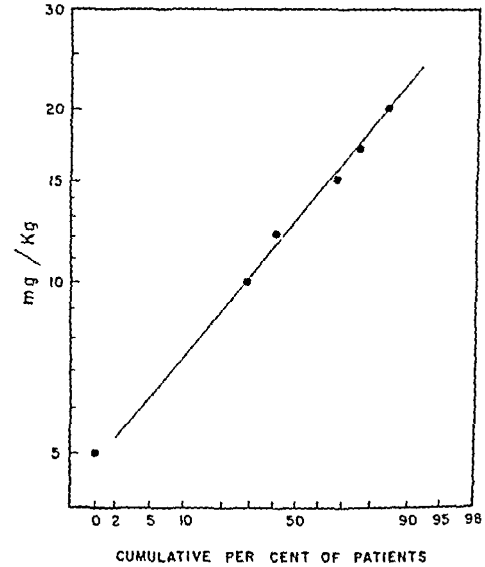


Fig. 2.—Effective doses resulting in peripheral white blood cell count of 2,000-3,000 per cubic millimeter with mannitol mustard therapy.

Side-Effects.—Nausea and vomiting developed in 13 patients treated with cyclophosphamide. These symptoms occurred in relation to the dosage of the drug which had been given and seldom developed if the daily dose was 200 mg. or less. Oral administration of the drug was not associated with gastrointestinal symptoms.

Alopecia, noted in 10 patients treated with cyclophosphamide, was the most troublesome side-effect. It was extremely severe in five patients, four women and one man. In these five instances the alopecia was diffuse; in the other patients it was patchy in distribution. Loss of axillary or pubic hair was not noted. Regrowth of hair occurred in 10 to 12 weeks.

Results

The results of therapy are summarized in tables 1 and 2. The criteria applied are those defined by Galton and co-workers.[3] Benefit refers to absence of signs or symptoms of disease for at least six months; effect refers to improvement of lesser extent or duration; no effect implies that the drug was therapeutically ineffective in terms of objective manifestations of disease.

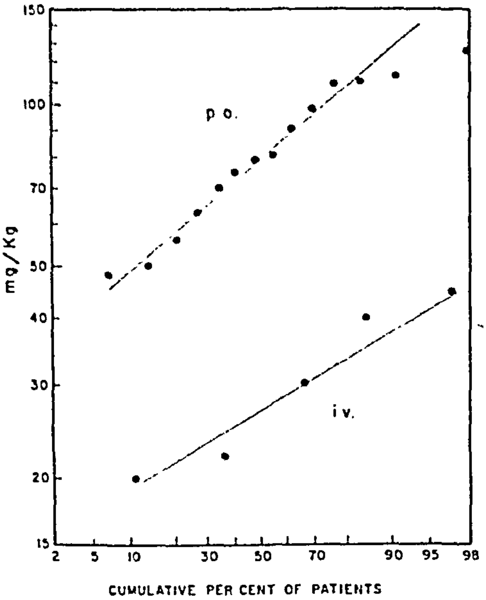

Fig. 3.—Effective doses resulting in peripheral white blood cell count of 2,000-3,000 per cubic millimeter with cyclophosphamide therapy.

Mannitol Mustard Therapy.—Three patients with lymphosarcoma derived substantial benefit from mannitol mustard therapy, one being free from clinical evidence of disease for 12 months. Below, a summary of this case is presented:

Report of a Case: A 73-year-old retired baker developed painless cervical lymphadenopathy on the left side in October, 1956. A biopsy specimen taken in February, 1957, revealed the presence of lymphosarcoma. Radiotherapy to the cervical region resulted in disappearance of the enlarged lymph node. In August, 1958, recurrent cervical masses and generalized lymphadenopathy with hepatosplenomegaly were noted. Peripheral blood cell count and bone marrow findings were within normal limits. An x-ray of the chest revealed mediastinal and hilar masses. On Nov. 18, 1958, the patient received 10 mg. per kilogram of body weight of mannitol mustard intravenously. Within a week marked regression of peripheral lymphadenopathy was evident, and within eight weeks there was complete regression of the enlarged lymph nodes as well as reduction in hepatosplenomegaly. One year later the patient showed no evidence of recurrence.

TABLE 1.—*Results of Treatment with Mannitol Mustard in Thirty-two Patients*

Diagnosis	No. of Patients	Results		
		Benefit	Some Effects	No Effect
Lymphosarcoma	6	3	3	
Reticulum cell sarcoma	4		3	1
Hodgkin's disease	3		3	
Chronic granulocytic leukemia	1		1

Cyclophosphamide Therapy.—Three patients with lymphoma obtained significant benefit from cyclophosphamide treatment. Below, a brief summary of one of these cases is presented:

Report of a Case: A 57-year-old machine-shop worker noted cervical enlargement on the left in May, 1958. In December, 1958, generalized lymphadenopathy was present and an inguinal node biopsy specimen revealed the presence of lymphosarcoma. An x-ray of the chest demonstrated hilar masses on the left. From April 29, 1959, to May 6, 1959, cyclophosphamide, 40 mg. per kilogram of body weight, was given. Regression of lymphadenopathy occurred four weeks after the last treatment and has persisted to the present time, a period of seven months.

In two patients with ovarian carcinoma suppression of ascites and regression of the palpable tumor masses occurred as a consequence of cyclophosphamide therapy.

In the patient with acute leukemia, the peripheral white blood cell count was reduced from 70,000 to 15,000 per cubic millimeter, with clinical improvement for a period of three weeks. This result, however, is not unique among alkylating agents, for Israels[4] described chlorambucil-induced remission in acute leukemia and Bierman advocated the use of busulfan (Myleran) in this disease. Recently, Bartlow[5] reported that mannitol mustard therapy occasionally achieved a similar response.

Hematopoietic Effects.—Maximum hematopoietic depression occurred from 30 to 45 days after completion of mannitol mustard therapy, with a return to pretreatment values 45 to 60 days later. Lymphocyte depression developed during the period of drug administration and persisted for 7 to 10 days. Granulocyte depression paralleled the peripheral white blood cell count change, occurring 30 to 45 days after therapy. The period of maximum platelet depression was also coincident with the time of leukopenia and frequently was relatively severe. The drug was not given to any patients with known thrombocytopenia prior to treatment. No leukopenia occurred in two cases of lymphoma in which therapeutic benefit occurred.

Intravenous administration of cyclophosphamide generally resulted in a depression of the peripheral blood elements in from 3 to 14 days after completion of treatment, with a return to prior levels in 7 to 10 days. Lymphopenia developed during therapy and persisted until the return of the peripheral white blood cell count to former levels. With oral administration of the drug, the development of lymphopenia was gradual and irregular. When the dose of cyclophosphamide was less than 50 mg. daily, a rise in lymphocytes occurred. Granulocytopenia was seldom remarkable, although in one instance the total granulocyte count fell to 10% of its original level. Since the total dose in this patient was 60 mg. per kilogram of body weight, given orally, the correlation between the development of granulocytopenia and the quantity of drug administered was not marked. Platelet depression was not significant in most instances. In one patient who received a total dose of 109 mg. per kilogram of body weight orally over an 80-day interval, the platelet count was reduced from 200,000 to 85,000 per cubic millimeter. In another patient whose total orally given dose was 113 mg. per kilogram of body weight over an 86-day interval, the platelet count dropped from 400,000 to 120,000 per cubic millimeter. Even with doses producing severe leukopenia, thrombocytopenia was not generally noted.

Comment

From our data it is not possible to state the therapeutic superiority of either mannitol mustard or cyclophosphamide. The cytotoxic effect of each is most notable in that group of human tumors which is generally responsive to the alkylating drugs. There are definite hematological differences in the effects of these compounds which are of interest. These are the differing time interval of marrow depression and the relative degree of thrombocytopenia.

The fact that the time interval of marrow depression varies suggests that the drugs exert their effect on cellular division at different phases of the mitotic cycle, or that they induce a varying degree of prolongation of the mitotic process at the same phase of interruption. Assuming that cellular division is affected at different phases of mitosis by each of these agents, it may be that mannitol mustard reduces the frequency of cell division because of its prolonged depressant effect on hematopoietic elements. This could be accomplished by lengthening of the intermitotic interval, as suggested by Elson[6] in his analysis of the effect of busulfan on the hematopoietic tissue of rats. It could then be postulated that the effect of cyclophosphamide is a destructive interference with cellular division at some other vulnerable phase, presumably early in mitosis or in the immediate premitotic interval.

It is also conceivable that the differences in hematological depression represent variations in quantitative effect. Rosin and Goldhaber[7] have demonstrated that ethyl carbamate (Urethane) induces prolongation of the mitotic process of both normal and leukemic myelocytes in rodents. Perhaps this phenomenon occurs with alkylating agents in general, being more prominent with such agents as mannitol mustard.

Since the spectrum of tumors responding to the use of these drugs is extremely similar, it is probable that the variation in cellular suppression does not represent increased specificity but possibly differing vulnerability, which depends on the proliferative activity of affected cell types.

Since increased specificity cannot be attributed to these agents, their clinical usefulness depends on whether the incidence of fewer toxic properties and side-effects was due to their use. With mannitol mustard therapy there is no evidence of such an advantage. With the use of cyclophosphamide, there is a relative lack of thrombocytopenia and a diminution in gastrointestinal side-effects, so that it may offer therapeutic advantages over other alkylating agents.

The development of newer alkylating agents has provided additional fundamental information to the biochemist and biologist and continues to stimulate investigations directed toward improvement of therapy of human neoplastic disease.

Summary

Mannitol mustard (mannomustine, Degranol) was administered to 32 patients with malignant disease and cyclophosphamide (Cytoxan, Endoxan) to 31 patients with various neoplasms. The best results with each drug were achieved in patients with lymphosarcoma, in whom striking remission occurred in three instances after administration of mannitol mustard and on three occasions with cyclophosphamide therapy.

With intravenous administration, both agents induced nausea and vomiting which was directly related to the dose given. With oral cyclophosphamide therapy this did not occur. Alopecia developed in one-third of the patients treated with cyclophosphamide.

Mannitol mustard appears to offer no particular therapeutic advantage over other alkylating agents. With cyclophosphamide therapy, the relative lack of thrombocytopenia and the absence of gastrointestinal symptoms with oral therapy suggest that it is a useful agent. A comparative evaluation of this agent with such drugs as triethylene melamine or chlorambucil is necessary to determine whether it is superior.

Drs. Calvin Zippin, Jean C. Sabine, and William M. Silliphant aided in the preparation of this paper, and Dr. William A. Atchley assisted in the medical care of the patients. Carla Schultz, Mary Davis, Marie Doherty, Rose Lee, and Lillian Kwok provided valuable technical assistance.

These studies were supported in part by a research grant from the National Cancer Institute, Public Health Service, Bethesda, Md., and in part by Cancer Research Funds of the University of California.

The mannitol mustard used in this study was supplied by courtesy of Dr. T. Phillip Waalkes, Cancer Chemotherapy Division of the National Cancer Institute, National Institutes of Health; the cyclophosphamide used in this study was supplied as Cytoxan by courtesy of Dr. James M. Tuholski, Mead Johnson & Company, Evansville 21, Ind.

STEROID THERAPY IN ASTHMA.—The value of corticotropin and corticoids in the short-term treatment of asthma is accepted. Their use does not replace standard treatment with broncho-dilators nor should it prevent a careful search for underlying etiological factors. Long-term treatment is sometimes of value, especially for older patients: it should only be employed in those whose asthma cannot be controlled by other means. . . . There are certain circumstances in which the use of steroids is contra-indicated: these include pulmonary tuberculosis and peptic ulcer, which should be excluded before treatment is commenced. Steps can be taken to minimize the risks in these conditions if the use of steroids is considered necessary to save life as in severe status [asthmaticus]; in pulmonary tuberculosis by simultaneous treatment with appropriate antibiotics; in peptic ulcer with alkalis. If there is evidence of cor pulmonale, the use of corticotropin or salt-retaining corticoids may precipitate failure, but the newer steroid preparations with diminished salt-retaining properties may be given cautiously. Hypertension may be increased. In diabetes mellitus it may be necessary to adjust the dosage of insulin. Long-term treatment of asthma with corticoids is rarely justified if these conditions are present.—R. S. B. Pearson, D.M., F. R. C. BIOSYNTHESIS OF RIBONUCLEIC ACIDS

RIBONUCLEIC acids (RNA) appear to play an important, if not critical, role in biosynthesis of macromolecules. In contrast to deoxyribonucleic acid (DNA) which is found solely in the nucleus, RNA is found primarily in the cytoplasm and in some manner appears to communicate the hereditary message of the chromosomes to the synthetic machinery of the cytoplasm. For this reason the elucidation of the mechanism of formation of RNA is of crucial importance in the understanding of cell physiology.

The class of substances grouped together under the generic term RNA as yet has not been resolved into constituents recognizable as individual molecular species. In spite of this difficulty, and of the fact that the structure and function of RNA still are not clearly established, a substantial body of information has been collected concerning biosynthetic pathways of RNA.

Early in the application of isotopic tracers, experiments with P^{32} (as inorganic phosphate)[1] and N^{15} (as ammonium citrate)[2] indicated that RNA was constantly synthesized and degraded in the adult mammal. The few N^{15}-labeled purines and pyrimidines which were tested as precursors in these feeding experiments were not, however, detected in RNA. Later it was shown, with the use of C^{14}-labeled compounds which could be detected at greater dilution than the N^{15} isotope, that purines and pyrimidine nucleosides are incorporated into RNA in the intact animal.[3] In vivo experiments with nucleotides indicated that they were poorer precursors than were the free bases, but in enzyme preparations derived from disrupted cells the reverse was found to be true.

By the time this was established, the important discovery of the enzyme polynucleotide phosphorylase had been made by Grunberg-Manago and Ochoa.[4] This enzyme, found in a variety of microorganisms and now highly purified, catalyzes the formation of RNA-like polynucleotides from the nucleoside dipurine or pyrimidine base, as shown, with R the ribose moiety of the nucleotide and P a phosphoryl group. The attachment to the ribose is on the number 5 carbon atom of the sugar:

$$n\,B - R - P - P \rightleftharpoons (B\text{-}R\text{-}P)n + n\,P$$

In this reaction one phosphate group is split from each nucleoside diphosphate as the phosphodiester bond of the polynucleotide is formed. The enzyme requires both Mg^{++} and a small amount of a polyribonucleotide or oligoribonucleotide present as a "primer." When a mixture of nucleoside diphosphates (e. g., adenosine, guanosine, cytidine, and uridine diphosphates) is used as substrate, the product is a mixed co-polymer which resembles RNA. If the enzyme acts on a single nucleoside diphosphate, however, the product is a homopolymer consisting of only one type of sub unit. These homopolymers have served as important model substances even though they do not exist naturally.

Polynucleotide phosphorylase has been found not only in bacteria but in higher plants, and indirect evidence of its existence in guinea pig liver cell nuclei has been obtained. There is no certainty that all (or even part) of RNA is formed by this pathway. The possibility remains that the enzyme, as is the case with glycogen phosphorylase, is concerned primarily with the breakdown of RNA rather than with synthesis of the macromolecule. Evidence has accumulated recently which indicates that RNA can be formed from the nucleoside triphosphate with the elimination of inorganic pyrophosphate.

The RNA found in the nonsedimentable fraction (105,000 × g) of broken rat liver cells (S-RNA) can accept activated amino acids as one of the steps leading to protein synthesis. This S-RNA only serves this function when a terminal adenosine phosphate residue is present. If, during isolation, the terminal adenosine phosphate residue is lost, it can be restored enzymatically by a reaction with adenosine triphosphate, coupling adenosine monophosphate to the RNA and eliminating inorganic pyrophosphate. While this type of reaction appears only to lengthen preexisting RNA polymers there is evidence that other systems (e. g., rat liver cell nuclei or cytoplasm of embryonic chick heart or liver), do form new RNA from mixtures of the nucleoside triphosphates. No report has yet appeared of net biosynthesis of RNA from nucleoside triphosphates in cell-free systems such as can be easily demonstrated with polynucleotide phosphorylase. It would seem only a matter of time, however, before polynucleotide pyrophosphorylase, or ribonucleic acid polymerase, will be isolated.

VIA PADUA

Venice, Milan, Verona, and Padua, the ancient cities of northern Italy, are famous not only for their beauty but also for their great achievements in the past. Currently they are delightful centers for tourism and historical studies. Padua claims the lion's share of medieval and Renaissance heritage, particularly in the evolution of medicine and anatomy. The University of Padua was outstanding in the emancipation of science from medieval fetters and was noteworthy for its zealous protection of freedom of thought. Venice, the most brilliant commercial city in the world during the 15th century, has lost none of its fascination for the 1960 tourist, even though it appears to be as busy as Times Square on New Year's Eve, with as high a percentage of American faces. Milan is the 20th-century commercial center that is the proud possessor of Leonardo da Vinci's "Last Supper,' 'painted in the master's own medium, on the north wall of the refectory of Santa Maria delle Grazie. Verona, the southern gateway from the Brenner Pass, was the residence in the sixth century of the Ostrogoth king Theodoric, the sovereign who urged that the monks of his realm read Hippocrates and Galen.

But it is Padua, some of her streets and a select few of her illustrious citizens of science, that claims particular attention. As one enters the modern city, an occasional student will be wearing a grey felt hat with a long, pointed peak and a jauntily placed tall feather. This is the mark of a medical student. A collector of headgear will have no difficulty in procuring a sample in one of the town shops. The University of Padua was founded in 1228 A. D. by a band of disgruntled students from the school in Bologna. It owed its spectacular rise in large measure to the learned physician, Pietro d'Abano (1250-1315). As a professor of medicine and author of a highly controversial book he struggled to reconcile the views of the medieval scholastics with the original writings of the Greeks and to dispel the contradictions which were hampering the progress of medicine.

No Via d'Abano commemorates him, but Pietro d'Abano's memory is perpetuated by his statue in one of the city squares. A number of other famous scientists of Padua, however, were honored by streets which were named after them. Thus the Via Fabrizio d'Aquapendente is in the outskirts of the town. Fabricius (1537-1619), the distinguished surgeon and anatomist, attracted students from all over Europe and himself arranged for the building of the famous Anatomical Amphitheater that can be visited today in the municipal museum maintained in a portion of the old university. Only a few blocks removed is the Via Vesalius, which honors the great anatomist Andreas Vesalius (1514-1564) whose *De humani corporis fabrica* revolutionized the study of anatomy. Another street in Padua is the Via Malpighi. Marcello Malpighi (1628-1694), one of the earliest microscopists, added the evidence for the one remaining question in Harvey's concept of the circulation of blood, namely, the discovery of the capillaries. This contribution was made but four years after Harvey's death. Prior to this observation, Harvey assumed the existence of such anastomoses, but was unable to demonstrate them because he worked with the naked eye.

The Via del Falloppio commemorates the famous pupil and successor of Vesalius, Gabriele Falloppio (1523-62). The first descriptions of numerous structures have been attributed to him, the chorda tympani, the semicircular canals, the sphenoid sinus, the round ligaments, the oviducts which bear his name; the trigeminal, ocular, and glossopharyngeal nerves, the circular folds of the small intestine, known as the valves of Kerckring, and the inguinal band, known as Poupart's ligament. Furthermore, he described the generative organs of the male and the female, the ocular muscles, and the cerebral nerves and named the vagina and the placenta. These are amazing accomplishments for one who lived only 40 years.

As streets in Boston are wont to do, Via del Falloppio changes its name to Via Morgagni before it reaches the new university. Giovanni Battista Morgagni (1682-1771) is famed for his publication of *De sedibus et causis morborum*, the first comprehensive treatise on pathological anatomy. A short distance from the Via del Falloppio is the Via Galileo Galilei, named for the great astronomer, mathematician, and physicist who revolutionized Renaissance science and introduced modern concepts into scientific thought. Galileo held the chair of mathematics in Padua from 1592 to 1610.

After witnessing such a distribution of honors among great scientists, the student of medical history feels somewhat disappointed to discover that William Harvey, the most famous man ever to have studied at the University of Padua, had been neglected by the Senatus Populusque Padovensis when they assigned street names after illustrious residents. Harvey came to Padua, then the leading center of anatomic studies in the world, because of his desire to learn from Fabricius of Aquapendente. To this teacher Harvey owed much, for his conception of the circulation of the blood was based in part on Fabricius' demonstration of the valves in the veins.

2. Castiglioni, A., History of Medicine, New York, Alfred A. Knopf, Inc., 1947.

Near the center of the town a plaque on a small house calls attention to the fact that Dante Alighieri, a presumed acquaintance of Pietro d'Abano, "once lived here." The Via Dante is two short blocks removed from the poet's house.

A portrait gallery in one wing of the municipal museum contains the portraits of many medieval and renaissance luminaries, including all those scientists described in this editorial. If Harvey was overlooked by the Commission for the Naming of City Streets, the oversight is partially balanced by a full-length portrait in the gallery.

As one leaves the Anatomical Amphitheater and the small art gallery through the courtyard, two symbols are prominently visible high on the opposite wall. One is the seal of the city of Padua. To the right of the seal, ineffectively covered at the present time with neutral paint, is a reminder of the Fascist regime. "Il Duce" is plainly legible in the bright sun.

If one or more physicians or anatomists of Padua has been overlooked, a notation to this effect would be welcome. Such an omission might serve as a happy excuse to return to northern Italy and to wander once more along the Via Vesalius or Via del Falloppio. Should this opportunity present prompt action, the traveler might wish to take along at least two books to replace an out-of-date Baedeker. Fielding's Guide to Europe[1] contains helpful general information, while Castiglioni's "History of Medicine"[2] is a volume filled with medical lore.

LEARNING MEDICINE

[Jean Fernel] judged the surest and quickest way of learning medicine was this. After a thorough grounding in the principles and elements of philosophy, to learn straightway from some terse and well-written medical precis such details as have to be known of the nature of the human body; then to master the flavours, powers and virtues of medicaments simple and compound; and then to learn to distinguish the signs and symptoms of the several diseases and their causes, and to gather these together, as a store within the memory; then, finally, to follow, long and attentively, the art of practice of some elderly practitioner, capable and experienced in treatment, and to observe in the sick patients themselves what you have read in the books and heard in the lecture-room. He held that there was much in the theoretical part of medicine which could not be explained truly, nor understood, except by way of long practice and experience. He judged that no one can get through on books alone, numerous although books are. The best instructors in medicine were in his view practice and experience; they clear up the obscure and equivocal which so embarrass and obstruct the beginner, and they fortify him. So it was that he dissented from growing grey in following theory, as in fact most do. Rather should one go forward early into the art of practice, since it is of all teachers the best, but in so doing take for guide an old physician of experience.—C. Sherrington, The Endeavour of Jean Fernel, New York, Cambridge University Press, 1946, page 157.

JEAN FERNEL (1485-1557)

Rising at about 4 o'clock every morning he went from his bedroom down to his library. There he looked over some page of text of the ancient masters, either because he did not feel satisfied about it, or that he did not sufficiently remember it, or in order to add to it something by way of commentary. After that, with the coming of daylight, he went out to his public lectures, or to visit his patients. Then it was that urines were brought to him and he would inspect them. What he opined about them he made known, and ordered treatment according to the cause of the disease, and the constitution of the patient, as far as he could gather those by conjecture.

Back again for his meal, he retired to his library while dinner was being prepared, and when dinner was over retired thither again, until the time for resuming his "visits." It was the same before supper while the table was being got ready. After supper he returned to his study and did not finally retire until 11 o'clock, by which time heaviness came on, and drove him to go up to sleep. This was his way of work and life for more than thirty years. Through all that time he kept up this programme of study. Amusement, whether of body or mind, he held as nothing in comparison with the study and practice of the art of medicine. There was no hour of his life which was not given to duty private or public, professional or domestic. If perchance he invited a guest to sup or to dine, he did not consider it wrong or discourteous to excuse himself soon after the meal, for the sake of his studies.—C. Sherrington, The Endeavour of Jean Fernel, New York, Cambridge University Press, 1946, pages 168-169.

BLADDER AND KIDNEYS

I say therefore that according to the opinion of the authorities the cause from which a stone arises in the bladder is a thick and viscous humor. And the indications by which it is manifested are many. For among these there is the fact that the urine issues from the bladder white and thin with sandy excrement, and with difficulty and severe pain in the pubic region; and a boy holds his yard with his hands and rubs it and works with it and often the yard is erect and the anus protrudes; and in drawing the hand over the bladder it feels hard.—The Surgery of Theodoric, vol. 2, books 3 and 4, translated by E. Campbell, M.D., and J. Colton, M.A., New York, Appleton-Century-Crofts, Inc., 1960, pp. 119-120.

THE PRESIDENT'S PAGE

A MONTHLY MESSAGE

In a dramatic, last-minute effort to win some kind of Forand-type legislation in the current session of Congress, officials of the AFL-CIO have launched a scurrilous assault on the American Medical Association.

With little regard for the truth, its political education arm, COPE, has attacked the good name of the A. M. A., its 178,000 member-physicians, and its affiliated state and county medical associations.

In a political memorandum a list of sweeping charges has been circulated with the intention of showing that the A. M. A. historically has opposed beneficial health measures. The memorandum suggests that A. M. A. disapproval of Forand-type legislation is ridiculous and without merit.

Let me cite briefly a few of the COPE allegations.

The memo begins by contending that "a generation ago, the A. M. A. opposed the requirement that all cases of tuberculosis be reported to a public authority—the foundation for tuberculosis control methods." This accusation is completely unfounded. The A. M. A. actually has advocated the reporting of all cases of tuberculosis to a public authority since 1899 and as recently as 1944.

COPE then charges that the A. M. A. was against smallpox vaccination, immunization against diphtheria, venereal disease clinics, tuberculosis and cancer clinics, blood banks, Medicare, and various other items. It alleges that the A. M. A. has opposed, and fought, them all. The facts are these:

The A. M. A. has campaigned for compulsory smallpox vaccination since 1863.

The A. M. A. has cooperated with public health agencies for the prevention of contagious diseases for more than 80 years. It has never attacked provisions for immunization against diphtheria by public health agencies.

Official A. M. A. actions on venereal diseases can be traced back to 1874, and it is categorically untrue that the Association was against the creation of public venereal disease clinics.

The charge that the A. M. A. opposed the creation of free diagnostic centers for tuberculosis and cancer also is utterly without foundation. Our cooperation in these matters is a recorded fact.

The allegation that the A. M. A. fought the Red Cross plan to set up a nationwide reserve of civilian blood banks is a gross distortion of the truth. While we may have differed on method, we supported the objectives—immediately and completely. Furthermore, I add this personal note: Nine years prior to the Red Cross efforts my wife and I made possible the establishment of the fourth blood bank in America and the first in Florida.

COPE implies that the A. M. A. opposed government medical care to dependents of men in the armed forces. The facts are that the A. M. A. did not oppose Medicare. In fact, the House of Delegates when expounding its policy on Medicare specifically stated "the policy advocated should not in any way be construed as one of opposition by the A. M. A. to dependent medical care . . . the position recommended refers only to the manner it should be provided, for it is determined by Congress to be a proper emolument of military service."

Contrary to COPE, the A. M. A. is busy every day of the year in hundreds of projects for the public and for medical science. It continuously emphasizes and promotes all positive programs in behalf of the American public. For an influential labor organization, and its "educational" arm, to attempt to destroy the American public's confidence in the world's greatest medical organization is most contemptible.

Louis M. Orr, M.D.
Orlando, Fla.

ORGANIZATION SECTION

THE NEW MEDICAL DISCIPLINARY COMMITTEE

In February, 1959, the Board of Trustees formed a new committee to inquire into the status of medical discipline in the United States. Dr. Raymond McKeown, a member of the Board, was named Chairman of the new Committee and appointed as members were Drs. James H. Berge, Paul G. Henley, H. Thomas McGuire, and E. G. Shelley.

The Committee soon felt the need for consultation with persons experienced in matters of medical discipline and two such men have accepted appointments to aid the Committee. They are Dr. Stiles D. Ezell, associate secretary of the federation of state licensing boards, and Dr. Harold E. Jervey Jr., the federation's president-elect. At the most recent meeting of the Board of Trustees, Dr. Louis A. Buie was named to the Committee.

The Committee is authorized to investigate, with the assistance of the Law Division, the adequacy of disciplinary rules, laws, and procedures as applied to medical practice and licensure and medical society membership, and the degree to which efficient discipline is maintained among medical practitioners, in the interests of the public and the medical profession.

Initial Activities

In pursuit of these objectives, the Committee has agreed on the following activities: (1) To examine the standards, procedures, and rules of medical societies and boards which deal with professional discipline and to evaluate the adequacy of the existing systems of medical discipline within the perspective of practical, ethical, and legal considerations. (2) To summarize and evaluate existing state laws and medical licensure board regulations affecting medical discipline; the adequacy of such laws and regulations; and the extent to which state licensure boards are equipped to or do maintain satisfactory medical discipline through revocation or suspension of medical licenses. (3) To study the extent to which discipline is maintained by medical staffs in hospitals throughout the United States. (4) To determine whether the A. M. A. could or should become more active in guidance and participation in matters relating to medical discipline; and, if an affirmative finding is made, to recommend the establishment of appropriate mechanisms and procedures to carry out such participation efficiently. (5) To conduct fact-finding surveys and field investigations, through regional or sectional studies, as a basis for reporting on the problems relating to medical discipline and recommending appropriate measures to improve the over-all mechanism of equitable medical discipline in the interests of the public and the profession; and (6) To recommend and draft, if necessary, on the basis of results of thorough studies and investigations, new legislation or amendments to existing legislation or to recommend, if necessary, additional procedures for medical societies in order that the quality of patient care may be improved by maintaining adequate standards of medical discipline.

Medical Disciplinary Committee Report

Three separate but related courses of action have been instituted by the Committee in the course of its year's activity in this field.

First, it has polled by mail the executive secretaries of all the state and some of the larger county medical societies as well as the secretaries of all state boards of medical examiners for opinions and suggestions relative to its area of interest.

Second, it has initiated a series of personal visits by members of the staff of the Law Division to state medical society and licensure board officials who are close to the matter of discipline.

And last, the Committee has so located its meetings geographically that it has been able to meet with representatives of regional areas in communal discussion of matters relating to medical discipline. Two such meetings have been held to date; the first was in Denver on July 24 and the second in Atlanta on Nov. 16. More are planned for the future.

Special Interests

In addition to its primary interests (to ascertain if disciplinary procedures exist and are used) a secondary Committee interest in certain ethical and legal matters has developed. Some of these were suggested by the members themselves at the organizational session; others were developed in the regional discussions. They include:

—The allegation that some physicians overcharge insurance companies or perpetrate fraud in the presentation of insurance claims.

—The allegation that proper disciplinary procedures do not follow convictions of physicians for various crimes, criminal negligence in practice, and gross incompetence.

—The contention that state boards of medical examiners have neither the funds nor the staff to investigate complaints against physicians properly.

–The belief that liaison between state boards is often faulty or lacking in the transmission of information on the suspension or revocation of licenses.

Although the Committee has mailed queries to many state and county society officials as well as secretaries of examining boards, it feels that personal contact will provide better insight into the problems that exist. Conducting regional sessions with invited guests is one method being used to provide this personal approach. Another is the series of state visits being undertaken by members of the staff of the Law Division. About one-fifth of the states have been visited to date.

Despite its other investigative operations, the Medical Disciplinary Committee is also anxious to hear from individual physicians who would like to make comments or recommendations concerning the Committee's work. Such comments should be sent to the Committee's secretary, Mr. C. Joseph Stetler, 535 N. Dearborn St., Chicago 10. The Chairman has pointed out, however, that the Committee is interested in individual cases only as they illustrate malfunctions of present procedures or point up a breach in disciplinary coverage. The Committee has neither the authority nor the desire to adjudicate specific problems in the disciplinary field.

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

FOREIGN MEDICAL GRADUATES OTHER THAN INTERNS AND RESIDENTS

The present policy of the Council on Medical Education and Hospitals and the American Hospital Association regarding Educational Council for Foreign Medical Graduates (ECFMG) certification for foreign medical graduates serving as interns or residents is based on a fundamental concern for the welfare of patients. Any foreign medical graduate engaging in patient-care activities should be expected to demonstrate acceptable professional qualifications even though not appointed formally as an intern or a resident in a program under the purview of this Council.

Those physicians engaged in whole or in part in programs approved as internships or residencies will be considered as interns or residents even though appointed for administrative purposes as fellows, trainees, or by other title.

Those special training opportunities beyond the internship which exist mostly in university hospitals as distinctly separate programs from residencies are not subject to Council review or approval; however, such experience is often creditable toward specialty board certification. Eligibility for certification at a future date may hinge upon the ECFMG certification of the individual foreign medical graduate, even though the training was otherwise acceptable to a specialty board.

Directors of individual programs as well as administrators of national or local foundations, organizations, and agencies which award training or research grants to foreign medical graduates are morally responsible for assuring that such trainees, if engaging in patient-care activities in hospitals or clinics, have been qualified by ECFMG certification.

GOVERNMENT SERVICES

PUBLIC HEALTH SERVICE

Ad Hoc Committee.—An ad hoc committee was appointed to develop principles for community-wide health facility planning. It is sponsored by the Public Health Service and the American Hospital Association, and will be headed by Mr. George Bugbee, president of the Health Information Foundation, New York City. One of the principal functions of the committee will be to establish authoritative guide lines for area planning groups in developing plans for improved hospital services and facilities, especially in metropolitan areas. Other major objectives set for the committee are the development of principles to be followed in the organization and composition of area planning groups and steps which should be taken to assure the acceptance of a planning organization as the authoritative central hospital planning agency of the community. According to PHS Surgeon General Leroy Burney the development of more hospital planning groups is essential if we are to make progress in solving the many problems now facing hospitals, particularly in the urban and metropolitan areas. Some of these problems include spiraling hospital costs and the growing obsolescence of older institutions.

Members of the committee, in addition to Mr. Bugbee, are Mr. J. Milo Anderson, administrator, Strong Memorial Hospital, University of Rochester, Rochester, N. Y.; Mr. Ray E. Brown, superintendent, University of Chicago Clinics, Chicago; Mr. Gordon Cumming, chief of the bureau of hospitals, California Department of Public Health, Berkeley, Calif.; Dr. Jack C. Haldeman, assistant surgeon general and chief, division of hospital and medical facilities, Public Health Service; Mr. John R. Mannix, executive vice-president, Blue Cross of Northeast Ohio, Cleveland, Ohio; Dr. Rayden C. Nicholson, executive director, Hospital Council of Greater New York, New York; Mr. Vincent Otis, director, division of hospital and related services, Wisconsin State Board of Health, Madison, Wis.; Mr. Delbert L. Pugh, executive director, Columbus Hospital Federation, Columbus, Ohio; Mr. Hiram Sibley, secretary, council on planning, financing, and prepayment, American Hospital Association, Chicago; Mr. Paul Snelson, director, hospital division, Oklahoma Department of Health, Oklahoma City; Mr. James J. Souder, project director, collaborative research in hospital planning, New York City; Dr. Ray E. Trussell, executive director, School of Public Health and Administrative Medicine, Columbia University, New York City; Dr. David B. Wilson, director, University Hospital, University of Mississippi, Jackson, Miss.; and Dr. Willard A. Wright, Chairman, Committee on Medical and Related Facilities, American Medical Association, Williston, N. D.

Quarantine Procedures.—Quarantine procedures at international airports have been simplified. The principal change is elimination of preliminary group clearance. Under the new procedures, if the aircraft captain certifies that no illness has been observed during flight, only individual clearance of passengers is required. Prior to adoption of these new procedures, both group clearance and individual clearance were required. Group clearance had been maintained to prevent spread of disease by travelers who may have symptoms of quarantinable illness on arrival. If such illness is reported aboard a plane, or there is an unusual disease problem in the country where the flight originates, the strictest quarantine procedures will be applied. The only major airport where passengers will be kept in groups is Miami, Fla., where the means of access to quarantine facilities makes the change impractical. Additional streamlining of quarantine procedures is being made wherever possible. The new procedures stress the responsibility of travelers for maintaining valid immunization records and the responsibility of airlines for reporting illness observed among passengers.

In preparation for travel abroad where a passport is required, prospective passengers receive the form for the international certificates of vaccination with the passport application. This form may also be obtained from travel agencies, transportation companies, local and state health departments, and offices of the Public Health Service, Department of Health, Education, and Welfare.

Sanitary Requirements.—Ships on the Great Lakes and St. Lawrence Seaway will be prohibited from polluting the water supplies of port communities by a ruling which requires ships either to avoid the areas from which communities draw their water supplies or to adopt specific safeguards against pollution. Community water purification systems are geared to deal with a uniform flow of pollutants. Any sudden and unexpected increase in pollutants could overload the system and some impurities might get into the drinking water supply before corrective measures could be taken. With more vessels using these waterways (tonnage increased about 80% in the seaway's first season) this could easily occur. Each ship captain, on entering the seaway at Montreal, will be given charts of the delimited areas of all the ports on his route. Ships entering these delimited areas must follow one of several methods of controlling pollution while there. They can (1) treat their waste material by an approved sewage treatment device, (2) store it in suitable retention tanks until they leave the area, (3) empty it into the port's sanitary sewer system, (4) adopt any other method of handling their waste which meets the approval of both the local authorities and the Public Health Service, and (5) unload garbage on the dock only if there are adequate facilities for handling it.

Vital Statistics.—Heart disease, cancer, apoplectic strokes, and accidents accounted for 71% of all deaths in 1958, according to the Office of Vital Statistics. The 1,647,886 deaths that occurred in 1958 gave the nation a death rate of 9.5 per 1,000 population, compared to a rate of 9.6 in 1957. The death rates for heart disease and cancer in 1958, 367.9 and 146.9 respectively, were slightly lower than the comparable rates in 1957, 369.6 and 148.7. The rate for vascular lesions remained about the same. The death rate for accidents, 52.3, was almost 7% lower than the rate of 56.0 in 1957. Chiefly as a result of the influenza epidemic of 1957-1958, the toll of deaths from influenza and pneumonia remained high in 1958—57,439 deaths, or a death rate of 33.2 per 100,000 population. The death rate for these conditions in 1958, the second highest in 10 years, was more than 7% lower than the rate of 35.8 recorded in 1957.

MEDICAL NEWS

COLORADO

Change of Address.—Effective Feb. 15, the new address of the Colorado State Department of Public Welfare is as follows: Colorado State Department of Public Welfare, State Services Building, 1525 Sherman St., Denver 3. Attention: Library.

Anesthesiologists Establish Student Award.—The Colorado Society of Anesthesiologists at the annual meeting of Feb. 20 elected the following officers for the coming year: president, Dr. Norma B. Bowles, Colorado Springs; vice-president, Dr. Rex D. Nash, Colorado Springs; president-elect, Dr. John C. McAfee, Denver; secretary-treasurer, Dr. Charles B. McCrory, 385 Forest St., Denver 20; assistant secretary-treasurer, Dr. Donald W. Stein, Denver. At this same meeting the society voted to establish an award at the University of Colorado School of Medicine for the senior student showing "outstanding interest in the field of anesthesia." The award is to be given at the annual awards convocation and is to be known as the C. Walter Metz Award of the Colorado Society of Anesthesiologists.

ILLINOIS

Changes in Admission Requirements.—Three changes in requirements for admission to the University of Illinois College of Medicine have been approved by the board of trustees. One change is that the prospective medical student will be required to follow a sequence of study in one subject matter area. Also, the student will have to present 94 semester hours for admission instead of the current 88. These six additional hours are to be in advanced courses toward which the student must work during his first two years as an undergraduate. The final change involves the study of nuclear physics as part of an already current physics requirement. The six-hour sequence does not have to be in a scientific area. The student will have a free hand in choosing his area of study. These changes become effective in September, 1962.

Chicago

Dr. Thorek Named Editor.—Dr. Philip Thorek, Chicago, was named editor-in-chief of the *Journal of the International College of Surgeons*. Dr. Thorek succeeds his father, the late Dr. Max Thorek, founder of the college.

Northwestern Alumni Reunions.—The annual Medical Faculty Alumni Reunion dinner of Northwestern University Medical School will be held May 14 at the Furniture Club of America, 666 Lake Shore Dr., Chicago. The social hour will start at 6 p. m. and dinner will be served at 7 p. m. A skit will be presented by the medical students as entertainment at the dinner. Reservations at $8 a person may be made at the Medical Alumni Office of Northwestern Medical School, 303 E. Chicago Ave., Chicago 11, not later than May 11. During the convention of the American Medical Association in Miami Beach, alumni of Northwestern Medical School will hold their annual luncheon on June 14 in the Imperial Room of the Roney-Plaza Hotel at 12:30 p. m. Tickets ($3.50) are available from the Medical Alumni Office.

MASSACHUSETTS

Harvard Pathologist Honored.—The second honorary doctoral degree to be awarded by the National University of Nicaragua in Leon was presented to Dr. Franz C. von Lichtenberg, of the Harvard Medical School and the Peter Bent Brigham Hospital, Boston. During the summer of 1959, Dr. von Lichtenberg worked in Nicaragua through an educational exchange grant awarded him under the Smith-Mundt Act. He is an associate in pathology at Harvard. While in Nicaragua he was visiting lecturer of medicine (pathology) at the National University of Nicaragua, was a consultant in the organization of the University Pathology Laboratory at San Vicente Hospital in Leon, and assisted in developing an Outpatient Department and Public Health Center at the university. Dr. von Lichtenberg received the degree of doctor honoris causa.

Hungarian Microbiologist Named Visiting Lecturer.—Dr. George Ivanovics, professor of microbiology, Medical University, Szeged, Hungary, was appointed a visiting lecturer in the department of bacteriology and immunology, Harvard Medical School, Boston, serving through May 31. While at Harvard, Dr. Ivanovics will conduct informal seminars in the department of bacteriology and immunology and will carry on his research in microbiology in the laboratory of Dr. Bernard D. Davis, head of the department. He will also lecture in other departments of the university. During his stay in the United States, Dr. Ivanovics plans to visit several other medical institutions. In 1948

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education, and public health. Programs should be received at least three weeks before the date of meeting.

again in 1952 Dr. Ivanovics was awarded the Hungarian National Prize (Kossuth Prize) for his microbiological research.

MICHIGAN

Course in Hospital Housekeeping.—A course in hospital housekeeping will be given April 4-May 26 for the 12th consecutive year at Michigan State University, East Lansing. The course is sponsored by the American Hospital Association in cooperation with the university. It will provide practical training in hospital housekeeping procedures for executive housekeepers, members of hospital housekeeping staffs, and prospective employees. Enrolment will be limited to 40 students. The course will include the philosophy of hospital care and institutional organization, personnel management, institutional management, housekeeping supplies, equipment, and procedure. For information, write the American Hospital Association, 840 N. Lake Shore Dr., Chicago 11.

MISSOURI

Annual Lecture.—Dr. J. Hartwell Harrison, clinical professor of genitourinary surgery, Harvard Medical School, Boston, will deliver the 10th annual Memorial Lecture at the Menorah Medical Center of Kansas City, Tuesday, April 26. The subject will be "The Present Status of Renal Transplantation," and the time, 8 p. m.

NEBRASKA

Plan Library for Medicine and Pharmacy Schools.—Creighton University Schools of Medicine and Pharmacy will soon have a new integrated library, according to the Very Rev. Carl M. Reinert, S. J., Creighton president. The university has purchased the building at 1401 Davenport St., located directly across from the two Creighton schools. Father Reinert asserted that purchase of this property in no way affects selection of a site for proposed construction of a new Creighton Medical Center in the future. The building was acquired at this time "to satisfy a need for additional space caused by rapid expansion" of the Creighton Library collection in pharmacy and medicine. This building will replace two large rooms located on separate floors in the Medical School building. Libraries of the two schools will be integrated into one unit. Main reading room in the new Medicine-Pharmacy Library will utilize fluorescent lighting. Separate rooms will house the periodicals and rare books collections. In addition the building includes four rooms for private offices and work rooms, plus seven fireproof vaults for storage.

Personal.—Dr. Robert C. Rosenlof was named to the full-time internal medicine faculty at the University of Nebraska College of Medicine, Omaha. Dr. Rosenlof has been in private practice in Kearney since his discharge from the Air Force in 1958.—Dr. John G. Freeman, former clinical director and for a time acting superintendent of the Jamestown (N. D.) State Hospital, was named assistant professor of neurology and psychiatry at the University of Nebraska College of Medicine and research psychiatrist at the Nebraska Psychiatric Institute at Omaha. In the latter position, Dr. Freeman has charge of a 10-bed research unit devoted to teaching and research in connection with patients admitted from any of the three state hospitals in Nebraska.

NEW JERSEY

Day School Program for Retarded Children.—The Training School at Vineland has a new day school program for mentally retarded children in the Southern New Jersey area, Dr. Walter L. Jacob, director of the school, announced. The new program is for nonresidential children and joins other outpatient clinic services of the school. It ranges from nursery classes for the very young child, to vocational training for the young adult. The first 6 to 12 weeks of a child's enrollment will serve as a trial period. During this time the child will be evaluated in terms of social, emotional, and academic status to determine the type of program deemed most suitable. If the program can be provided, the child will be accepted for continued training. Morning and afternoon classroom sessions will be available. Parents will be responsible for transportation to and from the training school. For information, write The Registrar, Day School Program, The Training School at Vineland, N. J.

TEXAS

Annual Meeting in Fort Worth.—The Texas Medical Association will hold its 1960 annual session in Fort Worth, April 9-12. Twenty-six guest speakers will be featured. Dr. Louis M. Orr, President, American Medical Association, will be the speaker at a general session luncheon on Monday, April 11, and Dr. John R. Heller, of Bethesda, Md., assistant surgeon general, U. S. Public Health Service, will be the main speaker for the luncheon the following day. The program will include two general sessions, nine section meetings, 13 refresher courses, and a daily film program. In addition, about 100 papers will be presented by Texas physicians during the three full days of scientific program. Exhibits will be shown by 90 commercial firms and 35 scientific exhibits will be presented. Over 20 related medical specialty groups will meet. The president's party will be held April 12. A sports program is arranged, including a golf tournament, sailing and boating, handball, swimming, tennis, and skeet shooting. For information, write the Texas Medical Association, 1801 N. Lamar Blvd., Austin, Texas.

VERMONT

Doctorate Program in Biophysics Approved.—A new Ph.D. program in physiology and biophysics was approved by the University of Vermont College of Medicine trustees. This is the third Ph.D. program to be approved and started in the last three years. The first two were in biochemistry and pharmacology. Biochemistry is a joint program of the College of Medicine and the College of Agriculture.

Loan Fund for Students.—Dr. G. Stedman Huard, Pasadena, Calif., a 1946 graduate of the University of Vermont College of Medicine, Burlington, and a native of Winooski, has established a $25,000 loan fund for university medical students. Establishing the fund with a gift of $5,000, Dr. Huard will add $20,000 over the next four years, making a total of $25,000 available by 1961. Under the terms of the fund, special consideration is to be given students in the third and fourth years of medical school and to students from Winooski and the State of Vermont. Loans will be awarded by the university's committee on student aid, on the recommendation of the dean.

GENERAL

Request for Ophthalmology and Otolaryngology Papers.—The section of ophthalmology and otolaryngology of the Southern Medical Association announced that they are accepting papers by physicians of either specialty living in the area of the association for consideration for presentation at the next annual meeting in St. Louis Oct. 31-Nov. 3. The paper or an abstract of the paper may be sent to the Secretary, Dr. Albert C. Esposito, Suite 1212, First Huntington National Bank Building, Huntington, W. Va., as soon as possible.

Congress on Physical Medicine.—The third International Congress of Physical Medicine will be held Aug. 21-26 at The Mayflower, Washington, D. C. The preliminary prospectus covering the international conference carries information on registration, application to present a paper, a scientific exhibit, a scientific film, etc. A copy of this preliminary program may be had on request by writing Dorothea C. Augustin, Executive Secretary, Third International Congress of Physical Medicine, 30 N. Michigan Ave., Chicago 2.

Allergy Symposium in Barcelona.—An International Symposium on Allergy, organized by the European Academy of Allergy in collaboration with the Spanish Society of Allergy, will be held in Barcelona, Spain, June 3-4. Subjects for the program include (a) evaluation of the diagnostic methods used in allergy and (b) functional exploration of the respiratory and cardiovascular systems in asthma, emphysema, and allied conditions. For information, write to the secretary: Mr. Camps, Academia de Ciencias Medicas, Via Layetana 31, Barcelona 3, Spain.

Prize for Essay on Surgery.—The Samuel D. Gross Fund Prize will be awarded at the end of this year by the Philadelphia Academy of Surgery. The prize, $1,500, will be paid to the writer of the "best original essay" not exceeding 150 printed pages, octavo in length, illustrative of some subject in surgical pathology or surgical practice founded on original investigation. The author must be an American citizen. All manuscripts should be submitted no later than Sept. 1 to Dr. George P. Rosemond, Chairman, Samuel D. Gross Fund, 3401 N. Broad St., Philadelphia 40.

Truth Drugs.—A Yale psychiatrist warns that the so-called "truth drugs" often produce untruthful statements from the patient and are therefore not reliable for criminal interrogation. Dr. Lawrence Z. Freedman, of the Yale School of Medicine, New Haven, Conn., emphasizes that sodium amobarbital and thiopental sodium are extremely useful in psychiatric treatment, but that the "truth" factor has been misinterpreted by the public. Narcoanalysis, the technique of using drugs to stimulate the patient's talk, will usually stimulate the noncommunicative patient to talk uninhibitedly and thus speed treatment, but the talk is not always the truth.

Psychosomatic Meeting in Montreal.—The annual meeting of the American Psychosomatic Society will be held March 25-27 at the Sheraton–Mt. Royal Hotel, Montreal. The program includes 25 papers. Dr. Eric D. Wittkower, associate professor of psychiatry, McGill University, Montreal, will give the presidential address the morning of March 27, after which a panel discussion, "Contributions of Behavioral Scientists to Psychosomatic Medicine," will be moderated by Dr. Wittkower. A business meeting will be held the afternoon of March 26. For information, write Dr. Eugene Meyer, 265 Nassau Road, Roosevelt, N. Y., Secretary-Treasurer.

Conference on Thrombolytic Agents.—On April 8-9 a Conference on Thrombolytic Agents, sponsored by the Hematology Study Section, will be held in Chicago. The conference will be concerned with the clinical application of thrombolytic agents, laboratory control of therapy, and standardization of agents. There will also be an assessment of the basic knowledge of the fibrinolytic system, including the purification of profibrinolysin and the action of activators and inhibitors. Speakers will include American and foreign investigators. Workers active in the field may obtain information about attendance from Dr. Kenneth M. Brinkhous, Department of Pathology, University of North Carolina, Chapel Hill, N. C.

New Fifty Year Club.—Dr. John H. McCurry, of Cash, Ark., is interested in forming an A. M. A. Fifty Year Club in which membership would be limited to members of the Association who have been in practice 50 years or more. The first meeting of the new club is expected to be held during the annual clinical meeting of the Association in Washington, D. C., in November, 1960. Those who are qualified and desire to join this organization are requested to so advise Dr. McCurry, giving their complete name and address. Dr. McCurry plans to be in Miami at the June meeting to begin organizational procedures and to see any who qualify at this meeting.

Meeting on Medical Television.—The Council on Medical Television, an organization concerned with the uses of television in the health science professions, will hold its second meeting on April 20-21 at the Clinical Center, National Institutes of Health, Bethesda, Md. This meeting, will have as its theme "Pedagogic Techniques in Televised Medical Education." Examples of techniques currently used in medical schools and institutions with television facilities will be demonstrated and discussed. Attendance is limited to council members and invited observers. For information, write Mr. John K. MacKenzie, Executive Secretary, Council on Medical Television, 33 E. 68th St., New York 21.

Meeting on Nuclear Medicine in San Antonio.—The Southwestern Society of Nuclear Medicine will hold its fifth annual meeting March 26-27 at the Menger Hotel, San Antonio, Texas. Dr. Peter E. Russo, Oklahoma City, president of the society, will open the meeting with an address. Twelve papers are scheduled, each to be followed by a discussion period. Two panel discussions will be held with the following titles and moderators: "Responsibilities of the Physician and Institution Using Radiation," Dr. Vincent P. Collins, Houston, Texas, and "Value of Isotopes in Hematology," Dr. William C. Levin, Galveston, Texas. For information, write Dr. James R. Maxfield Jr., 2711 Oak Lawn Ave., Dallas 19, Texas, Secretary and Treasurer.

Meeting of Anatomists in New York City.—The seventh International Congress of Anatomists and 73rd annual meeting of the American Association of Anatomists will be held at the Statler Hilton Hotel, New York City, April 11-16. Over 600 papers will be presented, and four symposiums have been organized on the following subjects:

The Structure of the Eye.
Microcirculatory: Pituitary and Bone Marrow.
Fine Structure.
Anatomy and Biomechanics.

Delegates from over 30 foreign countries will participate. Registrants from the United States and Canada will be assessed a registration fee. For information, write Dr. Oliver P. Jones, Program Secretary, Department of Anatomy, University of Buffalo, Buffalo 14, N. Y.

Orthoptic Council Examinations.—The annual examination of orthoptic technicians by the American Orthoptic Council will be conducted in August and October. The written examination will be nonassembled and will take place on Thursday, Aug. 18, in certain assigned cities and will be proctored by designated ophthalmologists. The oral and practical examinations will be on Saturday, Oct. 8, in Chicago preceding the meeting of the American Academy of Ophthalmology and Otolaryngology. Applications for examination will be received by the office of the Chairman of Examinations, Dr. Frank D. Costenbader, 1605 22nd St., N. W., Washington 8, D. C., and must be accompanied by the examination fee of $30. Applications will not be accepted after July 1.

Gastroenterology Groups Meeting in New Orleans.—The 61st annual meeting of the American Gastroenterological Association will be held April 1-2 at the Roosevelt Hotel, New Orleans. On March 30 the American Gastroscopic Society will hold its 19th annual meeting, and on March 31 the Gastroenterological Research Forum and the Gastroenterology Research Group will meet at the Roosevelt Hotel. The program for the American Gastroenterological Association is organized under the following major headings:

Peptic Ulcer.
Pancreas.
Exudative Gastroenteropathy.
Colon.
Small Intestine.
Gastric Cancer.
Postgastrectomy Steatorrhea.
Liver.
General.

The President's Address, "Our Responsibility to World Gastroenterology," will be given by Dr. H. Marvin Pollard, Ann Arbor, Mich., the morning of April 2, followed by the sixth annual Memorial Lecture of the association, "Causative Factors in Gastrointestinal Cancer," by Dr. G. Burroughs Mider, Bethesda, Md. Over 85 papers are scheduled. At the annual banquet, April 1, the Julius Friendenwald Medal will be presented to Dr. Chester M. Jones, Boston. For information, write Dr. Wade Volwiler, University of Washington School of Medicine, Seattle 5, Secretary.

Annual Dermatological Meeting.—The American Dermatological Association, Inc., will hold its 80th annual meeting April 8-12 at the Boca Raton Hotel and Club, Boca Raton, Fla. Dr. Marion B. Sulzberger, New York City, will give the presidential address, "Education for Dermatology in the United States," to open the first scientific session the morning of April 8. The program includes more than 25 papers, with following discussions. Election of officers will take place the morning of April 9. An awards session, April 12, will be followed by a noon luncheon meeting of the board of directors and the American Dermatological Association Research & Educational Fund, Inc. The 1961 meeting of the association will be held at the Castle Harbour Hotel, Tucker's Town, Bermuda. For information, write Dr. Wiley M. Sams, 308 Ingraham Bldg., Miami 32, Fla., Secretary.

Report on Heart Research Support.—Sums allotted to scientific research by the American Heart Association and its affiliates since its reorganization as a voluntary health agency in 1948 have approached 50 million dollars, according to the association's annual report. The 1959 Heart Fund drive raised $24,004,865, a total more than nine times the sum contributed in the association's first campaign in 1949. In reviewing the association's program, the annual report notes that community service programs have been developed, including work evaluation units to aid the heart patient in returning to work, programs for prevention of rheumatic fever, vocational guidance for cardiac-handicapped youth, assistance to families in rehabilitation of stroke patients, counseling to help patients follow prescribed diets, work simplification classes to show cardiac homemakers how to "take it easy," and information and referral services.

Scholarship for Health Museum Study.—Applications are being accepted for the 1960 Lester Taylor Scholarship of the Cleveland Health Museum, Dr. Bruno Gebhard, museum director, announced. The $500 scholarship is open to graduate students (having A.B., R.N., or equivalent) interested in health or museum education. The winner spends 6 to 12 weeks at the Health Museum studying visual techniques in education, under direction of the staff. The period of year is at the option of the candidate. The student selects a project suited to his needs and interests and submits a written report at the end of his internship. The scholarship is made available by the Women's Committee of the Cleveland Health Museum in honor of the Museum's first president. A tuition fee of $100 will be paid from the $500 stipend. The remainder is paid directly to the candidate for living expenses. Address requests to Dr. Bruno Gebhard, Director, Cleveland Health Museum, 8911 Euclid Ave., Cleveland 6.

American Board of Medical Hypnosis.[*]—The American Board of Medical Hypnosis will certify between Jan. 1, 1960, and June 30, 1960, those physicians who meet the following standards: (1) prior certification by one of the A. M. A. approved American Medical Specialty Boards, and (2) documented evidence, acceptable to the American Board of Medical Hypnosis, of seven years' experience with medical hypnosis as part of the practice of their basic specialties. In the case of general physicians, active membership in the American Academy of General Practice will be accepted in lieu of A. M. A. Specialty Board Certification. During this six-month period it will not be necessary for applicants to pass special examinations for this board, provided that the aforementioned requirements are satisfactorily fulfilled.

[*] Editor's Note: The American Board of Medical Hypnosis has not been approved by either the A. M. A. Council on Medical Education and Hospitals or by the Advisory Board for Medical Specialties. It is, therefore, not recognized by the A. M. A. as a regular medical specialty board.

International Symposium on Congenital Heart Disease.—The second International Symposium of the Deborah Hospital on "Current Concept in Medicine" will be held April 28-30 at the Bellevue Stratford Hotel, Philadelphia, on congenital heart disease. This is the second of a series of symposiums which attempt to present changing concepts regarding various types of thoracic disease. Sessions are scheduled under the following titles:

Pathogenetic Factors in Congenital Heart Disease.
Definitive Diagnosis of Congenital Heart Disease.
The Fate of the Child with Unrelieved Congenital Heart Disease.
Surgical Tools.
Special Surgical Considerations.
Surgery of Congenital Heart Disease.
Management of the Cyanotic Newborn.

Twelve fireside conferences are scheduled for the evening of April 28. There is no registration fee. For information, write Dr. Paul K. Bornstein, Northwest Corner, 9th and Walnut Streets, Philadelphia 7.

Dr. Plimpton Named President of Amherst.—Dr. Calvin H. Plimpton, associate professor of clinical medicine at Columbia University College of Physicians and Surgeons, New York City, will succeed Charles W. Cole, Ph.D., as president of Amherst College, Amherst, Mass. Dr. Cole is retiring in June to join the Rockefeller Foundation. In 1946 Dr. Cole left his post as professor of history at Columbia to become 12th president of Amherst. The 139-year-old New England institution's 13th president is also a Columbia alumnus. The university awarded Dr. Plimpton a doctor of medical science degree in 1951. Both men received their undergraduate degrees at Amherst. Dr. Plimpton, who joined the faculty of Columbia's College of Physicians and Surgeons in 1949, also serves as assistant dean of the medical school. He is assistant attending physician at Presbyterian Hospital in the Columbia-Presbyterian Medical Center. He has served on the admissions committee of the college of Physicians and Surgeons since 1950. In its 205-

year history, Columbia has produced among its alumni and staff more than 100 college and university presidents.

Railway Surgeons Meeting in Chicago.—The American Association of Railway Surgeons will hold their 72nd annual meeting in conjunction with the Surgeons of the Burlington Railroad April 7-9 at the Drake Hotel, Chicago, under the presidency of Dr. James S. Bell, of York, Neb. Two panel discussions are planned with the following titles and moderators: "Low Back Pain and the Working Man," Dr. John J. Fahey, Chicago, and "Cancer—New Developments in Treatment," Dr. Danely P. Slaughter, Chicago. The program includes 13 papers and the following movies:

Acute Gall Bladder Disease, Dr. Allen M. Boyden, Portland, Ore.
Flexion Exercises in Low Back Mechanical Disorders, Dr. Eugene M. Regen, Nashville, Tenn.
Staphylococcal Infections in Surgery, Dr. H. Rocke Robertson, Vancouver, B. C.

Technical exhibits are arranged. Dr. Bell will serve as toastmaster at the annual dinner the evening of April 8. The program is acceptable for 16½ hours of category II credit for members of the American Academy of General Practice. All physicians are invited. There is no registration fee. For information, write Dr. Chester C. Guy, 5800 Stony Island Ave., Chicago 37, Secretary.

Accelerate Campaign Against Tuberculosis.—A plan to speed up the campaign against tuberculosis was announced March 1 by Dr. H. McLeod Riggins, New York City, president of the National Tuberculosis Association. The plan has been approved both by the board of directors of the NTA and by the executive committee of its medical section, the American Trudeau Society. Essentially, the plan is to use available antituberculosis drugs to eliminate all sources of tuberculosis infection by the adequate treatment of every person with active tuberculosis, and also selected persons with inactive disease. "We estimate that there are at least 250,000 active cases of tuberculosis in the United States today," Dr. Riggins said. "Of these, some 100,000 are not known to health departments. An additional 550,000 Americans are believed to have tuberculosis in an inactive form." In the stepped-up program to detect and treat all tuberculosis patients, the 2,700 state and local voluntary tuberculosis associations affiliated with the NTA will work in cooperation with state and local health departments. The eradication program adopted by the NTA grew out of a conference held at Arden House, Harriman, N. Y., recently, under the joint auspices of the Tuberculosis Program of the U. S. Public Health Service and the NTA.

Meeting on Internal Medicine.—The annual meeting of the American Society of Internal Medicine will be held April 1-3 at the Sheraton-Palace Hotel, San Francisco. Dr. Dwight L. Wilbur, San Francisco, past-president, American College of Physicians, will be the keynote speaker at the April 3 socioeconomic program session, entitled "The Practice of Internal Medicine Today-Tomorrow." Four speakers representing the individual practice of internal medicine, hospital administration, the pharmaceutical industry, and the office management field will follow. Dr. E. Vincent Askey, President-Elect, American Medical Association, will discuss problems of the aging at the opening session of the socioeconomic program April 2. Mr. Walter Barlow, executive vice-president of Opinion Research, will present a discussion on the development of a corporate image by the society and its component societies. The scientific responsibilities of a component society will be discussed by Dr. Howard F. Root, Boston, president, Massachusetts Society of Internal Medicine. Scientific exhibits and a ladies' program are arranged. On Saturday, April 9, the postconvention tour to Hawaii will begin. For information, write the American Society of Internal Medicine, 350 Post St., San Francisco 8.

Society News.—Officers of the **Western Association of Physicians** elected for the coming year are as follows: president, Dr. Clement A. Finch, Seattle; vice-president, Dr. Henry D. Brainerd, San Francisco; councillors, Dr. George E. Cartwright, Salt Lake City, and Dr. Robert J. Glaser, Denver. The following officers continue by reason of term of office: secretary-treasurer, Dr. Wade Volwiler, Department of Medicine, University of Washington, Seattle 5; councillors, Dr. Arthur W. Frisch, Portland, Ore., and Dr. John H. Lawrence, Berkeley, Calif.——Dr. George W. Dana, of New York City, was named executive director of **Southwestern Medical Foundation** in Dallas. Dr. Dana for the past two years has been director of North Shore Hospital in Manhasset on Long Island.——Dr. Francis W. Lynch, St. Paul, was elected president of the **American Academy of Dermatology and Syphilology**, succeeding Dr. Anthony C. Cipollaro, New York City. Dr. C. Fred Lehmann, of San Antonio, Texas, replaces Dr. Norman M. Wrong, Toronto, Canada, as vice-president. Dr. Robert R. Kierland, Rochester, Minn., Dr. Stanley E. Huff of Evanston, Ill., and Dr. Samuel J. Zakon, of Chicago, continue in their offices as secretary-treasurer, assistant secretary-treasurer, and historian, respectively. The next annual meeting of the academy will be at the Palmer House, Chicago, Dec. 3-8.

Report Increase of Young Fathers.—Statisticians of the Metropolitan Life Insurance Company report that young fathers in our country are "increasing rapidly in number." The number of children born in families where the husband is under 20 years of age rose from 40,000 to 106,000, or 165%, between 1940 and 1957. Although the relative increase in births diminishes with advance in age of the husband, it was 64% for husbands aged 30-34 years, and as much as 45% for those 40-44 years of age. Only in families where the husband is 55 years or older, have births failed to rise. During the 1940-1957 period, the number of American husbands at ages under 45 increased by almost one-third. Moreover, at the teen ages—where the sharpest rise in births has occurred—the number of married men has increased by about two-thirds. In 1957, births occurred at a rate of 598 per 1,000 in families where the husband was under 20 years of age; 3 out of 5 families with a teen-age husband had a child during the year. The proportion was about 2 in 5 in families where the husband was 20-24 years old, and well over 1 in 4 where he was 5 years older. The median age of the husband in families which had a child in 1957 was only 29.2 years; in 1940 the corresponding age was about 0.7 years higher. During 1957, families in which the husband was under 35 years of age contributed more than three-fourths of our newborn, whereas only one-tenth of the births were in families in which the husband was past age 40.

Population Growth in United States and Canada.—Statisticians of the Metropolitan Life Insurance Company reported that both the United States and Canada recorded large population gains during 1959. In the U. S., including Alaska and Hawaii, the increase exceeded 2,900,000, raising the total population of the states, including the Armed Forces overseas, to 179,250,000 at the end of the year. In the 9¾ years since the 1950 census more than 27.5 million people have been added to the population, an increase averaging 1.7% annually. Canada has been experiencing a higher rate of growth, the population having increased by 2.7% a year since the June, 1951, census. At the close of 1959 Canada's population reached 17,682,000 an increment of about 400,000 during the year and of almost 3,700,000 since June, 1951. Births in the U. S. have exceeded 4.1 million annually for six successive years. There were about 4,320,000 babies born in 1959, compared with the all-time high of 4,334,000 in 1957. In every year of the 1950's the birth rate was 24 per 1,000 or higher. General mortality in the United States declined slightly in 1959, the death rate decreasing to 9.4 per 1,000 population, from 9.5 in 1958. The rate for 1959 was only 2% above the all-time low of 9.2 per 1,000 in 1954. The number of births exceeded deaths by about 2,660,000 in 1959. In Canada during 1959 the birth rate was 27.9 per 1,000 population. The number of deaths totaled about 139,000, and the death rate was 8.0 per 1,000 population. The all-time low of 7.9 was established in 1958. Canada had a gain through migration in 1959, of about 50,000 persons. This was the smallest number for any year since 1951.

LATIN AMERICA

Tuberculosis Congress in Brazil.—The eighth Panamerican Congress on Tuberculosis, under the auspices of the Latin-American Union of Societies of Phthisiology, will be held under the presidency of Prof. Jose Silveira, of Brazil, July 10-16 at Cidade do Salvador, Bahia, Brazil. Official communications will include revision of value of epidemiology indices in tuberculosis and prognosis for tuberculous patients apparently cured. Symposiums are planned on the following subjects: B. C. G. in Latin America, present status of Abreugraphy in prophylaxis of tuberculosis, pulmonary mycosis, teaching of phthisiology, public health education, and publicity. Address all correspondence to M. Ezequiel Da Costa, Caixa Postal, 635, Bahia, Brazil.

FOREIGN

Charter Flight for Vienna Seminars.—The American Medical Society of Vienna, (Universitatsstrasse 11, Vienna I) has arranged a special charter flight for its members, to enable them to attend one of the seminar congresses which are held in Vienna Aug. 18 to Sept. 10. At a round-trip fare of $290, the plane will leave New York Aug. 11 for London and return from Paris Sept. 14. The stay in Europe will be on an individual basis. Several similar flights are being planned for 1961.

Conference on Electron Microscopy in Delft.—A European Regional Conference on Electron Microscopy will be held in Delft, Netherlands, Aug. 28-Sept. 3. The program will consider the following subjects: physics and technique of the electron microscope; image formation; ion-microscopy; preparation techniques; results of ultrastructure research in biology, medicine, chemistry, and metallography. Plenary and sectional meetings and colloquiums are planned. Contributors to plenary and sectional meetings should send an application form to the secretary of the organizing committee, A. L. Houwink, Lab. v. Microbiologie, Julianalaan 67A, Delft, Netherlands, and before May 1 should send in an outline of their paper, together with micrographs and a duplicate abstract of the paper. Contributors to the colloquiums should send in an application form and duplicate papers before June 15. Official languages of the congress are English, French, and German.

Conference on Congenital Malformations.—The International Conference on Congenital Malformations will be held in London July 18-22 under the sponsorship of the National Foundation. The meetings will take place in Church House and the headquarters hotel will be Grosvenor House. The honorary presidents of the conference include Sir Geoffrey Marshall, president, Royal Society of Medicine, and Mr. Basil O'Connor, president of the foundation. Prof. James D. Boyd, Cambridge University, will be the general chairman. The program will deal particularly with the incidence of congenital malformations and their relationship to social and medical conditions, the genetic and environmental factors that may be responsible, the normal mechanisms of embryogenesis and the conditions which result in abnormalities, the relationships between mother and fetus during pregnancy, and the obstetrical problems related to deformity. Investigators from more than 10 nations will participate. Information may be obtained by addressing the secretariat, Mr. Stanley E. Henwood, Executive Secretary, International Medical Congress, Ltd., 120 Broadway, New York City.

CORRECTION

Age Limit for Fellowships Is Thirty-five.—The executive secretary of the Helen Hay Whitney Foundation has written that in the item in the Medical News section of THE JOURNAL of Feb. 20, Volume 172, No. 8, page 829, reporting the availability of Helen Hay Whitney Research Fellowships, the age limit should have read 35 years not 25.

EXAMINATIONS AND LICENSURE

MEDICAL SPECIALTY BOARDS

AMERICAN BOARD OF ANESTHESIOLOGY: *Written.* Various locations, June 24. Final date for filing application was January 10. *Oral.* Miami Beach, April 25-30. Applications already on file. Sec., Dr. Forrest E. Leffingwell, 217 Farmington Ave., Hartford 5, Conn.

AMERICAN BOARD OF DERMATOLOGY: *Written.* Various locations, June 5, 1961. Final date for filing application is March 1, 1961. *Oral.* Philadelphia, Oct. 13-16. Sec., Dr. Beatrice M. Kesten, One Haven Ave., New York 32, New York.

AMERICAN BOARD OF INTERNAL MEDICINE: *Oral.* San Francisco, March 30-April 1; New York City, Nov. 14-17. Closing date for filing application: Jan. 2 and July 1. *Written.* Oct. 17. Closing date for filing application is May 1. Sec.-Treas., Dr. William A. Werrell, One West Main St., Madison 3, Wis.

AMERICAN BOARD OF NEUROLOGICAL SURGERY: Examination given twice annually, in the spring and fall. St. Louis, April 10-12. In order to be eligible a candidate must have his application filed at least six months before the examination time. Sec., Dr. Donald D. Matson, 300 Longwood Ave., Boston, Mass.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Part II, Oral and Clinical.* Chicago, April 11-16. Final date for filing application was August 1. Applications for certification in Part I, new and reopened, and requests for re-examination in Part II are now being accepted. Deadline for receipt of applications is August 1, 1960. After July 1, 1962 a minimum of three years of approved progressive residency training will be required. Training by preceptorship will no longer be acceptable. The initiation of preceptorships will not be approved after July 1, 1960. Sec., Dr. Robert L. Faulkner, 2105 Adelbert Road, Cleveland 6.

AMERICAN BOARD OF OPHTHALMOLOGY: *Written.* Jan. 23, 1961. Deadline for filing applications is July 1. *Oral.* San Francisco, May 9-13; Chicago, Oct. 3-7. Sec., Dr. Merrill J. King, Box 236 Cape Cottage Branch, Portland, Maine.

AMERICAN BOARD OF ORTHOPAEDIC Surgery: *Part I,* Nashville, Denver and Philadelphia, Apr. 13-14. Deadline for receipt of applications was Nov. 30. *Oral and Written, Part II.* Miami Beach, Jan. 3-5, 1961. Final date for filing application is July 1. Sec., Dr. Sam W. Banks, 116 South Michigan Ave., Chicago 3.

AMERICAN BOARD OF OTOLARYNGOLOGY: *Oral,* Chicago, Oct. 3-6. Final date for filing application is April 1. Sec., Dr. Dean M. Lierle, University Hospitals, Iowa City.

AMERICAN BOARD OF PATHOLOGY: Memphis, April 21-23. Final date for filing application was March 7. *Examination in Forensic Pathology.* Memphis, April 22. Final date for filing application was March 7. Sec., Dr. Edward B. Smith, Indiana University Medical Center, 1100 W. Michigan St., Indianapolis 7.

AMERICAN BOARD OF PEDIATRICS: *Written.* New York City, January 1961. Final date for filing application is Dec. 1. Administrative Sec., Mrs. Eleanor J. Mitchell, Rosemont, Pa.

AMERICAN BOARD OF PHYSICAL MEDICINE AND REHABILITATION: *Oral and Written.* New York, June 17-18. Sec., Dr. Earl C. Elkins, Mayo Clinic, Rochester, Minn.

AMERICAN BOARD OF PLASTIC SURGERY: *Oral and Written.* Milwaukee, May 1960. Final date for filing application was January 1. Corresponding Secretary, Mrs. Estelle E. Hillerich, 4647 Pershing Ave., St. Louis 8, Mo.

AMERICAN BOARD OF PROCTOLOGY: *Oral and Written, Parts I and III,* Philadelphia, Sept. 24. Final date for filing application is June 30. Sec., Dr. Stuart T. Ross, 520 Franklin Ave., Garden City, N. Y.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: New York, New York, Dec. 12-13. *Child Psychiatry.* Chicago, April 25-26. Sec., Dr. David A. Boyd, Jr., 102-110 Second Ave., S.W., Rochester, Minn.

AMERICAN BOARD OF RADIOLOGY: *Examination.* Cincinnati, June 6-10; Dec. 5-9. Deadline for filing applications for the June examination was Jan. 1. Filing deadline for the December examination is July 1. A special examination in Nuclear Medicine (for those diplomates in Radiology or Therapeutic Radiology) will be offered provided there are sufficient applications. Sec., Dr. H. Dabney Kerr, Kahler Hotel Bldg., Rochester, Minn.

AMERICAN BOARD OF SURGERY: *Oral Examinations (Part II):* Kansas City, Kans., May 16-17, and Los Angeles, May 19-20. Sec., Dr. John B. Flick, 1617 Pennsylvania Blvd., Philadelphia 3.

BOARD OF THORACIC SURGERY: *Oral.* May 1960. Final date for filing application was Dec. 1. Sec., Dr. Wm. M. Tuttle, 1151 Taylor Ave., Detroit 2.

AMERICAN BOARD OF UROLOGY: *Written.* December. *Oral-Clinical.* Chicago, February 1961. Exec. Sec., Mrs. Ruby L. Griggs, 30 Westwood Road, Minneapolis 26.

DEATHS

Armstrong, Thomas Morrell Ⓜ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1913; member of the Association of Life Insurance Medical Directors of America; veteran of World War I and was awarded the Croix de Guerre by the French government for meritorious service; medical director of the Philadelphia Life Insurance Company; died Dec. 31, aged 70, of diffuse obstructive emphysema.

Ashcraft, Virgil Lee, Reform, Ala.; University of Alabama School of Medicine, 1912; for many years secretary of the Pickens County Medical Society; director of the Bank of Reform; died Jan. 4, aged 73.

Baer, Walter Kreider Ⓜ Lancaster, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1905; formerly affiliated with the city bureau of health and school medical inspection service; on the staff of the Lancaster General Hospital, where he died Jan. 4, aged 79.

Barker, Joseph Michael Ⓜ Beverly Hills, Calif.; born in Washington, D. C., May 16, 1910; Georgetown University School of Medicine, Washington, D. C., 1939; interned at the Georgetown University Hospital in Washington, D. C., where he served a fellowship; served a fellowship at the University Hospital in Ann Arbor, Mich.; specialist certified by the American Board of Internal Medicine; certified by the National Board of Medical Examiners; fellow of the American College of Physicians; associate clinical professor of medicine at the University of California at Los Angeles School of Medicine; served on the faculty of his alma mater and the University of Southern California School of Medicine at Los Angeles; veteran of World War II; affiliated with St. John's Hospital, Santa Monica, Cedars of Lebanon Hospital, Hollywood Presbyterian Hospital, Queen of Angels Hospital, Mount Sinai Hospital, and St. Vincent's Hospital, all in Los Angeles; author of "The Unipolar Electrocardiogram"; died in Arlington, Va., Jan. 12, aged 49.

Barnett, Charles Eldridge, St. Petersburg, Fla.; Fort Wayne College of Medicine, 1890; member of the American Urological Association; fellow of the American College of Surgeons; served as adjunct professor of genitourinary surgery at the Purdue University Medical Department and as professor of surgical anatomy at his alma mater; formerly practiced in Fort Wayne, Ind.; past-president of the Allen County (Ind.) Medical Society; veteran of the Spanish-American War and World War I; died Dec. 28, aged 93.

Bartell, Jack Orvis, Oklahoma City, Okla.; University of Oklahoma School of Medicine in Oklahoma City, 1930; interned at the Baptist Hospital in Houston, Texas; for many years practiced in Conroe, Texas, where he was asociated with the Montgomery County Hospital; died Jan. 2, aged 58.

Beall, Dorsey Carlyle Ⓜ Morgantown, W. Va.; Medical College of Virginia, Richmond, 1950; interned at the Charleston General Hospital in Charleston, where he served a residency; served a residency at the Boiarsky Memorial Hospital in Charleston and the Bellevue Hospital in New York City; specialist certified by the American Board of Dermatology; died Jan. 11, aged 42.

Beller, Abraham Jacob Ⓜ Philadelphia; Columbia University College of Physicians and Surgeons, New York City, 1910; fellow of the International College of Surgeons and the American College of Surgeons; formerly taught at the Cornell University Medical College, and served on the staffs of the Home and Hospital of the Daughters of Israel, Beth Abraham Home, and the Hospital for Joint Diseases, in New York City; died in the Albert Einstein Medical Center Jan. 14, aged 73, of cancer of the bronchus.

Beynon, James Valentine Ⓜ Rockford, Ill.; Chicago College of Medicine and Surgery, 1913; served on the staff of the St. Anthony Hospital, where he died Jan. 1, aged 75.

Black, Wilmer DeWitt Ⓜ Pecos, Texas; Dallas Medical College, 1903; for many years health officer of the city of Barstow and Ward County; served as president of the Barstow Chamber of Commerce; died in the Memorial Hospital Jan. 3, aged 84.

Blankenship, Clifford R., Dunedin, Fla.; Keokuk (Iowa) Medical College, College of Physicians and Surgeons, 1908; died Jan. 4, aged 76.

Branaman, Ernest L., Taylorsville, Ky.; University of Louisville Medical Department, 1894; served as a member of the Spencer County Board of Health; died in the Guerrant Clinic and Hospital, Winchester, Jan. 3, aged 87.

Braun, Martin, New York City; Hamburgische Universität Medizinische Fakultät, Hamburg, Germany, 1926; died Jan. 7, aged 59, of myocardial infarction and diabetes mellitus.

Bruecken, Gilbert Albert Ⓜ Pittsburgh; University of Pittsburgh School of Medicine, 1931; member of the Industrial Medical Association; fellow of the American College of Surgeons; veteran of World

Treatment of Toxic Nodular Goiter with I^{131}.—B.-A. Lamberg and co-workers (*Acta med. scandinav.* 165:245-258, 1959) treated a series of 144 patients who had hyperthyroidism with radioactive iodine (I^{131}). In 12 of these patients the thyroid was not demonstrable, 34 had a diffuse goiter, and 98 had a nodular goiter. Remissions of symptoms occurred in 71.8% of the first two groups, and 21.7% became hypothyroid. In the group with nodular goiter, the corresponding figures were 81.6 and 8.2%. In nine patients (6.3%) the response was characterized as failing. Two of these patients died, and the others were operated on or given antithyroid drugs. In seven patients (4.9%) a severe post-treatment reaction occurred. In two patients the condition was classified as thyroid storm and in three as impending storm; in one patient a myocardial infarction occurred. In 11.1% a temporary aggravation of the thyrotoxicosis occurred. Temporary hypothyroidism was diagnosed in 7.7%. There was a postoperative relapse in 31 patients. Of these, 87.1% became euthyroid. In 27 patients there was a recurrence after long-term antithyroid treatment. Of these patients 74.1% became euthyroid. In three patients there was a marked increase of the thyrohypophysial eye syndrome and in many there was an increase of the ocular signs. In one patient, however, there was a gradual improvement of the ocular condition.

The present results substantiated the fact that the occurrence of hypothyroidism after treatment with I^{131} was definitely less in patients with toxic nodular goiter than in those with diffuse goiter. With increasing experience, the incidence might even be brought to a lower level. It seemed, however, that the dose was not the only factor influencing the production of hypothyroidism. Another factor was the sensitivity of the cells to radiation. After observing that some fairly serious reactions occurred after administration of I^{131} the authors stated that the regions in Northern Europe in which goiter is endemic probably exhibited special problems because of the presence of multinodular goiter. It seemed possible that the careful use of antithyroid therapy before and after giving I^{131} might greatly diminish the occurrence of such reactions.

The risk of producing thyroid carcinoma by giving antithyroid agents with I^{131} seemed to be slight. The number of patients needing such a combined treatment was small, and they belonged to an age group where such risks could be taken. In presenting a general scheme for the different types of treatment related to nature of goiter and age, the authors stated that after the age 40 to 45 years an increasing number of patients will be treated with I^{131}, including those with a large nodular goiter, the greatest advantage with this type of treatment in an endemic goiter zone being the curative effect in patients with pronounced intrathoracic nodular goiter and hyperthyroidism. In Finland goiter is almost always multinodular in patients over 60 years of age, an age group in which the proportion of patients in whom surgery is to be avoided is fairly large.

FRANCE

Test for Arteritis Obliterans.—At a meeting of the Société française de Cardiologie in May, Lian and Tursz reported on the reabsorption time of wheals produced by the intradermal injection of two drops of a 9:1,000 sodium chloride solution in patients with arteritis of the extremities. In patients with arteritis the sodium chloride solution is injected in the thigh, knee, leg, instep, and big toe. The reabsorption time, which in normal subjects is longer than 30 minutes, is reduced to less than 20 minutes and often to about 4 minutes in patients with arteritis obliterans. If the obliteration is in the middle or the lower section of the femoral artery, the reabsorption time is normal at the thigh. If the obliteration is higher the reabsorption at the thigh is accelerated.

The authors applied the test before and after exercise. In some subjects effort accelerated reabsorption. The reabsorption time is meaningless if the patient suffers from renal, cardiac, or hepatic insufficiency, but it is not influenced by the presence of varices. The test is equally applicable to the study of vascular conditions in the upper extremities. If the obliteration involves the subclavian artery, the reabsorption is accelerated in the forearm. The variation from the normal time, however, is less marked in the upper than in the lower extremities.

Chronic Progressive Polyarthritis.—At the Sixth International Congress of Therapeutics in Strasbourg in October, M. H. Picard reported that he and his co-workers treated a series of 70 patients who had chronic progressive polyarthritis with a combination

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

of copper and silver gluconate and colloidal gold, all active ion exchangers. The author added fluorine, which is effective in the treatment of osteoporosis and capsuloligamental disturbances. He also gave potassium gluconate intramuscularly to increase the anti-inflammatory activity of the catalyzers.

The patients were divided in groups according to the stage of their disease. In 24 patients in stage 1, in whom the duration of polyarthritis was one to four years, with acute inflammation, moderate ankylosis, and a sedimentation rate of more than 25 mm., there was satisfactory improvement after a period of 6 to 24 months of treatment. This improvement was maintained for two years. In 18 of these patients the sedimentation rate and the serum globulin levels returned to normal. In the rest the sedimentation rate was brought to between 15 and 20 mm. In 32 patients in stage 2, with polyarthritis of four to five years' duration and with evident articular alterations but incomplete ankylosis, the painful inflammatory manifestation decreased but the articular deformations persisted. The therapy was ineffective in 14 patients in stage 3, who had had polyarthritis for more than 15 years.

Dexamethasone for Rheumatic Disease.—At the same meeting Rubens-Duval and co-workers reported that they treated a series of 10 patients, 9 of whom had chronic progressive polyarthritis and 1 of whom had ankylosing spondylarthritis, with dexamethasone. With one exception, these patients had already been treated with deltacortisone and deltahydrocortisone. The authors first gave dexamethasone in doses that produced results similar to those of deltacortisone. Then the dosage was increased in order to obtain better results. The largest dose given was 8 to 10 mg. The dosage was then gradually decreased until it reached the lowest amount required for maintenance of the improvement obtained. The maintenance dosage was established at 2 to 3 mg. a day. As a therapeutic adjuvant the authors used androgens.

The results were excellent in all patients. Not only did the pain decrease while the patients were resting but also some patients regained mobility of which they had been deprived for a long time. The sedimentation rate decreased in eight of the patients. These results were definitely better than those obtained with deltacortisone. With identical doses the therapeutic power of dexamethasone was five to six times greater than that of deltacortisone. One of the polyarthritic patients who required a large dose because of an articular lesion died of pneumonia in spite of treatment with antibiotics. At autopsy a recent prepyloric ulcer in the process of perforating into the peritoneal cavity was found. Three patients had temporary edematous manifestations, and in two hypertensives the blood pressure increased. Most patients complained of sleep disorders, swelling of the face, and excessive sweating. Five patients observed the development of cutaneous ecchymoses and even purpura after light trauma. The authors used the same treatment in two patients with sciatica, one with lumbago, and one with scapulohumeral arthritis. They too were definitely relieved, and at the end of the treatment their recovery was complete.

INDIA

Potassium Deficiency and Operation.—Srivastava and Khanna studied a series of 50 patients before and after various operations (*J. Indian M. A.*, vol. 33, Dec. 16, 1959). The potassium, sodium, and chloride content of the blood were determined on admission, on the morning of operation, and at frequent intervals during the postoperative period till the potassium values returned to normal. None of the patients had a deficient preoperative serum potassium level. Most of them ate a normal diet until the night before operation. The postoperative urinary excretion of potassium was estimated in some patients and was found to be the same or even in excess of the preoperative level, although there was no intake of potassium during this period. In most patients the total output of urine was decreased, but the fall in excretion of potassium was not proportional to it.

Most patients did not receive any potassium for 24 hours after operation and some for up to four days. These latter had continuous gastrointestinal suction and fluid given intravenously after such operations as partial gastrectomy and hemicolectomy. In some of these, although the total potassium excretion was reduced, an adequate amount was still excreted in spite of the absence of potassium intake and loss of potassium through gastrointestinal suction. The serum potassium level in some patients showed a slight postoperative rise but then fell to a degree which varied from patient to patient. The extent of the fall was proportional to the severity of the operation. After herniorrhaphy and appendectomy the fall was less than that after partial gastrectomy, hemicolectomy, or thoracoplasty. Patients receiving fluid intravenously for a long time showed a constant fall in the serum potassium level. This fall was more marked when associated with gastrointestinal suction. Administration of 5 or 10% dextrose solution increased the total urinary excretion of potassium and was accompanied by diuresis after 5% dextrose solution. Only two patients showed severe hypochloremia, and they had pyloric stenosis and did not respond to 5% dextrose in saline solution given intravenously. They remained drowsy, listless, and weak. Recovery occurred after normal diet was instituted supplemented in one patient with potassium salt.

muscle pattern more than a liver pattern. There were several indications that musculature was also involved sometimes in chronic alcoholism. Muscle necrosis with myoglobinuria was demonstrated in several patients. In rare cases there might also be necrosis of the calf musculature in chronic alcoholics. In four patients liver biopsy showed normal histological findings, without fatty degeneration, in spite of the fact that these patients had appreciable transaminase elevation. Probably liver cell necrosis, manifested in an increase in transaminase activity, was the earliest sign of liver damage in chronic alcoholism and preceded the fatty degeneration of the liver.

ACTH-Treatment of Acute Viral Hepatitis.—O. Naglo and co-workers (*Acta med. scandinav.* 165:167-171, 1959) treated 50 patients who had acute uncomplicated viral hepatitis with ACTH. No differentiation was made between patients with infectious hepatitis and those with inoculation hepatitis. Only patients aged between 15 and 60 years and who had a serum bilirubin value of 3.0 mg. or more per 100 ml. were included. The series was divided into an ACTH-treated and a control group, each group consisting of 25 patients. The mean age of the ACTH-treated group was 36.0 and of the controls 28.6 years. All patients who received ACTH showed decreasing serum bilirubin levels, while among the controls an increase occurred in three patients. The mean of the serum bilirubin level decreased more rapidly in the treated group than in the controls, but no significant difference could be demonstrated. The thymol turbidity also showed a more rapid decrease in the treated group. This difference was significant. A bilirubin level of 2 mg. per 100 ml. or less was reached within a shorter period in the treated than in the control group, as was a sulfobromophthalein level of 10% or less in the sulfobromophthalein retention test.

The difference was, however, not significant. The advantages of the ACTH treatment, however, seemed to be counteracted by the risk of side-effects. Furthermore patients with acute viral hepatitis, with few exceptions, were completely restored to health by the usual methods of treatment. Therefore routine ACTH or cortisone treatment did not seem to be justified. The question as to the effect of these hormones in connection with fulminating or in otherwise complicated cases of acute hepatitis or as to their ability to prevent chronic hepatitis or cirrhosis was perhaps of greater practical importance. It had been emphasized that the adrenals in infectious conditions and particularly in liver affections were subject to deficient function. Consequently, the authors concluded that direct substitutional therapy with cortisone seemed to be preferable to treatment with ACTH.

Alcohol and Driving.—A Medical Research Council memorandum described experiments designed to determine the effect of small doses of alcohol on a skill resembling the driving of an automobile (Medical Research Council Memorandum 38, Her Majesty's Stationery Office, 1959). Investigations were also made on individual variations in response to alcohol, particularly in relation to personality differences, and on the comparison of methods of estimating blood alcohol by Professor Drew. The subjects were automobile drivers of high intelligence and were moderate or occasional drinkers. They were tested on an apparatus with all the internal fittings of an automobile that appears to the driver to be passing along a winding tree-fringed road. Personality tests were made on the drivers and driving tests carried out both before and after the consumption of graded amounts of alcohol or placebos. The amount of alcohol consumed corresponded to 0.20, 0.30, 0.50, and 0.65 Gm. per kilogram of body weight. During the tests an automatic record was made of speed, tracking errors, curb bumpings, steering wheel and acceleration movements, brake applications, and gear changings. Samples of blood, urine, and breath were taken every half hour for alcohol estimation.

Tests on breath samples showed that the amount of alcohol in the breath, as estimated by the drunkometer and breathalyzer, gave good agreement with blood alcohol figures. The results showed a steady decline in driving skill with increasing alcohol consumption. There was a deterioration in driving skill of 12% when the blood alcohol level registered 80 mg. per 100 ml. Steering and tracking were also adversely affected, resembling the effects produced by fatigue. After ingestion of alcohol, extroverts drove on with maintained speed and many errors; introverts either slowed down appreciably or speeded up. The effect of the alcohol persisted for two hours. Age, sex, drinking habits, and driving experience showed no relation to individual differences in response to alcohol. Even the smallest amount of alcohol detectable caused measurable deterioration in skill.

Professor Drew said that he was in favor of chemical tests of urine or blood for determining whether a person who had indulged in alcohol was fit to drive. He said that it was impossible to set a level of alcohol at which everybody could be stated to be drunk. Clinical tests of drunkenness, tiredness, or lack of oxygen may be unreliable because a person can pull himself together for a while during the performance of the test. A definite level of blood alcohol should be set, above which a person should be considered legally unfit to drive. At the moment, all that the courts require is evidence that a person is sufficiently under the influence of alcohol to be unfit to drive. A critical blood alcohol level should be defined for legal purposes. Experience would show at what alcohol level drivers were getting involved in accidents, and the level could be lowered if necessary.

Lawyers and the press, however, are not in favor of convictions of drunkenness on the basis of blood alcohol levels. They say that while a high, low, or zero alcohol level is a guide to the court, most cases fall between, and personal idiosyncrasies are such that the courts would have little valid guidance. Adoption of a standard level would really mean that no one should consume any alcohol within a few hours of driving.

Freezing Point of Skin.—The determination of the freezing point of human skin is important to persons suffering from exposure in ice-cold sea water or arctic surroundings. Kestinge and Cannon determined the freezing point of the skin of the fingers, recording the temperature by means of a thermocouple of copper and constantan wire applied to the skin under several layers of adhesive tape (*Lancet* 1:11, 1960). The fingers were cooled by immersion in brine of the same composition as sea water, which freezes at −1.9 C, or by a cooling spray of a quickly evaporating solvent. Freezing was considered to have occurred when the finger was white and felt and sounded hard when tapped with a piece of wood and when the cooling curve revealed a sudden increase in temperature. Tests made on 11 subjects disclosed that the freezing point of skin is between −0.53 and −0.65 C. Repeated experiments on the same subjects caused hyperemia and tenderness of the fingers, followed by blistering and sloughing of the skin. These results show that, contrary to general belief, human tissues can freeze at the temperature of freezing sea water and that as a result they can sustain injury. It is important to provide sufficient protection to keep the skin temperature at more than 1 C (above water temperature) when immersion in freezing sea water occurs.

Serum Fatty Acids and Heart Attacks.—Many fatal heart attacks, while demonstrably due to ischemic heart disease, present no recent lesions in the myocardium or arteries to account for sudden heart failure. In a survey in which enzyme tests were used to elucidate the nature of these attacks, Enticknap also determined the serum fatty acid level (*Lancet* 1:32, 1960). The pathological diagnoses were simple coronary atherosclerotic narrowing or occlusion, fibrosis of the myocardium without recent change or thrombosis of the arteries, myocardial necrosis with or without accompanying coronary thrombosis, and arterial thrombus without gross myocardial change. In these four groups, comprising 50 cases, the serum fatty acid levels were 14.2, 12.6, 15.5, and 16.1 mEq. per liter respectively. The mean value was 14.7 mEq. per liter, whereas that of 57 controls of similar age was 9.9. The difference was highly significant. Most of the values higher than 17 mEq. per liter were from patients with ischemic heart disease. This suggests that high levels of serum fatty acids may be a factor in the causation of this condition.

New Analgesic.—Results of trials with a new analgesic, chlorthenoxazin, were described by Wilson and co-workers (*Brit. M. J.* 1:36, 1960). Screening tests on mice showed that on a weight-for-weight basis it had twice the analgesic activity of aspirin and also possessed antipyretic and anti-inflammatory action. Estimation of metabolite levels by paper chromatography indicated that in man maximal levels of chlorthenoxazin are present seven hours after ingestion. Aspirin levels reach a peak in three hours.

The analgesic was evaluated by a double-blind trial in patients suffering from joint pains due to osteoarthritis. Tablets containing aspirin, caffeine, and codeine (compound codeine tablets, B. P.) were used as a control. The results showed that the new drug and control did not differ significantly. Further tests were made with chlorthenoxazin and acetophenetidin, the analgesic action of which is equivalent to that of compound codeine tablets. During the trials, which lasted 18 months, no toxic effects from the new drug were seen. Its advantage over aspirin is that it does not cause gastrointestinal bleeding, and the lethal dose is much larger. In Britain, 177 deaths occur annually as a result of aspirin poisoning. Since the lethal dose of chlorthenoxazin in man is of the order of 1,000 tablets, the chances of suicide or accidental poisoning from it are remote.

Vital Statistics.—The population of England and Wales has been increasing by an average of 180,000 a year since 1951 (Registrar General's Statistical Review for England, part 3, Her Majesty's Stationery Office, 1959). About 106 boys were born for every 100 girls, but the death rates for males were higher than for females in all age groups. At ages from birth to 4 years there were 1,053 boys per 1,000 girls, at ages 30 to 34 the numbers were about equal, at ages 60 to 64 there were 770 men per 1,000 women, and at ages 75 and over there were nearly twice as many women as men.

The number of deaths from all forms of tuberculosis was 4,785, or 11% less than in the previous year. The number of deaths from pulmonary tuberculosis decreased by 12%, but for the first time in many years there was a rise in the number of deaths from extrapulmonary tuberculosis. There were no deaths from respiratory tuberculosis in the group 9 to 14 years of age. Many more men than women suffered from tuberculosis. The rate per 1,000 population was 82 for men and 49 for women. Over 3,500,000 mass radiography examinations were made. These were responsible for picking muscle pattern more than a liver pattern. There were several indications that musculature was also involved sometimes in chronic alcoholism. Muscle necrosis with myoglobinuria was demonstrated in several patients. In rare cases there might also be necrosis of the calf musculature in chronic alcoholics. In four patients liver biopsy showed normal histological findings, without fatty degeneration, in spite of the fact that these patients had appreciable transaminase elevation. Probably liver cell necrosis, manifested in an increase in transaminase activity, was the earliest sign of liver damage in chronic alcoholism and preceded the fatty degeneration of the liver.

Further tests were made with chlorthenoxazin and acetophenetidin, the analgesic action of which is equivalent to that of compound codeine tablets. During the trials, which lasted 18 months, no toxic effects from the new drug were seen. Its advantage over aspirin is that it does not cause gastrointestinal bleeding, and the lethal dose is much larger. In Britain, 177 deaths occur annually as a result of aspirin poisoning. Since the lethal dose of chlorthenoxazin in man is of the order of 1,000 tablets, the chances of suicide or accidental poisoning from it are remote.

Vital Statistics.—The population of England and Wales has been increasing by an average of 180,000 a year since 1951 (Registrar General's Statistical Review for England, part 3, Her Majesty's Stationery Office, 1959). About 106 boys were born for every 100 girls, but the death rates for males were higher than for females in all age groups. At ages from birth to 4 years there were 1,053 boys per 1,000 girls, at ages 30 to 34 the numbers were about equal, at ages 60 to 64 there were 770 men per 1,000 women, and at ages 75 and over there were nearly twice as many women as men.

The number of deaths from all forms of tuberculosis was 4,785, or 11% less than in the previous year. The number of deaths from pulmonary tuberculosis decreased by 12%, but for the first time in many years there was a rise in the number of deaths from extrapulmonary tuberculosis. There were no deaths from respiratory tuberculosis in the group 9 to 14 years of age. Many more men than women suffered from tuberculosis. The rate per 1,000 population was 82 for men and 49 for women. Over 3,500,000 mass radiography examinations were made. These were responsible for picking up 22% of all cases of pulmonary tuberculosis that were reported. The highest incidence of the disease was found in those referred to the mass radiography units by general practitioners.

The number of deaths from cancer, 94,017, was greater than in any previous year, the number of deaths of men exceeded the number of deaths in women by 6,095. The greatest increase in both sexes was in cancer of the lung, which accounted for nearly 33% of all the deaths from cancer in men but only 6% of such deaths in women. There were 188,630 deaths from diseases of the circulatory system and 73,669 from vascular lesions of the central nervous system, which together accounted for just over 50% of all deaths. There were 21,561 deaths resulting from accidents and violence.

Sarcolysin Peptides.—In 1956, the antimitotic, sarcolysin, was used by Larionov and other Russian workers for treatment of Hodgkin's disease and reticuloses. Since then, these workers have synthesized a number of peptides on the assumption that these may act as carriers of the chloroethylamino groups of nitrogen mustard and may be more effective in reaching the tumor site than sarcolysin itself. Larionov and Perevodchikova (*Brit. M. J.* 1:109, 1960) used the peptides of N-formyl-sarcolysin, which showed antitumor activity in mice and did not inhibit hemopoiesis as much as sarcolysin itself. Peptides of N-acetyl-sarcolysin and N-acetyl-sarcolysin-valine ethyl ester (asaline) were made, and asaline was given to 19 patients at the Institute of Experimental Pathology and Cancer Therapy in Moscow. A daily dosage of 1 to 2 Gm. was used. The only tumors in which asaline produced any regression were seminoma metastases, reticulosarcoma, Ewing's tumor, myelomatosis, and plasmocytoma. Partial regression occurred and relapses resulted within three months of stopping treatment. The effect on Ewing's tumor was only transient. Asaline was well tolerated and no depressant effect on hematopoiesis was observed.

Hypothyroidism and the Nervous System.—At a meeting of the Royal College of Surgeons in London, Prof. E. J. Wayne stated that reaction time was increased in 46 of 50 untreated patients with hypothyroidism and decreased in all patients who were treated. Dexamphetamine was found to shorten the reaction time in such patients. Prolongation of reaction time was thought to result from changes in cerebral function rather than in nerve conduction. Fifty-six percent of the patients complained of numbness and tingling, which occurred mainly during use of the hands or during the night.

Workers in Wayne's laboratory made an electromyographic study of this phenomenon and found that the median nerve was usually involved and, in addition to the paresthesia, there was often some motor paresis and slowing of conduction of the median nerve in the region of the wrist. The findings indicated compression of this nerve in the carpal tunnel, similar to that found in the carpal tunnel syndrome. Accumulation of myxedematous tissue under the flexor retinaculum is the cause of the compression. This impairment of conduction seemed to occur more in overweight persons, and it was relieved after treatment with thyroxin. Wayne suggested that many unnecessary operations for relief of the carpal tunnel syndrome might have been avoided if the patients were first examined for manifestations of hypothyroidism.

Amebic Dysentery.—Antibiotics have proved useful in treatment of amebic dysentery. Tetracycline, chlortetracycline, and oxytetracycline are almost equally effective in a dosage of 1 Gm. daily. Their main disadvantage is that the relapse rate is high and that they fail to prevent liver involvement. Powell and co-workers showed that their action is potentiated by such quinoline derivatives as chloroquine and diiodohydroxyquin (*Lancet* 1:76, 1960). They treated 125 Africans who had amebic dysentery with these drugs. The patients were divided into groups and treated with (1) chloroquine, diiodohydroxyquin, and suboptimal doses of tetracycline; (2) diiodohydroxyquin and suboptimal doses of tetracycline; (3) chloroquine and suboptimal doses of tetracycline; and (4) diiodohydroxyquin and chloroquine. Although addition of either chloroquine or diiodohydroxyquin alone to tetracycline had little effect, a combination of the two drugs with the antibiotic resulted in an immediate cure rate of 94%. The cure rate of a combination of diiodohydroxyquin and chloroquine was 60%. The use of chloroquine prevented liver complications. The rate of healing of rectal ulcers was slower when tetracycline was used in suboptimal doses, but the end-result was satisfactory.

Prolonged Survival of a Marrow Transfusion.—Reports have been made on patients afflicted with acute leukemia who have been treated with large doses of total body irradiation followed by marrow transfusions, but in none has the donor marrow survived for more than two or three weeks. Beilby and co-workers observed a patient in whom a marrow transfusion persisted after nearly 10 months although it resulted in the blood-group picture of a red cell chimera (*Brit. M. J.* 1:96, 1960). The patient was a woman who had had Hodgkin's disease for about five years and had received two courses of irradiation. After five months' treatment with chlorambucil there was evidence of marrow failure and, in spite of blood transfusions, the hemoglobin level decreased to 7.6 Gm.%, the leukocyte count to 25, and the platelet count to 5,000. The patient's condition was critical. From the sternum and ischia of her sister, 40 ml. of marrow was obtained, and after dilution, centrifugation, and removal of the fat, it was injected intravenously into the patient. It was estimated that about 1.1×10^{11} nucleated erythrocytes were transfused.

The patient started to get better on the next day and steadily improved. Three weeks later the hemoglobin level was 66%, the leukocyte count was 2,620, and the platelet count was 170,000. Sixteen weeks later the hematologic findings were within normal limits. The blood group of the patient and donor had been determined before the transfusion. Four months later there was evidence that the patient had developed new blood-group antigens identical with those of her sister. It was considered that these were due to the proliferation of the transfused marrow, although somatic mutation from irradiation could not be ruled out. The transfusion was responsible for the production of 24% of the patient's erythrocytes.

It is believed that this is the first example of prolonged survival of a marrow graft in a human being. This may have been due to the destruction of the patient's antibodies by repeated irradiation and treatment with chlorambucil.

Neurological Centenary.—The National Hospital, Queen Square, will celebrate its centenary from June 20 to 25. The occasion will be marked by neurohistorical presentations and a wide range of social functions. In addition, the hospital will extend a cordial welcome to neurologists, neurosurgeons, and others to participate in these activities. Those who wish further details can obtain them from Dr. Macdonald Critchley, National Hospital, Queen Square, London, W. C. 1.

Antibiotics and Staphylococcus.—According to Prof. Ronald Hare (*Practitioner* 184:80, 1960) it was not so much the appearance of antibiotics as the disappearance of treatment at home that created the current staphylococcic problem. In a well thought out paper he pointed out the fallacies in the widely disseminated view that in the act of becoming resistant to an antibiotic a Staphylococcus becomes more aggressive. Resistance is a result of a single mutation, whereas for aggression several mutations of a different sort would be required. In support of this thesis the author noted that, although antibiotic-resistant staphylococci may be present in noses of most inmates of a surgical ward, it is only those belonging to certain bacteriophage types that produce infection. This suggests that it is not ability to resist antibiotics as much as membership in certain bacteriophage types that confers pathogenic power on a Staphylococcus.

In England members of only three bacteriophage types (80, 75/77, and 47/53/75/77) are responsible for over 50% of the infections that occur in surgical wards while types 80, 52A/79, 71, and 7/47/53/54/75 are the predominant organisms causing infection in maternity wards. These epidemic strains produce most of the infections and are apparently endowed with sufficient aggressive ability to oust other strains of staphylococci that may be present in the noses of nurses or patients at the time they enter a hospital in which such epidemic strains are producing infection.

Although the resurgence of staphylococci within the last 10 years may have been due to the activities of certain special strains, it is difficult to believe that similar strains did not exist before then. Prof. Hare suggested that they were less of a problem before the introduction of antibiotics than they are today because of changes not in the parasite but in the treatment and surroundings of the host. Some of the new drugs, such as the corticosteroids, depress ability to resist infection. There is more surgical interference, and many of the operations are almost designed to increase the risk of infection in that they last a long time, involve the exposure of large areas of tissue, and necessitate the presence of many people. Furthermore the modern tendency is to concentrate virtually all the seriously ill persons in large wards that are in close proximity to similar wards, the whole enclosed within the walls of an enormous hospital. This is a very different environment from that of the private home, small cottage hospital, or nursing home where much illness was previously treated. An organism so well endowed as the Staphylococcus to take advantage of any opportunity of parasitizing the noses of normal persons and producing cross-infection has chances of causing mischief in a modern hospital that were denied to its ancestors.

Children and Colored Tablets.—The annual report of the health officer for Plymouth included an article by Drs. T. Forrest and Hugh Jolly on an investigation they made to discover which color is preferred by children. The purpose of the investigation was to find out whether there was any color which, used for medicinal tablets, would help to reduce the incidence of accidental poisoning in children. The investigation, which included 613 children 1 to 8 years of age, showed that bright colors were the most popular. Magenta was easily the winner, being chosen by 104 children, followed by pink (74), blue (66), orange (64), brown (61), white (52), black (45), and wine (44). The low position of white was attributed to the fact the children recognized the white ones as pills and not candy. The authors concluded that tablets should be white so they would be less likely to be mistaken for candy.

Home Confinements.—If the experience of Ilford, one of the numerous townships that make up Greater London, is typical of the country as a whole, English women prefer to give birth at home rather than in a hospital. According to Gordon and Elias-Jones (*Brit. M. J.* 1:52, 1960), of 336 mothers who had had at least one baby born in a hospital and one at home, 80% preferred home confinement, 14% hospital confinement, and 6% had no preference. Of the 269 mothers expressing preference for home confinement, 13 could give no reason for their preference. The remaining 256 gave 338 individual reasons for their choice. Of these, 228 referred to separation from home, husband, or family. Of the 48 who preferred hospital confinement, 9 could give no reason for their choice. The remaining 39 gave 49 reasons, of which the two most frequent were that they obtained more rest in the hospital (23) and that it was safer to have a baby in the hospital (11).

Academy of Forensic Sciences.—At a meeting last year it was decided to establish a British Academy of Forensic Sciences. This academy is now formally established. Its objects are to encourage the study, improve the practice, and advance the knowledge of the forensic sciences; to hold meetings; to publish such material as is calculated to further the objects of the academy; and to do all things that may widen, improve, and develop the education and knowledge of those engaged in the forensic sciences and of the public. The academy will have three main sections—law, medicine, and science. A research committee has also been formed. The secretary of the council of the academy is Dr. F. E. Camps.

Amateur Boxing.—In 1953, a medical welfare scheme was introduced by the London Amateur Boxing Association. The aim of the scheme was to ensure that only medically fit boxers were allowed to compete, that they received adequate medical attention, and that they ceased boxing for a sufficient time to allow them to recover from injuries, if any, sustained during a bout. Since the scheme was introduced there have been no deaths among amateur boxers in the London area. From 1946 to 1959 there were seven deaths due to boxing among amateurs in Great Britain. Since all were due to cerebral hemorrhage, resulting from a blow to the head and a fall backwards, the association introduced a resilient under cover to the ring. In two of the fatal cases the boxers were found to have very thin skulls. These are some of the facts produced in "Medical Aspects of Amateur Boxing" issued by the London Amateur Boxing Association.

From October, 1955, to April, 1956, there were about 300 tournaments, representing some 3,000 contests, under the control of the London Amateur Boxing Association. About 3,000 boxers were involved. There were no skull fractures, and injuries elsewhere in the body were few. One boxer suffered a spontaneous pneumothorax, another fractured a fibula, and there were 11 cases of fractured metacarpals. There was not a single case of fractured nose or serious ocular injury. Twenty-nine boxers who had suffered severe concussions or who had been knocked out more than once were picked out for special study. Their ages ranged from 17 to 26 years. The electroencephalogram was normal in all, and neurological abnormalities were few. Three had retrograde amnesia of up to one hour, and in seven the post-traumatic amnesia lasted from one-half to three hours. The maximum period of unconsciousness was one-half hour. The figures for the 1956-1957 season, when there were 4,350 contests, were similar. There were 60 knock-downs, and nine boxers were unable to continue a further round. There were two fractures of the hand, one of the thumb, and two of the nose. There were five general injuries, such as sprains and abrasions. Facial cuts totaled 57. Seventeen boxers were referred for neurological and electrocardiographic examination, and all results were negative.

In an introductory chapter, called Boxing and Health, Dr. J. Sharp Grant pointed out that although thousands of amateur contests take place every year in Great Britain, there are few serious injuries—far fewer, proportionately, than in rugby or association football or in other athletic events. In his opinion, the physical training, road work, and moderation in smoking and drinking required of a conscientious boxer lead to physical fitness and good health. As a deterrent to juvenile delinquency it can play an important part by being the outlet for psychopathic traits—such as aggressiveness and feelings of inadequacy and inferiority.

Phencyclidine in Anesthesia.—Phencyclidine (Sernyl) is the most potent general analgesic agent which has been used in clinical medicine, according to M. Johnstone and co-workers (*Brit. J. Anaesth.* 31:433, 1959). They used the drug in 42 patients who underwent herniorrhaphy, hemorrhoidectomy, cholecystectomy, mastectomy, thyroidectomy, and prostatectomy. It was highly effective for pain arising in skin, subcutaneous tissue, muscle, bone, joints, pelvic floor, and perineum, but it did not give complete relief from pain arising in the peritoneum, celiac plexus, kidney, and testis. It has advantages over other sedatives and analgesics as it does not depress cardiovascular and respiratory functions and it can be safely used in treating elderly patients when opiates and other agents are contraindicated. Another advantage is that doses sufficient to permit such painful operations as hemorrhoidectomy or skin grafting fail to cause any depression of pharyngeal and laryngeal reflexes, thereby eliminating the risk of respiratory obstruction from anatomic causes.

The usefulness of the drug, however, is limited by the excitation which it sometimes causes and which may persist for 12 hours after a single dose. This excitation is said to have a disturbing resemblance to acute toxic psychoses, but it has not been encountered in elderly patients. Phencyclidine is, therefore, considered a safe and effective analgesic agent in the following circumstances: (1) as the sole anesthetic agent for elderly hospitalized patients undergoing relatively superficial operations and endoscopies when anesthesia with conventional agents is considered inadvisable; (2) postoperatively as it provides excellent relief from pain arising in skin, muscle, bone, perineum, and pelvic floor (excitement is suppressed by the previous administration of halothane-oxygen); and (3) as a useful supplement to conventional anesthesia in operations involving the perineum and pelvic floor.

Ambulation After Hematemesis.—Patients bleeding from a peptic ulcer who are mobilized as soon as massive hemorrhage stops did as well as those kept in bed, according to Pollard and Summerskill (*Brit. M. J.* 1:171, 1960), who investigated the problem in a series of 66 patients. Half of them were allowed to sit out of bed for three hours on the day after bleeding ceased and were ambulatory all day by the third day. The other 33 were kept in bed for a week after the bleeding ceased. No ill effects were noted as result of early ambulation. Rapid mobilization was particularly advantageous from the social and economic aspects. The saving in hospital beds alone in this series of patients was calculated to have been equivalent to a saving of $9,100 during the course of the year covered by the investigation.

Control of Lipemia in Diabetic Children.—The effects of feeding unsaturated fats on the serum lipid levels were studied by H. B. Salt and coworkers (*Lancet* 1:71, 1960) in 13 diabetic children whose ages ranged from 2 to 14 years and in whom the condition was being controlled with insulin. Eight were given an emulsion of sunflower-seed oil which led to a lowering of serum β-lipoprotein, esterified fatty acids, phospholipid, esterified cholesterol, and triglyceride concentrations to below the control levels. Five were given a diet in which most of the usual (animal) fat had been replaced by corn oil. The isocaloric change from the control to the corn oil diet led to a decrease in esterified cholesterol and β-lipoprotein to about 60% of the initial control levels, esterified fatty acid levels to about 75%, and unesterified cholesterol and phospholipid levels to about 80%. Although the mechanism whereby unsaturated dietary fat lowers the level of serum β-lipoprotein is not clearly understood, the authors suggested that their observations indicate that a transfer of lipid from β-lipoprotein to α-lipoprotein might be an intermediate stop, since the α-lipoprotein level was seen to increase transitorily at the time when the β-lipoprotein level was being lowered.

In two patients on the corn oil diet the effects of lessening the dosage of insulin were observed. The cholesterol and phospholipid levels remained low, but the diet did not prevent an increase in triglyceride, esterified fatty acid, and the chylomicron lipid fractions. This finding has a special significance for the diabetic in whom the disorder of carbohydrate metabolism, unless constantly well controlled, leads to an increase in cholesterol, phospholipid, and β-lipoprotein levels under usual dietary conditions. The hyperlipemia of diabetes was similar to that preceding atheroma in older nondiabetics and might play an important part in the causation of the vascular complications of the disease. Although hyperlipemia can no doubt be prevented by perfect control of the diabetes with insulin, such control is rarely, if ever, maintained over long periods. It was therefore urged that, as an additional controlling measure, a diet rich in unsaturated fat deserves long-term trial.

Dumping Syndrome.—In the *British Medical Journal*, Jan. 16, Dr. Le Quesne and co-workers set out to estimate changes in plasma volume and to discover why some patients have dumping symptoms with a given decrease in plasma volume while others do not. By applying tourniquets around the thigh to simulate loss of blood, they were able to show that those patients who experienced symptoms of dumping, but who had a small decrease in plasma volume, were sensitive to similar small changes produced by thigh tourniquets. Likewise, patients with large changes in plasma volume but who did not experience dumping were immune to the effects of thigh tourniquets. Results of other workers showing that dumping can occur without any significant change in plasma volume need explanation, as does the fact that balloon distension alone can cause characteristic dumping.

The authors showed that a change in plasma volume was directly proportional to the rate at which the blood sugar level increased in the first 10 minutes after oral ingestion of a standard glucose drink. One explanation was that, in the patient who experienced dumping, gastric emptying was rapid and therefore glucose passed quickly into the jejunum and was absorbed rapidly. The authors suggested that the rapid increase in blood glucose level was the cause rather than the effect of dumping. They argued that this quick increase in blood sugar level interfered osmotically with the fluid shift across the jejunal epithelium and caused a greater and more rapid transfer of fluid into the lumen of the intestine. To account for the great variation in the frequency of dumping, they suggested that some people are metabolically different from others in that they do not metabolize blood glucose rapidly and therefore develop a high concentration shortly after ingesting a carbohydrate meal. Patients with dumping symptoms were given insulin in varying doses and found that the changes in plasma volume were significantly decreased as a result. They also found that dumping symptoms were diminished by the administration of insulin before a meal.

Investigations, however, did not show directly that there was a rapid shift of fluid across the jejunal mucosa in patients who had a gastrectomy. The evidence was by inference from the change in plasma volume. This change could be due to pooling of blood in the venous system instead of actual loss of fluid across the jejunal wall. If a high blood sugar level is one of the factors in inducing dumping, it could be reproduced experimentally, in those patients who did not have symptoms, by intravenous administration of glucose at the same time as the meal was taken. There are a few practical steps that may be taken to prevent or diminish dumping. The incidence was less after a Billroth 1 than after a Polya gastrectomy, and it was less after the Polya operation if a narrow stoma was made. If symptoms are incapacitating after a Polya gastrectomy, it may be justifiable to convert it to a Billroth 1, though this is not always successful. A patient who experiences dumping symptoms after operation should be reassured that they will disappear, as only 5% are affected after two years. He will gain relief if he lies down when eating and if he takes fluid between instead of during meals. No drugs influence the symptoms in any way.

Teaching Social Medicine.—In a report published by the British Medical Students' Association on teaching social medicine in 17 British medical schools, it is noted that in three schools this subject is not taught at all. The number of lectures given ranged from 0 to 60. Thirteen schools arranged visits as part of the social medicine course which included trips to industrial works, canteens, public health centers, geriatric units, special schools, and special clinics. The subject matter taught was based on medical sociology, epidemiology, and National Health Service administration. Only a minority of schools included any mention of international health service organization. In five schools no examination of any kind was held in social medicine, and two held a class or terminal examination on completion of the course. In 10 schools social medicine formed a part of the degree examination. On the subject of examinations, the association believed that only when an examination was held in a particular subject was it guaranteed that most of the students would pay sufficient attention to the teaching and thus benefit from it.

Student opinion on the subject was obtained from 15 medical schools. In 10 schools the view was that the student should be given an insight into those social aspects which affected the health of the community. In the remainder the opinion was that social medicine ought not to be given a prominent place in undergraduate education and that the different aspects taught could be integrated with other subjects. The final recommendation was that social medicine should be taught as an individual subject but that the course ought not be too detailed. More emphasis, however, should be placed on the social aspect of clinical cases in the wards. In spite of the views expressed about the importance of examinations as a stimulus to interest, the final recommendation was that the standard of knowledge required ought not to be such as would make social medicine a subject in the final examination. As a compromise, the view was expressed that an integrated examination in social medicine and infectious diseases would meet the requirements.

Teaching of Psychiatry.—Teaching of psychiatry and psychological medicine was the subject of another report published by the British Medical Students' Association. Of the 17 medical schools covered by the report, 6 indicated that no teaching in normal psychology was given. In the teaching of psychiatry the number of lectures given ranged from 7 to 32, excluding lectures on normal psychology. In most of the schools lecture-demonstrations were arranged, but the number of compulsory ward rounds varied from 0 to 16. Nine of the schools indicated that no formal inpatient ward rounds were arranged. Attendance at psychiatric outpatient clinics ranged from 0 to 26. In three schools arrangements were made for students to reside in psychiatric units, but in no school was there a period of compulsory attendance as a student in a mental hospital or unit.

A new scheme for the teaching of psychiatry was introduced in the University of Sheffield last autumn. In the preclinical period, 10 lectures on psychology are given by the head of the psychology department, and three to six lecture-seminars are given on normal and abnormal psychology. In the clinical course there is an introductory lecture during the introductory clinical course, followed by two social psychiatry seminars as part of the social medicine clerkship in the fourth year. In the fourth year there is also a period of clerkship in the department of psychiatry as part of a neuropsychiatric clerkship of one month, and in the fourth and sixth years there are weekly ward rounds by the professor of psychiatry in the medical wards with junior and senior medical clerks. In the fifth year there are two lectures to students doing their obstetrics, and in the sixth year there are weekly lecture-demonstrations in mental hospitals.

There is to be an obligatory question on psychology in the final examination and a voluntary examination and prize examination in psychiatry in the fifth year. The final examination in medicine is to become an examination in medicine, including psychiatry, and the professor of psychiatry is to examine with the professor of medicine. There will be one or two obligatory questions in the written medical examination and probably an obligatory clinical examination.

CORRESPONDENCE

STATEMENT OF AMERICAN CANCER SOCIETY ON CIGARETTE SMOKING AND LUNG CANCER

To the Editor:—The following statement was approved by the board of directors of the American Cancer Society on Jan. 21, 1960.

"In 1959 the death rate from lung cancer among men in the United States was over 10 times as high as it was in 1930. The disease is now one of the most common and most lethal of all forms of human cancer. This tremendous increase in number of deaths and the reported association of cigarette smoking with lung cancer has led the American Cancer Society to pursue an aggressive program of research on lung cancer and to disseminate new evidence bearing on the subject to the medical profession and to the public.

"In October, 1954, the board of directors of the American Cancer Society declared that 'the presently available evidence indicates an association between smoking and lung cancer.' In November, 1957, the board reviewed the report of the study group on smoking and health and agreed with its conclusions that 'the evidence of a cause-effect relationship is adequate for considering the initiation of public health measures.'

"The board now believes that it has a further responsibility both to the medical profession and to the general public to state that in its judgement the clinical, epidemiologic, experimental, chemical, and pathological evidence presented by the many studies reported in recent years indicates beyond reasonable doubt that cigarette smoking is the major cause of the unprecedented increase in lung cancer. The board further believes that all organizations and agencies concerned with cancer have a responsibility to formulate programs of action based on this information in order to reduce the incidence of this largely preventable disease.

"The strong association between cigarette smoking and lung cancer has been established by an extraordinarily large amount of evidence. Twenty-eight studies have indicated that a history of smoking is more common among lung cancer patients than among those without the disease. Three follow-up studies of smokers and nonsmokers have demonstrated that the death rate from lung cancer among cigarette smokers is about 10 times as great as among nonsmokers. Epidemiologic studies indicate also that cigarette smoking is associated with about 75% of all cases of lung cancer. The incidence of the disease increases with the amount of cigarette smoking, and no threshhold below which lung cancer will not occur has been identified.

"The fact that the association is one of cause and effect is well supported by several types of evidence. For example, in experiments condensates of tobacco smoke have produced cancers on the skin of mice and rabbits. After experimental exposure of mice to tobacco smoke or its condensates, abnormal cellular growths have been reported on mouse bronchial epithelium, in tissue cultures, and on the cervix. Cilia, one of the lung's major defenses against inhaled particulate matter, have been shown to be paralyzed by tobacco smoke. At least 10 chemical agents that have been identified in cigarette smoke have caused the development of cancer in laboratory animals. Studies of pathological changes in bronchial tubes of smokers have shown that abnormal cellular changes in the bronchi of the lung increase in degree and frequency as the amount of cigarette smoking increases and that in nonsmokers these changes are scarcely present at all.

"Some studies indicate that cigarette smoking is not the only causative factor in lung cancer. Certain occupational causes are recognized, and other factors such as air pollution have been implicated. The evidence indicates that the development of most cases of lung cancer is a complicated process in which cigarette smoking is the major controllable, though possibly not the only, factor. The existing evidence does not support the alternative hypotheses suggested to explain the exceptionally high degree of association of cigarette smoking with lung cancer.

"In presenting its conclusions the American Cancer Society recognizes that cigarette smoking is a personal habit and that the risk involved is at the option of the individual. The Society, nevertheless, believes that it has a responsibility to do everything possible within its established policies to reduce the alarming and rapidly increasing number of deaths from lung cancer. To that end the Society plans to continue support of research on lung cancer and to promote the widespread dissemination of information regarding causes and prevention of the disease to physicians and to the public with primary initial emphasis on teen-agers."

MEDICAL LITERATURE ABSTRACTS

INTERNAL MEDICINE

Catheterization of the Left Heart by the Percutaneous Femoral Route: Technique and Results in Acquired Cardiopathies. M. Mouquin, E. Chartrain, J. Y. Pierron and G. Bacquet. Presse méd. 67:2081-2084 (Nov. 28) 1959 (In French) [Paris].

The technique and advantages of catheterization of the left heart by way of the percutaneous femoral artery are described. The authors have performed 200 such catheterizations without considerable accident. They have used the method successfully in children even younger than 10 years of age, but have not used it in patients over 55 years, since it is contraindicated in older patients. Catheterization of the left heart is also contraindicated in patients with a severe cardiac or kidney condition or with fever and in those who are being treated with anticoagulants or show a positive iodine test. Treatment with antibiotics 2 days before catheterization is advisable. An iodine test is indispensable before the angiocardiography. The authors experienced failure in about 10% of the cases, but in the last 100 patients of the series observed, there were only 2 failures.

The authors point out that the main advantage of this method is to make possible a method of angiography that can provide data so far unobtainable by venous angiography. Catheterization of the left heart is especially useful in doubtful cases of mitral insufficiency in which commissurotomy is debatable.

Lipoproteins, Cholesterol and Serum Proteins as Predictors of Myocardial Infarction. I. H. Page and L. A. Lewis. Circulation 20:1011-1027 (Dec.) 1959 [New York].

The normal variability of lipoproteins and Cholesterol levels was studied in 6 healthy women, ranging in age from 20 to 50 years. Tests were made at weekly intervals for about 5 months. In 3 of the women the serum total cholesterol levels were stable, and in the other 3 much less so. Single measurements of cholesterol or lipoproteins can be dangerously misleading.

The authors also report the results of a 7-year study on 107 "normal" Cleveland executives who were examined annually; myocardial infarction developed in 11, and angina pectoris or coronary insufficiency in 6. This provided "before" and "after" data in the same patient. Little change in lipid levels was associated with these events, when the changes occurring during the first 2 months after infarction were ignored.

Serum lipoprotein and electrophoretic protein patterns were studied in 84 patients shortly after myocardial infarction and in 66 repeatedly, at 5-to-10-day intervals, for 3 or 4 weeks. Four of the patients were studied after a second infarction as well. Most patients within a week of infarction showed increased beta and gamma-2 globulins with moderate increase in fibrinogen. Some exhibited increase in –S 20-25 and in low-density (–S 40-70 and 70-400) lipoproteins as well as in the electrophoretic changes. Finally, a few had a progressive rise during the 2 or 3 weeks after infarction in low-density lipoproteins. Serum cholesterol value was higher in young male patients with infarction than in the oldest age group with infarction. Similar age trends did not occur in women. After a second infarction, the low-density lipoproteins increased just as after the first one. The electrophoretic and lipoprotein changes after each infarction were strikingly similar. There was little correlation, however, between the lipoprotein pattern and the severity of the infarction, as measured by the electrocardiographic and clinical evidence. Increase in gamma-2 globulin was usually greatest in patients with the most extensive myocardial damage.

Three months to 10 years after infarction the range of lipoprotein values tended to fall within normal levels, but continued to exhibit slight preponderance toward values higher than the mean "normal." As a group, patients with coronary atherosclerosis with myocardial infarction exhibit slightly elevated cholesterol and lipoprotein values.

Electrocardiogram in Tetanic Patients. L. R. Perez. Rev. Clín. españ. 74:20-25 (Oct. 15) 1959 (In Spanish) [Madrid].

The cause of death in tetanus is not always the asphyxia, which originates the functional spasms of the respiratory muscles, or the pulmonary complications or the hyperpyrexia; death may also be

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by persons in continental United States or Canada who subscribe to its scientific periodicals. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover 1956 to date for English language and 1958 to date for foreign language journals. No photoduplication services are available. No charge is made to members, but the fee for others is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

caused by myocardial involvement. The author reports on the results of the electrocardiographic study of 12 patients with tetanus, as part of an investigation stimulated by his observation of more than 70 tetanic patients. The analysis of the electrocardiograms taken periodically during the course of the disease revealed that in all the patients studied the electrocardiographic alterations occurred with identical characteristics. The most constant alteration was the flattening of the T wave in all the leads. Although the intensity of the alteration varied in the various leads, it was always more intense in lead 3 where the T wave appeared almost always inverted. Less constant was the widening of the QRS complex. These changes were not correlated to the intensity of the tetanic symptoms or to their complications. They appeared as early as the third day after the onset of the disease and steadily increased in intensity, lasting even for some time after the recovery. These findings raise the problem of determining whether the electrocardiographic changes correspond to a functional disturbance, to a metabolic alteration, or to a myocardial lesion caused by the toxin of tetanus. It is recommended that the possibility of a myocardial lesion be taken into consideration for the purpose of both prognosis and therapy in patients with tetanus.

Determination of Uropepsin as an Aid in the Differential Diagnosis Between Gastroduodenal Ulcer and Neoplasm of the Stomach. H. Cesnik. Arch. klin. Chir. 293:1-9 (no. 1) 1959 (In German) [Berlin].

In more than 1,000 determinations of uropepsin in patients with various diseases, it was noted that the urine of those with gastroduodenal ulceration generally had increased uropepsin values, whereas in those with gastric carcinoma the uropepsin levels were below normal. The possible differential diagnostic value of this difference in the uropepsin content of the urine was investigated at the surgical clinic of the University of Graz, in Austria, by the method of West, Ellis, and Scott. Comparative tests on the uropepsin excretion were made in 220 patients. The 50 persons in this group serving as controls were mostly patients who were about to be discharged from the hospital after a minor operation or accident. Of the 150 patients with gastrointestinal lesions, 50 had duodenal ulcers, 50 had gastric ulcers, and 50 had gastric neoplasms, all but 3 of which were malignant. The 5th group of 20 patients had been hospitalized because a gastrointestinal disorder was suspected.

The average uropepsin excretion in patients with duodenal ulcers was 201 mg. per 100 cc.; in patients with gastric ulcers, 144 mg. per 100 cc.; and in patients with gastric neoplasms, 69 mg. per 100 cc.; in persons without gastric lesions it was close to 100 mg. per 100 cc. The uropepsin values were above normal in 90% of the patients with gastroduodenal ulcers, and below normal in 90% of those with gastric neoplasms. A difficulty in the comparison between the pathological and normal values arises from the fact that, although in the individual patient the values are rather constant, they vary considerably from patient to patient. For this reason, the diagnosis of ulcer or carcinoma cannot be based exclusively on the uropepsin values, but the author feels that the uropepsin test is a valuable addition to the differential diagnosis for patients with gastroduodenal disorders.

Relationship Between Plasma and Extracellular Fluid Volume Depletion and the Antihypertensive Effect of Chlorothiazide. I. M. Wilson and E. D. Freis. Circulation 20:1028-1036 (Dec.) 1959 [New York].

The discovery of the antihypertensive action of chlorothiazide raised questions as to its mechanism of action, such as whether the hypotensive response was caused by salt depletion or some other factor. The importance of plasma and extracellular fluid volumes in the mechanism of the antihypertensive effect of chlorothiazide is disputed. The authors made studies on 20 male hypertensive patients, without symptoms of congestive heart failure or edema, who were hospitalized and placed on a standard diet containing 1.5 Gm. of salt per day plus a supplement of 3 Gm. of salt in tablet form. This supplied a sodium intake of approximately 75 mEq. per day. Most of these patients were under treatment with other antihypertensive agents, which were continued during the period of study. A 4-day period for acclimatization to the diet was instituted in order to obtain stabilization of body weight and electrolyte excretions as well as average basal blood pressure readings. Determinations of plasma and extracellular fluid volumes, serum electrolyte concentrations, and serum bicarbonate levels were carried out on the 5th day. Each patient was then given 500 mg. of chlorothiazide twice daily, and the studies were repeated after 3 to 8 (average, 6) days.

Plasma and extracellular fluid volumes decreased during the early phases of treatment. This was accompanied by a reduction of arterial pressure and body weight. Sodium losses could be accounted for on the basis of depletion of the extracellular fluid volume. Restoration of plasma volume, either with or without partial replenishment of sodium, reversed the antihypertensive effect of chlorothiazide. Withdrawal of chlorothiazide after 3 to 7 months of treatment was followed by an elevation of plasma volume and of the blood pressure. Significant reductions of plasma volume and body weight were not found after 6 months, and of extracellular fluid volume after 12 months, of therapy, even though the blood pressure remained reduced. However, the latter may not be a valid criterion of drug activity after long-term modification of the blood pressure level. The only significant change in serum electrolyte concentration was a reduction in serum potassium level. Serum bicarbonate levels were not altered. It is suggested that the decrease in plasma volume is an important factor in the initial antihypertensive effect. Reduction in tissue pressure, secondary to extracellular fluid volume depletion, could also contribute to this response.

Evaluation of Chlorothiazide Alone in the Treatment of Moderately Severe and Severe Hypertension. F. A. Finnerty Jr., J. H. Buchholz, J. Tuckman and others. Circulation 20:1037-1042 (Dec.) 1959 [New York].

The authors compared the effectiveness of alternate 6-month courses with chlorothiazide medication alone and with standard antihypertensive therapy in 11 patients with severe hypertension and in 30 patients with moderately severe hypertension. The results obtained were then compared with the effects of a 6-month period of treatment during which the patients received both chlorothiazide and standard antihypertensive therapy.

It was found that neither the administration of chlorothiazide alone nor the administration of ganglionic-blocking agents plus reserpine constituted effective treatment in the 11 patients with severe hypertension. However, the addition of chlorothiazide to ganglionic-blocking agents plus reserpine reversed the accelerated phase of hypertension in each of these patients. Once papilledema had cleared and retinal hemorrhages had regressed, it was possible to substitute hydralazine or veratrum for the ganglionic-blocking agents in these patients.

Chlorothiazide alone and veratrum or hydralazine plus reserpine were found effective in controlling the blood pressure in about half of the 30 patients with moderately severe hypertension. The addition of chlorothiazide to either of these agents resulted in satisfactory control of the arterial pressure in all the patients with moderately severe hypertension. Once a hypotensive effect had been attained with veratrum or hydralazine, these agents could be withdrawn, and antihypertensive therapy continued with reserpine plus chlorothiazide.

Stress Ulcers in the Stomach. I. M. Breckenridge, E. W. Walton and W. F. Walker. Brit. M. J. 2:1362-1364 (Dec. 19) 1959 [London].

Six cases of acute gastric erosions are reported, in which the ulcers developed, after exposure to various forms of stress, in patients previously eupeptic, none of whom had been receiving salicylate treatment. The disease was fatal in the 6 patients; hemorrhage occurred in 5. The gastric ulceration followed cerebral hemorrhage in 2 patients, diffuse encephalomyelitis in 1, fracture of a long bone in another, and operation for carcinoma in 2. The patients were over 50 years of age, with the exception of a 26-year-old woman who had developed encephalomyelitis during pregnancy. In the 4 patients for whom microscopic examination was available, the ulcers were sharply demarcated and presented an area of necrosis with little or no cellular reaction, with no evidence of healing. The ulcers were regarded as acute and between 1 and 7 days old.

The occurrence of gastric erosions after such diverse forms of stress recalls the association between peptic ulceration and adrenocortical hormones, which was suggested by Selye in 1936 and which is generally recognized at present. Though there is ample evidence to connect the neuroendocrine system with the development of stress ulcers, the exact mode of production is unknown. Antacid therapy should be considered whenever a trauma, an operation, or cerebral lesions may initiate the gastric erosion sequence.

Treatment of Hypertension: A 23-Year Follow-Up of 453 Patients with a Selected Review and Report of Current Experience. R. S. Palmer. J. Chron. Dis. 10:500-512 (Dec.) 1959 [St. Louis].

This is the fourth and final report on 453 medically treated patients with hypertension, since there are now only 79 survivors. The majority were seen first in the years 1935-1940. No new patients have been added to the series since 1941. Survivals over the years demonstrated the usefulness of the original classification into the following grades: grade 1, including patients with hypertension, but without organic changes or functional failure; grade 2, patients without functional failure, but with organic changes in one or more of the 3 vital areas—head, heart, or kidneys; grade 3, patients with organic changes plus functional failure in one or more vital areas; and grade 4, patients with the clinical syndrome of malignant hypertension, the diagnostic sign of which is papilledema. Cardiovascular renal disease was the cause of death in 75 to 90% of the hypertensive patients (as compared with 50% for the general population) and appears earlier in life with each rise in grade of hypertensive disease.

It is safe, cheap, and often possible to control the blood pressure level by diet plus phenobarbital in grades 1 and 2, and sometimes it is possible in grade 3. Drugs are easy to prescribe and are far more easily accepted by the patient than is restriction in diet. Rauwolfia and its fractions or derivatives are slightly, if at all, more effective than phenobarbital and have more side-effects. The chief use of rauwolfia is as a tranquilizer, rendering acceptable more rigorous drug treatment. Chlorothiazide is a substitute for salt restriction; the bulk of the evidence indicates that its mode of action is diuretic, depleting the body of salt and water; the effect of years of use on the kidneys and other organs and tissues awaits further observation. Since chlorothiazide may cause a rise in uric acid and muscle and joint pains, use of small doses is effective and recommended; it should be combined with small doses of ganglionic-blocking drugs in grade 3 patients with actual or threatened congestive heart failure, and used alone in less severe grades with high blood pressure levels. Grade 4 patients, with clinically malignant hypertension with papilledema, require every resource of diet and drugs to control the blood pressure level, which by itself in this condition is rapidly fatal.

The ease with which the blood pressure level is observed and the ease with which it is treated by a multitude of hypotensive drugs have misled many practitioners (and those who teach them) to neglect the equally important therapeutic problem of patients with hypertension, and also of the general population, namely, degenerative vascular disease. Patients with hypertension differ from nonhypertensives only by having the condition oftener and sooner. Degenerative vascular disease is related to age, hypertension, and unknown factors as well as to ingested animal fat, the latter fact having been known for 50 years. Evidence is presented that a basic treatment of all patients with hypertension is a low-salt, low-animal-fat diet.

Hereditary Spherocytosis. J. R. Meier. J. Louisiana M. Soc. 111:472-475 (Dec.) 1959 [New Orleans].

The subject of this study in hereditary spherocytosis was a 48-year-old man who was admitted to the Hotel Dieu in New Orleans in March, 1958, with severe right upper quadrant pain, nausea, and vomiting. He was well developed but poorly nourished, and showed a severe jaundice. He appeared to be acutely ill, exhibiting the complete form of spherocytosis, with long-standing anemia, splenomegaly, jaundice, cholelithiasis, and chronic leg ulcers. Cholecystostomy was performed, with removal of multiple pigment stones from an acutely inflamed gallbladder; the postoperative course was uneventful. In January, 1959, the patient underwent splenectomy, and the immediate postoperative course was complicated by a subdiaphragmatic abscess from which coagulase-positive Staphylococcus aureus was isolated. The patient was discharged on the 30th day after the operation. At that time the hemoglobin value was 10.6 Gm. per 100 cc., and the hematocrit was 36%.

The anemia in this patient, as determined by the hemoglobin concentration, was never severe except at 2 points, the first during the acute episode of cholecystitis and the second after the subdiaphragmatic abscess. At one point the patient had an apparent hemolytic crisis, with a further drop in hemoglobin value and marked bilirubinemia. During the entire duration of follow-up examination the reticulocyte counts followed an expected pattern, being highest just prior to splenectomy, and gradually returning to normal as the hemoglobin value rose. The platelet counts also fell to 50,000 per cubic millimeter at the time the hemoglobin was at its lowest level. After splenectomy, thrombocytosis occurred without evidence of the thrombotic phenomenon. At the last follow-up visit, the serum bilirubin level had returned to 1.5 mg. per 100 cc., and the clinical jaundice had subsided. The patient had regained 18 lb. (8.2 kg.), and his condition was markedly improved.

The patient's 2 children have spherocytosis, with characteristic laboratory findings but with a milder anemia. The inheritance of the disease cannot be traced back farther than one generation, owing to lack of laboratory studies on the patient's family.

Treatment of Alcoholic Cirrhosis with Ascites: A Study Based on Statistical Data of 449 Cases, Including 85 Survivals of Over Two Years. M. Levrat, R. Brette and P. Grandmottet. Arch. mal. app. digest. 48:1265-1293 (Nov.) 1959 (In French) [Paris].

The prognosis in decompensated alcoholic cirrhosis has changed during the last 10 years as a result of new therapeutic procedures and of changes in the physiopathological concept and the control of ascites. Four hundred forty-nine patients with alcoholic ascitic cirrhosis were hospitalized and observed between 1953 and 1958. The findings are analyzed in relation to 3 time periods: (1) before 1953; (2) from 1953 to 1956; and (3) from 1956 to 1958. The frequency of death during the first month of observation was 37% in period 1, 37% in period 2, and 27% in period 3. These frequencies show the spontaneous gravity of the disease, especially during period 2 when consumption of alcohol increased after wartime restrictions were lifted. The frequency of death during the first year of treatment decreased from 68% in period 1 to 56% in period 3. The circumstances of death also changed. Although the picture of terminal hepatic coma is still the most common, the occurrence of serous cachexia due to irreversible ascites has almost disappeared. Digestive tract hemorrhage is at present a more important cause of death and occurs in 20% of the cases, while only 11% of the patients succumb owing to complications without edematous elements.

The therapeutic procedures have included administration of delta cortisone (prednisone) combined with mercurial diuretics and intravenous perfusion with human plasma. Abdominal paracentesis was abandoned. Only 2 or 3 of 50 patients who were freed from ascites underwent paracentesis in addition to the medical treatment. The combined therapy is illustrated in the report on a 55-year-old patient with alcoholic ascitic cirrhosis and edema of the lower extremities, who during 20 years had consumed 2 liters of wine daily. The patient received an initial dose of 30 mg. of delta cortisone, which later was increased to 40 mg., combined with an intramuscular injection of mercurophylline every other day. Eleven perfusions of 400 cc. of plasma were given—2 or 3 per week. After 2 months of this treatment the patient was discharged in excellent condition. He was rehospitalized 4 months later, however, with ascitic jaundice after a new period of alcoholism, and died 10 days after readmission, in intense jaundice.

The authors recommend that the over-all therapeutic conduct in alcoholic ascitic cirrhosis include a hypercaloric, high-protein diet and the administration of corticosteroids and mercurial diuretics. If the results are not satisfactory within 15 to 20 days, plasma should be given in intravenous perfusion. The patient whose condition is serious from the start should receive the 3 therapeutic agents combined. Under this management the prognosis is that 50% of the patients become free from ascites, 25% survive more than one year, and 15 to 20% survive more than 2 years.

Cirrhosis of the Liver: A Study of Alcoholic and Nonalcoholic Patients in Boston and London. W. H. J. Summerskill, C. S. Davidson, J. H. Dible and others. New England J. Med. 262:1-9 (Jan. 7) 1960 [Boston].

Seventy patients, comprising 35 from Hammersmith Hospital, London, and 35 from Boston City Hospital, were studied. Information based on history, physical examination, pathological findings, and relevant investigations was obtained. In the Boston group, evidence of chronic alcoholism was mandatory for inclusion, whereas patients with a steady or excessive intake of alcohol or a history of malnutrition were excluded from the London series, the etiology of the hepatic cirrhosis in this latter series being cryptogenic. No patient was included if a diagnosis of hepatolenticular degeneration (Wilson's disease), hemochromatosis, cardiac failure, biliary obstruction, or ulcerative colitis had been established or if L. E. cells had been identified in the peripheral blood. Among the alcoholic patients in Boston, men predominated 2:1; working, domestic, and financial conditions were poor, and malnutrition was common, but a history of hepatitis was not frequent. In contrast, the nonalcoholic patients in London were mostly women (2:1); environments were not unusual, evidence of severe nutritional disturbances was rare, and previous hepatitis had been known in 11.

The prominent clinical features of patients in the cryptogenic group were usually related to portal hypertension, and episodes of hepatic precoma were common. The alcoholic patients, although frequently showing these abnormalities, could be separated from the cryptogenic group by the frequency of deep jaundice, fever, high neutrophil counts, and macrocytic anemia. Parotid-gland enlargement, gynecomastia, and Dupuytren's contracture were confined to the alcoholic group, and hepatomegaly was frequent. Splenomegaly, rather than hepatomegaly, characterized the nonalcoholic subjects. Serum albumin concentrations, although initially abnormal for both groups, often rose toward normal during improvement of the alcoholic patients with cirrhosis, but tended to change little in the nonalcoholic group. The globulin concentrations of the nonjaundiced, ascites-free patients were usually between 3 and 5 Gm. per 100 cc. in the London group, but below 3 Gm. per 100 cc. in the Boston group.

Pathological studies showed that the liver was small in the nonalcoholic and large in the alcoholic patients. Large and irregularly sized regeneration nodules were a feature of the nonalcoholic group, the picture resembling postnecrotic cirrhosis. Small and regular regeneration nodules were a feature of the alcoholic group, the picture resembling portal cirrhosis. In the Boston patients the liver cells showed increased amounts of fat and often necrosis—unusual findings in the London group. "Alcoholic hyalin" was confined to liver specimens from the Boston group. Relapses, usually with jaundice, after renewed ingestion of alcohol were common among the Boston patients and, although sometimes fatal, often responded dramatically to abstinence and a nutritious diet. The liver disease of the London patients was less dramatic, but *inexorable progress was the rule.*

Marked Enlargement of the Liver and Transient Ascites Associated with the Treatment of Diabetic Acidosis. H. D. Bronstein, P. A. Kantrowitz and F. Schaffner. New England J. Med. 261:1314-1318 (Dec. 24) 1959 [Boston].

The case of a 7-year-old girl with unusual juvenile diabetic acidosis is reported. The salient clinical features included unusually high insulin requirement, acute massive hepatomegaly, with rapid regression, and transient ascites. The acute hepatomegaly that developed during the correction of diabetic acidosis appeared to depend on 3 factors: the rapid administration of very high doses of regular insulin; the presence of a high blood sugar level; and the deposition of massive amounts of glycogen in the liver parenchyma, distorting cell structure as seen electron microscopically. Hepatic sinusoidal obstruction and reduced inactivation of antidiuretic substances by the glycogen-laden hepatic cells are suggested as an explanation for the transient ascites. The unusual clinical course in this case is presented as a complication in the treatment of diabetic acidosis. The brief report of it should encourage wider use of liver biopsy, with application of histochemical and electron-microscope techniques, to clarify further the pathological physiology of hepatomegaly in diabetic acidosis.

Considerations on Severe Carbon Monoxide Intoxication: Its Treatment, Especially by Neurovegetative Disconnection. L. Binet, H. Bour and S. Elosma. Presse méd. 67:2125-2127 (Dec. 5) 1959 (In French) [Paris].

Seventy patients with carbon monoxide intoxication were seen by the authors during the period from 1954 to 1956. Eleven of the 70 patients died. Six patients with severe intoxication were treated by artificial hibernation; 3 recovered, and 3 died. In 2 of the 3 patients that died, hibernation was started apparently on time, but was interrupted too early, and there was a relapse of coma; both patients died in hyperthermia. In the third patient that died, hibernation was started too late. In all 3 patients that survived, hibernation was started early and was maintained well beyond the recovery of consciousness. Some neuropsychic sequelae remained in one patient.

The authors point out that the difficulty of knowing the extent of anoxia in each case and the length of time that the patient has been exposed to toxic elements pose the fundamental problem in the treatment of carbon monoxide intoxication. Hibernation may be an effective remedy in cases of severe carbon monoxide intoxication on 2 conditions: (1) that it is started early, as, for instance, if coma persists despite first-aid help or when there are signs of persisting reflex disturbances or severe vasomotor disturbances; (2) that it is continued for some time beyond the recovery of consciousness. As for the indication for hibernation in carbon monoxide intoxication, the authors believe that the absence of response of consciousness to immediate treatment, high temperature, vasomotor disturbances, particularly reddish purple complexion, and the existence of a subacute pulmonary edema point out the importance of the manifestations of the central nervous system and the vasomotor disturbances that follow cerebral anoxia. This justifies a treatment based both on the increase of the caliber of the cerebral blood vessels, which is obtained with sympatholytic agents, and on a general decrease in the consumption of oxygen, which is obtained by refrigeration.

Potassium and Myocardial Energetics. P. Michon, A. Larcan and P. Gaucher. Semaine hôp. Paris 35:3289-3301 (Dec. 4) 1959 (In French) [Paris].

Nine patients with cardiac insufficiency of varied etiology received a potassium replacement therapy by intravenous perfusion. Potassium chloride was administered to 7 patients in a continuous perfusion of 500 cc. of isotonic dextrose solution, to which 2 ampuls of 20 cc. of hypertonic dextrose solution and 15 units of regular insulin were added. The dose of potassium chloride varied from 4 to 12 Gm., and the duration of the perfusion was approximately one hour for 4 Gm. of chloride. The treatment was controlled by electrocardiography, by the measurement of intensity-duration curves, and by the determination of potassium and sodium blood levels. Three urine specimens were collected, one 4 hours after starting the perfusion, the second at the end of 8 hours, and the third at the end of 24 hours. In the remaining 2 patients the potassium replacement was performed in 2 stages. The first stage consisted of the administration of potassium chloride in an isotonic sodium chloride solution without either insulin or hypertonic dextrose solution. In the second stage the perfusion of 250 cc. of 20% dextrose solution included 30 units of insulin. Both patients received 6 Gm. of potassium chloride administered in approximately 2½ hours. In this 2-stage treatment the electrocardiographic control and the urinary examinations were approximately the same as in the first method.

The main clinical features in both groups of patients, before starting the therapy, were moderate hypokaliemia, increased muscular rheobase, slightly increased or normal kaliuria, and decreased or absent natruria. In the 7 patients who received a one-step potassium replacement, the kaliemia increased by an average of 1 mEq. The change in natremia was light and difficult to interpret. The only change observed in the electrocardiogram took place in the T wave, which exhibited the aspect characteristic of hyperkaliemia. The changes in urinary elimination were not always consistent. Kaliuria increased in most patients; natruria increased in all of them within 24 hours after the start of the perfusion. In the 2 patients who received a 2-step treatment, the results were of the same type. The main characteristic of this 2-step technique was that in the second stage, when insulin was added to the perfusion, there was a sudden and considerable fall in the kaliemia level, a decrease in muscular rheobase, and a further decrease in the urinary elimination of potassium. All 9 patients experienced a feeling of well-being after the perfusion, regardless of the difference in the technique. The clinical picture improved, with regression of edema, disappearance of dyspnea, and, in some patients, disappearance of the gallop rhythm.

The authors conclude that the slight increase in kaliemia, together with the low level of kaliuria, indicates that the potassium ion had reached the intracellular sector. The results obtained with the association of insulin and hypertonic dextrose solution suggest that this association allows a more rapid intracellular penetration of the potassium ion. A slow, strictly controlled administration of potassium chloride is beneficial to patients with decompensated cardiac insufficiency.

Hereditary Hypophysial Diabetes Insipidus: Observation During Pregnancy and Description of Family. E. Enger. Tidsskr. norske laegefor. 79:1291-1294 (Nov. 15) 1959 (In Norwegian) [Oslo].

Diabetes insipidus is marked by polyuria and thirst. The hypophysial form may be secondary and due to disease or injury of the hypothalamico-hypophysial apparatus, or primary and due to a defect on genetic basis of the apparatus producing the antidiuretic hormone. The hereditary hypophysial type was recognized as early as 1841. In most of the families studied, the inheritance has been autosomal, dominant; a recessive sex-bound inheritance has also been described, with transmission of the gene by healthy women. Hereditary hypophysial diabetes insipidus is a lifelong condition with favorable prognosis. In a given family the disease manifests itself with about the same intensity. Enger reports on the first family in Norway with recorded hereditary diabetes insipidus, inherited as a clear-cut autosomal dominance. In all cases the syndrome appeared in early childhood. Of 21 persons in the second and third generations of the family, 11 have a pathological thirst. All drink from 2 or 3 to 12 or 13 glasses of water nightly. At an older age the symptoms may become less marked. In the case described in a pregnant woman of this family, there was greatly increased thirst during the first part of pregnancy. Administration of extract of posterior pituitary lobe improved the condition. In the last trimester of the pregnancy, and particularly during lactation, there was a remarkable reduction of thirst. After the lactation period ended, thirst recurred on the same level as before. Information about the nature and prognosis of the disease can remove unnecessary dread and embarrassment. Diagnosis is possible by simple means, and administration of extract of posterior pituitary lobe is effective in most cases.

The Pleural and Pulmonary Complications of Rheumatoid Arthritis. A. R. Horler and M. Thompson. Ann. Int. Med. 51:1179-1203 (Dec.) 1959 [Lancaster, Pa.].

Rheumatoid arthritis is now widely considered as a generalized disease, involving, in addition to the joints, various other tissues and organs, including the lungs and pleura. In the 2-year period from January, 1956, to December, 1957, inclusive, 180 patients with rheumatoid arthritis (52 men and 128 women), ranging in age from 18 to 78 years, were referred to one of the authors at the department of physical medicine from other clinics and wards of the Royal Victoria Infirmary in Newcastle upon Tyne, England. These patients were studied with regard to the existence of pleural and pulmonary lesions and questioned about previous chest illnesses; their hospital records were searched for evidence of former respiratory complications. Nine patients were found to have, or to have had, a pleural effusion for which no cause could be found other than rheumatoid disease; 8 of them were males. One other patient had roentgenologic evidence of a "honeycomb lung." The case histories of these 10 patients are presented.

The 9 patients with pleural effusion have been under observation for periods ranging from 14 to 100 months (average, 48 months), and there has been no evidence that any other disease process could have been responsible for the effusion. Special efforts were made to exclude pulmonary tuberculosis, bronchogenic carcinoma, and systemic lupus erythematosus. Two of these patients (both males) also had coincident parenchymatous lung lesions; they were nodular in one, and diffuse and fibrotic in the other. The pleural and pulmonary lesions developed in both patients sometime after the onset of arthritis. The other 6 male patients with pleural effusion had no evident lesions of the underlying lung. The appearance of the effusion was accompanied by an acute febrile respiratory illness related to the onset of the arthritis.

A review of the relevant literature has confirmed the view that pleural effusion complicating rheumatoid arthritis occurs predominantly in men. In the only female patient in this series, the effusions developed several years after the onset of the arthritis. The authors conclude that rheumatoid arthritis merits consideration in the differential diagnosis of pleural effusion, especially when the effusion occurs in middle-aged men and is associated with the recent development of joint symptoms.

Oral Antidiabetic Therapy. R. H. Williams, R. H. Pollen, D. C. Tanner and R. H. Barnes. Ann. Int. Med. 51:1121-1133 (Dec.) 1959 [Lancaster, Pa.].

The authors discuss the 4 orally administered antidiabetic drugs—tolbutamide, chlorpropamide, metahexamide, and phenethylbiguanide. The 3 sulfonylureas—tolbutamide, chlorpropamide, and metahexamide—presumably lower the blood sugar level by stimulating increased insulin secretion and by decreasing hepatic glucogenesis, particularly in the presence of insulin. They seem to have their greatest effect in patients who most nearly approach normality in the amount of assayable insulin in the plasma and pancreas; these tend to be elderly persons with stable diabetes of recent onset. A poor response is apt to be obtained in depancreatized patients or in diabetes that is unstable or of long duration, or requires large insulin doses, or is prone to produce keto-acidosis. There is no evidence that treatment with sulfonylurea compounds causes beta-cell exhaustion. Side-effects with tolbutamide have been few and mild. Chlorpropamide and metahexamide have caused side-reactions more frequently, and occasionally have produced jaundice of the cholestatic type, usually reversed upon cessation of treatment. Metahexamide has caused jaundice with sufficient frequency to preclude its further use. While metahexamide and chlorpropamide are more potent than tolbutamide, this higher potency seems to have advantage in only a small proportion of patients.

Guanidine and many of its derivatives have long been known to produce hypoglycemia, but interest has recently been centered on a condensed diguanidine, phenethylbiguanide (PEBG). Phenethylbiguanide inhibits certain oxidative enzymes of the Krebs cycle, particularly succinodehydrogenase and cytochrome oxidase. This produces: (1) an increase in anaerobic glycolysis with an increase in glucose uptake, and (2) a decrease in gluconeogenesis, liver glycogen, and hepatic glucogenesis. As a result, glucose disappearance from the blood increases, and its entrance from the liver decreases, both factors contributing to hypoglycemia. This biguanide may lower the blood sugar level in all types of diabetes, but the greatest effect is observed in those with the mild, stable type. Combined with insulin, it produces smoother control in patients with unstable diabetes. In some subjects, chiefly with the stable type of diabetes, better control is obtained with the biguanide plus a sulfonylurea than with either drug alone. The high incidence of side-effects, even though rapidly reversible, has limited the extent of usage of phenethylbiguanide. Tolbutamide, chlorpropamide, and phenethylbiguanide all have value in the treatment of some diabetics. New orally effective compounds must be evaluated objectively, their effects being noted not only on the levels of sugar in the blood and urine but also on various phases of the metabolism of carbohydrates, fats, and proteins, as well as on the general health with prolonged usage.

Resistance to Ketosis in Obese Subjects. A. Kekwick, G. L. S. Pawan, T. M. Chalmers. Lancet 2:1157-1159 (Dec. 26) 1959 [London].

The authors tested the following 2 concepts of the resistance of obese persons to ketosis: (1) that the obese may utilize or excrete ketone bodies (acetone, acetoacetic acid, and beta-hydroxybutyric acid) faster than the nonobese, and thus prevent their accumulation in the body; (2) that the obese may not form ketone bodies so rapidly. To test the first concept, sodium beta-hydroxybutyrate was given to 6 obese and 6 nonobese persons. After intravenous injection of 30 mg. of this ketone body per kilogram of body weight, the rate of its disappearance from the blood was found to be the same in the obese as in the nonobese persons. Less than 1% of the injected dose was excreted in the urine; the amount excreted was the same in the 2 groups. Hence, the first concept—that the resistance to ketosis in obese persons results from their greater ability to excrete ketone bodies or to utilize them metabolically—does not appear to be tenable.

To test the second concept—that the rate of production of ketone bodies is less in the obese, an attempt to induce ketosis was made in 14 obese and 8 nonobese persons by giving them a diet providing 1,000 calories, of which 90% was supplied in the form of fat. In the nonobese persons the development of ketonemia and ketosis was preceded by a fall in the fasting blood sugar concentration. In the obese persons placed on this diet, there was no such fall, or it was small; ketosis to any significant degree did not develop. Taken in conjunction with the first experiments, these results suggest that resistance to ketosis in the obese results from a diminished production of ketone bodies. Reasons are given for believing that net conversion of fat to carbohydrate took place in both groups. It is suggested that obese persons may be able to produce more carbohydrate from nonprotein sources, i. e., from fat, than nonobese persons.

SURGERY

Diagnostic and Functional Evaluation of Candidates for Coronary Endarterectomy. A. A. Kattus, W. P. Longmire Jr., J. A. Cannon and others. A. M. A. Arch. Int. Med. 104:870-885 (Dec.) 1959 [Chicago].

The authors report on 23 patients with coronary occlusive disease, who had been referred or had presented themselves for consideration of surgical treatment at the University of California Hospital in Los Angeles. These patients had incapacitating angina pectoris and were evaluated from the point of view of establishing the diagnosis of coronary occlusive disease and of determining its severity. Electrocardiograms disclosing nonfixed ST-segment depression, either at rest or after exercise, proved to be a highly reliable indication of extensive occlusive coronary disease, usually involving more than one major arterial branch. In patients having normal resting electrocardiograms, the positive Master two-step test was reliable in producing diagnostic ST-segment depression. In patients showing ST-segment depression at rest, it is not necessary to impose any further stress on the patient with the intention of reproducing the anginal pain. The authors' studies and those performed previously by other workers have shown that, in the progression of events leading up to anginal pain, ST-segments become depressed before the onset of pain and often remain depressed long after the pain has disappeared. Of the 23 patients who were evaluated for endarterectomy, ST-segment depression in the electrocardiogram was associated with complete occlusion of at least one major coronary branch in 10 patients; the ST-depression was present at rest in 4 of these, and in 6 it was induced by exercise. These 10 patients and an additional one, in whom atypical history and equivocal results of the electrocardiographic test after exercise prompted the use of coronary angiocardiography as diagnostic method, underwent endarterectomy. Coronary angiography may be useful in locating segments of arterial occlusion.

Having established the diagnosis and then having decided to operate, the authors were faced with the problem of obtaining some sort of semiquantitative baseline from which to evaluate the postoperative results. Exercise on a motor-driven treadmill can be performed during continuous electrocardiographic monitoring. Treadmill testing was useful in demonstrating objective indications of improved coronary perfusion in 4 survivors of coronary endarterectomy who were available for study. Of the 4 patients, the postoperative treadmill tests disclosed no deviations of ST-segments in walks of up to 20 minutes' duration, of 2½ miles per hour speed, in 2 patients who were restored to full activity and were capable of heavy physical exertion. Of the other 2, one had postoperative anginal pain requiring glyceryl trinitrate on rather strenuous effort. While his postoperative tracings showed some variations in the T-wave patterns, there were no changes in ST-segments, and he was able to walk up to 15 minutes on one occasion without pain. Postoperative tests gave mildly positive results during the first 2 months in the 4th patient, though on one occasion he was able to walk 10 minutes without pain. Treadmill testing also was helpful in evaluating the effect of glyceryl trinitrate and procainamide on the anginal syndrome.

The Surgical Treatment of Angina Pectoris. W. P. Longmire Jr., J. A. Cannon and A. A. Kattus. A. M. A. Arch. Int. Med. 104:886-892 (Dec.) 1959 [Chicago].

Current surgical attempts to improve myocardial circulations in patients with angina pectoris have been directed along 2 lines: (1) attempting to increase the intramural coronary anastomosis, and thereby provide more efficient and effective utilization of arterial blood available to the heart, and (2) increasing arterial flow, both into the coronary arterial system and into available intramural collateral channels. After extensive studies on autopsy specimens and dissection of the coronary arteries of dogs, a suitable technique and special instruments were devised by one of the authors for reestablishing blood flow through the obstructed main coronary arteries and their major branches by removal of the thickened atheromatous intima (direct-vision endarterectomy). This procedure was carried out in 10 patients, between the ages of 38 and 63 years, with incapacitating angina pectoris. Nine of the 10 patients were considered to have angina decubitus. Four patients were considered to have a normal electrocardiogram at rest; in the other 6 patients the electrocardiographic tracing made at rest showed abnormalities compatible with myocardial ischemia or questionable infarction. Typical temporary ST-segment depression and depression of the T wave occurred with exercise on the treadmill in 7 patients.

In all of the 10 patients operated on, the extensive coronary atherosclerosis observed at surgical intervention substantiated the preoperative diagnosis of severe incapacitating angina pectoris. Disease of the major coronary arteries with patent distal vessels was found in each patient, and theoretically total coronary blood flow could have been increased by the proposed operation. Five patients have survived the endarterectomy, one for 1 year and 3 months. All have been improved, as judged by their clinical course and by evaluation of the treadmill exercise test.

Emergency Mitral Valvular Commissurotomy Preceding a Second Aortic Embolectomy. E. S. Hurwitt, P. Glotzer and J. B. Schwedel. A. M. A. Arch. Surg. 79:1009-1012 (Dec.) 1959 [Chicago].

The authors report on a 53-year-old woman on whom emergency mitral valvular commissurotomy was performed at the Montefiore Hospital in New York. The patient was admitted to the hospital with the chief complaint of progressive dyspnea of 2 weeks' duration. She had an attack of acute rheumatic fever 21 years previously. For the past 18 years she had noted progressive dyspnea on exertion. On admission, the patient was considered to be in mild congestive failure, with an uncontrolled atrial fibrillation, and she was given a digitalis preparation. On the morning of her third hospital day she suddenly showed the classical signs of embolization to the bifurcation of the abdominal aorta. Embolectomy was performed with the aid of spinal anesthesia within 4 hours of the embolization. A large clot was removed from the bifurcation of the aorta and from both iliac arteries, with prompt restoration of the pulses in both legs. Anticoagulant therapy was instituted with heparin and continued with warfarin; the patient was ambulatory on the 5th postoperative day. On the 7th postoperative day the patient again showed the clinical picture of embolization to the aortic bifurcation. Phytonadione (vitamin K_1) oxide was given intravenously, and within 4 hours of the onset of this acute episode, a mitral valvular commissurotomy was accomplished, with the aid of general anesthesia, through the left auricular appendage. There was a tight mitral stenosis, with no insufficiency, and no thrombi were felt; a satisfactory opening of the valve was accomplished. After closure of the chest, the previous laparotomy incision was opened, and a large, completely obstructing embolus was removed through the previous aortotomy incision. The total operating time for the 2 procedures was 2 hours and 20 minutes.

After a complicated postoperative course, the patient was discharged from the hospital after a 7 weeks' stay. She has continued to be well to date, with no evidence of circulatory insufficiency to her legs or neurological deficit and with profound relief of her complaints at the time of her admission. This is the case of the second known patient to survive 2 aortic embolectomies, and of the third reported patient with aortic embolization who was treated with combined commissurotomy and embolectomy. Emergency mitral commissurotomy preceding aortic embolectomy in patients with mitral stenosis merits favorable consideration.

Pulmonary Nocardiosis: Case. M. M. Brea, G. P. Ansaldo and C. M. Brea. Rev. Asoc. méd. argent. 73:441-444 (Nov.) 1959 (In Spanish) [Buenos Aires].

Pulmonary nocardiosis causes severe pulmonary lesions, becomes systemic with formation of multiple abscesses, and causes rapid emaciation and death, unless early treatment with sulfadiazine is established. The early symptoms of the acute form are those of pneumonia, with suppuration and cavitation of the lung tissue, empyema, early enlargement of the regional lymph nodes, and formation of abscesses on the ribs. Pulmonary tuberculosis is the most frequent complication. Splenomegaly and hepatomegaly appear in the late stages of the disease. The disease should be suspected in the presence of symptoms of acute or subacute pulmonary infection which do not subside on the administration of antibiotics, the only exception being sulfadiazine to which pulmonary nocardiosis always responds. A diagnosis is made by identification of Nocardia asteroides in the material obtained from the lesion as well as from the sputum. The diagnosis should be confirmed by cultures with special mediums. Pulmonary nocardiosis was always fatal before the appearance of antibiotics. The treatment consists of drainage of the pleural empyema and the parietal abscesses and of the administration of sulfadiazine in daily doses which range between 6 and 7 Gm. for as long as 5 or 6 months.

A man, 56 years old, requested treatment for mild pulmonary symptoms of 6 months' duration. He had lost weight, and an abscess had developed on the ribs. A roentgenogram of the chest showed an extensive infiltrating lesion of the upper lobe of the lung. A diagnosis of nocardiosis was made on the positive results of microscopic examination of pus from the abscess and by cultures of the same material. The treatment consisted of surgical removal and drainage of the abscess and the administration of sulfadiazine in daily doses of 7 mg. for 5 consecutive months. The roentgenogram of the chest, after completion of the treatment, showed healing of the pulmonary lesion, with transformation of tissue into a zone of fibrosis.

Bacterial Endocarditis After Mitral Commissurotomy: Report of Four Cases. Y. Bouvrain, R. Slama and J. N. Mercier. Arch. mal. coeur 52:1227-1237 (Nov.) 1959 (In French) [Paris].

The authors report on 2 men and 2 women, between the ages of 29 and 39 years, who underwent mitral commissurotomy and in whom subacute bacterial endocarditis followed the surgical intervention. In the first patient, Staphylococcus pyogenes var. albus was determined by blood culture as the pathogenic agent. In the second patient Pseudomonas aeruginosa (pyocyanic) was found on culture of the blood, and in the third patient Staph. pyogenes var. aureus was found. More than 20 bacteriological cultures of the blood of the fourth patient remained negative. The marked increase in the size of the spleen and the fact that antibiotic treatment with streptomycin and penicillin, and, in addition, prednisolone therapy, restored the temperature to normal were thought to be sufficiently significant for considering the presence of subacute bacterial endocarditis with negative blood cultures.

The onset of the condition occurs within less than one month after the surgical intervention. In most of the cases a staphylococcus is the pathogenic agent; this may be due to the systematic employment of penicillin combined with streptomycin for postoperative prophylaxis. The clinical picture is remarkable for the absence of the fundamental classic symptoms, such as petechiae and clubbed fingers. Subacute bacterial endocarditis follows more frequently surgical intervention on the aortic valve than a mitral commissurotomy. Its prognosis is unfavorable. Of the small number of 38 patients whose cases were collected from the literature, 20 died, and 2 of the 4 patients in the authors' series died, a mortality rate of about 50%.

Chronic Idiopathic Pericardial Effusion Without Tamponade. D. C. Connolly, T. J. Dry, C. A. Good and others. Circulation 20:1095-1105 (Dec.) 1959 [New York].

Persistent pericardial effusion in the absence of obvious preceding or concurrent disease presents a baffling problem. In such cases chylopericardium, cholesterol pericarditis, lupus erythematosus, malignant disease, myxedema, severe anemia, and scleroderma must be considered. The authors present the histories of 6 patients who had chronic pericardial effusion, without cardiac tamponade. All 6 patients were women, and 5 were menopausal. There was no evidence of active tuberculosis or rheumatic disease at the time of examination, and none had myxedema or signs of systemic lupus erythematosus. Evidence of cardiac tamponade was not present in any of these patients, but the venous pressure was grossly increased in one because of superior vena caval obstruction some 25 years previously. The duration of the pericardial effusion ranged from 1 to 11 years; fluid may have been present as long as 29 years in one of the patients. In another patient the chronicity of the effusion was assumed from the roentgenologic findings of cardiac enlargement 2 years before. In a third case the pericardial effusion was possibly present for only a short period.

None of the 6 patients gave a history suggesting an episode of acute pericarditis. Examination of the pericardial fluid or tissue gave no clue to the etiological factor. One case is of interest in view of the coincidence of pericardial effusion and polycythemia, which almost certainly was induced by ingestion of a cobalt-containing preparation of iron. In this patient disappearance of the effusion followed correction of the polycythemia.

In 5 patients the pericardial fluid measured from 700 to 1,200 ml. at the time of operation. The operation on 4 patients consisted in the creation of a "pleuropericardial window," which previously had been found satisfactory in patients with pericardial effusion. Follow-up for variable periods has not revealed any evidence of recurrence of pericardial effusion in these 6 patients, all of whom noted subjective improvement. The importance of angiocardiography as an aid to the diagnosis of pericardial effusion again is emphasized.

Primary Lymphosarcoma of the Lung. E. R. Hall Jr. and B. Blades. Dis. Chest 36:571-578 (Dec.) 1959 [Chicago].

The authors report on a 61-year-old man and 2 women, aged 49 and 70 years, with primary lymphosarcoma of the lung, who were operated on at the George Washington University Hospital in Washington, D. C. In the man, thoracotomy revealed that the middle lobe was completely atelectatic. There were nodular infiltrations throughout the middle lobe and the superior portion of the lower lobe. Neoplastic tissue engulfed the pulmonary artery and the main bronchus. The lesions were considered inoperable. On the 5th day after the thoracotomy, irradiation therapy was administered to the anterior and the posterior chest on the left. The patient was discharged from the hospital, but was readmitted 5 months later when a general bone survey by roentgenogram revealed metastatic lesions involving the skull, spine, and left 5th rib. The patient died 10 months after the thoracotomy.

The younger woman was subjected to a right-sided pneumonectomy because of a 6-cm. mass in the right lower lobe extending across the oblique fissure into the right middle lobe; there was no evidence of enlarged hilar nodes. Seven years after the surgical intervention, there was no evidence of recurrence or metastasis in this patient. Thoracotomy performed on the older woman revealed a 4-by-5-cm. triangular area in the left upper lobe, which appeared red and atelectatic. Extending from this area toward the hilus was an irregular, hard tumor invading the mediastinal structures. The pulmonary artery and the superior vena cava were surrounded by the tumor. The lesions were considered inoperable. Two weeks later irradiation therapy was started, and the patient was also treated with nitrogen mustard and triethylene thiophosphoramide for palliation. The patient died 2 years after the thoracotomy.

From this small series, one would believe that the prognosis in patients with resectable pulmonary lymphosarcoma is more promising than in those with bronchiogenic carcinoma. The extent of resection must depend on the location of the lesion and the age of the patient. There are varying views on the use of irradiation therapy. Some workers feel it should always be employed, regardless of the extent of the lesion or the thoroughness of the operation, while other workers use it only for recurring lesions.

Hemorrhage from Esophageal and Gastric Varices. L. Leger, P. Dêtrie and P. Guyet. Arch. mal. app. digest. 48:1304-1332 (Nov.) 1959 (In French) [Paris].

The origin of hemorrhages in portal hypertension is far from being established. Gastric hemorrhage occurs frequently as an isolated accident which endangers the patient's life and may require an emergency hemostasis. Although vasomotor disorders and disturbances in the blood constitution play a role, the reality of hemorrhages from ulcerations of esophageal varices is undeniable, whatever the mechanism may be. The esophageal varices often reach beyond the greater curvature of the stomach where the source of bleeding may be situated. Associated lesions, especially the ulcerative, are also responsible. The controversial point is the frequency of any particular mechanism. The role of varicose ulceration in gastric hemorrhage is dominant, although not exclusive.

Twelve cases of hemorrhage from esophageal varices associated with different lesions are reported and analyzed from the clinical and therapeutic points of view. Therapeutic emergency measures include the application of a double-balloon gastroesophageal tube, blood transfusion, drip feeding, and vitamin therapy for a period of time compatible with the patient's respiratory condition. Failure of the tamponade or recurrence of the bleeding is indication for surgical treatment. Ligation of esophageal varices is often a first emergency step before portacaval anastomosis. The surgical approach varies. The transthoracic approach is technically the most convenient, as it gives a desirable visualization of the stomach's greater curvature. It is contraindicated in patients who are exhausted or not well prepared for the operation. The abdominal approach permits an easy lowering of the esophagus after resection of the xiphoid process.

Once the esophagus is reached, a longitudinal incision should reach the entire thickness of the wall.

It may be advisable to add a double vagotomy and a gastroenterostomy to the ligation of the esophageal varices, as a means of reducing the gastric acidity and its effect on the esophagus. It is preferable to operate early after a short attempt of tamponade with balloon, the time interval being used to transfuse and prepare the patient. Once the operation has been undertaken, the surgeon should not hesitate to continue the investigation and to secure the indispensable visualization until the hemorrhagic focus is found. These procedures represent a possibility of improving the prognosis in portal hypertension with gastroesophageal hemorrhage.

The After-Effects of Removal of a Ruptured Spleen.

H. Begemann and W. Gehle. German M. Month. 4:378-384 (Nov.) 1959 (In English) [Stuttgart, Germany].

The authors report on 310 previously healthy persons who underwent splenectomy for traumatic rupture of the spleen. Seventy of these patients died in the postoperative period. Of the 240 survivors, 209 (170 male and 39 female patients), between the ages of 4 and 67 years, were subjected to follow-up examinations, mostly in their own homes in Freiburg im Breisgau, Germany, within 6 months to 36 years after the splenectomy, and, on the average, within 8 years and 9 months postoperatively. Postoperative infections of the lung and pleura were more common among these patients than among those who had undergone other upper abdominal operations, but the incidence of all types of infections years after the splenectomy was not higher among these patients than among the general population. Disturbances of growth and development were not observed in patients who at the time of the splenectomy were still children. Functional disorders of the autonomic nervous system were frequently manifested by gastric and cardiac symptoms and by a general reduction of physical capacity. A striking symptom in many patients was intolerance to alcohol. This intolerance was manifested by nausea, vomiting, and, in some patients, abdominal pain, and it was often the only after-effect of the splenectomy or, at least, the only significant one. Apart from an increase in siderocytes and Howell's bodies, the only moderately constant change in the blood picture was a lymphocytosis. The hemoglobin concentration and the red blood cell count returned to normal in 5 to 8 months.

These observations suggest that splenectomy has little effect on most healthy persons, but in a few it may lead to troublesome syndromes or an increased susceptibility to infections; this may be due to a failure of other organs to take over the functions of the spleen. It is difficult to lay down any general principles for the medicolegal assessment of patients after splenectomy.

On the Drying Test of Gallbladder Bile: A New Method for Diagnosis of Gallstones.

H. Miyake. A. M. A. Arch. Surg. 79:1032-1043 (Dec.) 1959 [Chicago].

The author reports on a new method for diagnosis of cholelithiasis, as devised and practiced in the department of surgery of the University Hospital in Fukuoka, Japan, particularly in patients in whom the stones are composed of bile pigment (bilirubin). This type of biliary calculi may be found in a high percentage of Japanese patients with gallbladder disease. To perform the "bile drying test," bile was obtained from the gallbladder by needle aspiration during laparotomy; the aspirated fluid was placed on a glass plate and dried in an incubator at 37 C for 24 hours. Macroscopic examination of the specimen revealed a regular pattern of crystals lined up radically in most cases of cholecystitis with calculi, while no crystals or partial crystallization were observed in cases of cholecystitis without calculi. Microscopic examination of the dried bile specimens revealed various patterns of crystallization; there were typical crystals which showed a fern-like structure or a crystal nucleus; atypical crystals showed a thrum-like, cross, or plate structure. Of 176 patients on whom drying tests were performed, 85 had cholecystitis with calculi, 67 had cholecystitis without stones, and 24 had a normal biliary tract. Of the 85 patients, microscopic examination of dried bile specimens showed typical crystals in 68, atypical crystals in 15, and no crystals in 2. Of the 67 patients, the drying test showed typical crystals in 4, atypical crystals in 19, and negative results were obtained in 44. In the 4 patients with typical crystallization in the dried bile, the operative findings seemed to indicate that calculi might have been present and passed through the biliary tract.

The reported data, obtained by gallbladder puncture during surgical intervention, show that there is a distinct difference in the dried bile pattern of patients with cholecystitis with calculi, those without calculi, and those with a normal biliary tract, even though there are a few exceptions. In an attempt to obtain gallbladder bile (bile "B") before surgical intervention to serve as an aid in diagnosis of gallstones, "B" bile was obtained through a duodenal tube and subjected to the drying test. Results were as follows: Crystallization was rarely observed when the biliary tract was normal. Crystallization was mostly negative or atypical in patients with cholecystitis without calculi. Typical crystals were observed in most patients with cholecystitis with calculi. The special forms of crystallization, as revealed by the drying test, are not directly related to the presence of calculi, but chiefly to the function of the gallbladder or the degree of its inflammation. Since the function of the gallbladder is usually impaired in patients with cholelithiasis, especially in those with "bilirubin stones," who frequently show severe inflammation, the drying test is far more effective as a diagnostic aid in the presence of biliary calculi than any other customary test, particularly in Japan where "bilirubin stones" dominate. If "B" bile can be obtained, this test is the method of choice for the determination of the functional impairment and the degree of inflammation of the gallbladder.

Hirschsprung's Disease in the Newborn. O. Swenson and J. H. Fisher. A. M. A. Arch. Surg. 79:987-993 (Dec.) 1959 [Chicago].

The authors report on 55 newborn infants with congenital megacolon (Hirschsprung's disease), who were observed at the Boston Floating Hospital for Infants and Children. This disease is one of the most frequent causes of acute intestinal obstruction. with symptoms and signs, such as vomiting (present in 27 infants of this series), intractable constipation (present in 40 infants), and abdominal distention (present in 38 infants), which may be indistinguishable from those due to another cause of intestinal obstruction, such as ileal atresia. There are certain conditions, such as meconium plug syndrome or cretinism, which give rise to symptoms of intestinal obstruction, while the roentgenographic findings may be suggestive of Hirschsprung's disease by identifying dilated loops to be colon and thus excluding obstruction of small intestine. A rectal biopsy should be performed to rule out these other conditions. Rectal biopsy is also indicated in certain infants who have the symptoms of Hirschsprung's disease and yet do not have characteristic roentgenographic findings. Barium enema failed to establish the diagnosis in 10 infants, but rectal biopsy established it. Photomicrographs of a rectal biopsy section which show ganglion cells in Auerbach's plexus exclude the diagnosis of Hirschsprung's disease, while a rectal biopsy section containing no ganglion cells establishes this diagnosis.

In most of the newborn infants with Hirschsprung's disease, the aganglionic lesion extends no higher than the sigmoid colon. In these patients a small rectal tube may be passed beyond the aganglionic segment, and the intestinal obstruction relieved by colonic irrigations with small quantities of sodium chloride solution. It is best to treat enteritis, to which infants with Hirschsprung's disease are susceptible, by intravenous feedings, in addition to colonic irrigations similar to those given to relieve the acute intestinal obstruction. An elective colostomy may be done when the infant is several days old, after the diagnosis of Hirschsprung's disease has been substantiated by rectal biopsy. The definite resection of the aganglionic segment and the colostomy may be carried out when the child weighs 25 to 30 lb. (11.3 to 13.6 kg.). A biopsy of the colon wall should be secured at the time of colostomy to be certain that ganglion cells are present in this segment. If the colostomy is placed in an aganglionic segment, it will not function properly.

Mallet Finger. D. Flinchum. J. M. A. Georgia 48:601-603 (Dec.) 1959 [Atlanta].

The term "mallet finger" implies the characteristic droop of the distal phalanx from disruption of the terminal extensor mechanism. The lesion may be caused by a sudden blow against the end of the finger, as from a ball, or else by striking the finger tip against some object or by dorsal laceration over the distal interphalangeal joint. There are 2 main types of injury in mallet fingers. The most common is a frayed break or stretch through the distal portion of the extensor tendon. Occasionally a laceration is noted. The other type of injury is an avulsion fracture of the proximal portion of the dorsal aspect of the distal phalanx, where the insertion of the distal tendon is pulled off with the bone fragment; the tendon is intact. Mallet finger is extremely difficult to treat without some residual cosmetic or functional loss. The finger must be splinted, so as to hold the lateral bands extending through to the distal phalanx relaxed. This is done by holding the proximal interphalangeal joint flexed and the distal interphalangeal joint in extension. It is difficult to hold this relaxation.

Of 25 cases of mallet finger observed during the past 3 years and treated by various methods, only 5 results can be considered normal; 6 conditions are good, 8 are improved, and 1 was not helped. Five patients were not treated. The author believes that the following methods of treatment are desirable. External splinting with a dorsal and palmar padded aluminum splint, holding the proximal interphalangeal joint in flexion and the distal one in extension for 6 weeks, offers the best chance of satisfactory results in younger patients. In older persons, laborers, and those apt to have some joint limitation, a Kirschner wire should be inserted across the distal interphalangeal joint to hold this joint in extended position, and this should be combined with an external aluminum splint to hold the proximal interphalangeal joint flexed. The splint is removed after 3 weeks to allow flexion and extension of the proximal interphalangeal joint. The Kirschner wire can be inserted initially or after 3 weeks of external splinting. This splinting method of treatment should be done early, within the first week of injury, although it can be tried as long as a month after the injury has been sustained. The distal interphalangeal joint should be kept extended for 6 weeks. Some slight residual drooping or hyperextension of the proximal interphalangeal joint will remain in most patients.

Accidental Seeding of Cancer in the Operative Area. J. Sonneland. Northwest Med. 58:1687-1692 (Dec.) 1959 [Seattle].

Some of the failures in cancer surgery are due to accidental seeding of cancer in the operative field. The author presents 5 cases of recurrence in the abdominal incision observed in the Spokane (Wash.) area; 2 of the 5 cases are personal cases. Increased attention should be paid to the local contagion of cancer. Local recurrences may be reduced by preoperative surface sterilization of the tumor where applicable, by scrupulous local quarantine of the cancer, by treatment of the fomites of the operating table with resterilization or with one-half strength Dakin's solution, and by treatment of the operative area with Clorpactin.

Postoperative Nourishment. H. F. Harbitz and Ø. Oyen. Tidsskr. norske laegefor. 79:1219-1222 (Nov. 1) 1959 (In Norwegian) [Oslo].

The ordinary postoperative diet in Aker Hospital, Oslo, for patients undergoing surgery in the gastrointestinal tract has been low in protein and calories. The new postoperative diet adopted furnishes 100 Gm. of protein and consists of 2,000 calories a day, and is given earlier in the postoperative course than the former diet. The increased protein content depends on the addition of dried milk, eggs, and cheese. Nitrogen-balance studies on 17 patients after partial gastrectomy (7 of whom were given the previous diet and 10, the new diet) showed that none of the 7 were in positive protein balance after 13 days, while on the diet rich in protein positive protein balance was attained by 8 of the 10 on the 7th postoperative day and by all 10 after 13 days.

NEUROLOGY & PSYCHIATRY

Diagnosis of Huntington's Chorea. O. S. Dalgaard and K. Noreik. Tidsskr. norske laegefor. 79:1224-1227 (Nov. 1) 1959 (In Norwegian) [Oslo].

The characteristic picture in Huntington's chorea depends on hereditary occurrence of typical choreatic movements in a grown person, progressive in course, with simultaneously developing dementia. Heredity is dominant. Less clear symptoms can give the basis for the diagnosis only when compared with the characteristic transmission. The symptoms may occur as preliminary stages or early symptoms, with later development of the typical picture, and in some atypical cases remain the only or the dominating symptoms; this condition is designated as "chorea sive chorea." Of 14 patients (10 men and 4 women) with Huntington's chorea treated at Gausdal Hospital, in Norway, 8 were admitted with incorrect diagnosis. If there is positive family history and the classical symptoms are present, the diagnosis is assured. If positive family history is lacking but the classical symptoms are present, more intensive family investigation will probably give positive results. If the classical symptoms are absent or not marked but other symptoms are seen and the family history is positive, possible progression of the symptoms may be decisive; if there is no positive family history, renewed intensified investigation of the family may give results. Since at present no curative treatment is known, reduction in the number of Huntington chorea patients can occur only by reduction of the reproductive frequency in bearers of the hereditary tendency.

Vestibular Dysfunction in Childhood Schizophrenia. E. G. Colbert, R. R. Koegler and C. H. Markham. A. M. A. Arch. Gen. Psychiat. 1:600-617 (Dec.) 1959 [Chicago].

Hyporeactivity and paradoxical vestibular reactions have been reported in adults with schizophrenia. There is also a good deal of presumptive evidence that children with schizophrenia have some problems in the area of vestibular functioning. Since, moreover, there continues to be doubt about schizophrenia occurring before adolescence, the authors felt that it would be important to find whether there are common physiological denominators among adult schizophrenics and so-called childhood schizophrenics. Tests of vestibular and optokinetic function were performed on 43 children with schizophrenia, 18 with behavior problems, and 32 normal children. The normal and behavior-problem children had reactions similar to those of normal adults. The majority of schizophrenic children had markedly depressed or absent vestibular responses to caloric and rotational tests. The degree of hypoactivity was more marked in the younger children with schizophrenia. The responses of some schizophrenic children varied from one observation period to the next, unlike the responses of the controls and of normal adults. There were fewer and less severe manifestations of vertigo than were seen in the controls. This study suggests the possible existence of a neurophysiological continuum between a type of childhood schizophrenia and a type of adult schizophrenia.

Long Survival in Medulloblastoma: Three Cases. A. Lima, L. Antunes and C. Marçal. Rev. españ. oto-neuro.-oftal. 18:233-237 (July-Aug.) 1959 (In Portuguese) [Valencia, Spain].

Medulloblastomas are highly malignant and rapidly fatal if they are not surgically removed; yet the average survival period after removal does not exceed 1½ years. During the years from 1943 to 1958, however, 42 patients with medulloblastomas were observed in the Instituto de Neurologia of the Faculty of Medicine of Lisbon University, and 3 of these patients lived for more than 4 years after the operation; they included 2 adults (a man and a woman) and a child, 7 years old. The 3 patients were seen for the first time from 4 to 8 months after the appearance of severe neurological symptoms. The tumor was located in the cerebellar fossa and in the left cerebellar hemisphere, respectively, in the 2 adults; in the child it was located in the vermis cerebelli. The treatment consisted of surgical removal of the tumor, followed by roentgenotherapy. The immediate and late postoperative periods were uneventful.

The patients lived from 4 to 4½ years in good health, but by the end of this period severe neurological symptoms reappeared in the 2 adults. The man was subjected to a cervical laminectomy; a tumor was encountered, but further operation was interdicted. Autopsy revealed that the spinal leptomeninges were involved by a tumor, from the lower bulbar region to the cauda equina, which differed histologically from the one previously removed from the cerebellar fossa. The woman underwent a second operation for a recurrent medulloblastoma. Today this patient is free from neurological symptoms, but she is still under roentgenotherapy. The child is well 4 years after the first and only operation, which was followed by roentgenotherapy up to a total dosage of 27,000 r. Histologically the tumor removed from the vermis cerebelli consisted of neuroblasts and adult nerve cells. The authors believe that the rare cases of long postoperative survival in patients with medulloblastomas are due to the structure of the tumors which consist mainly or purely of either glial or nerve cells.

Inferior Nasal Quadrantanopsia in Pseudotumor Cerebri. J Dersh and N. S. Schlezinger. A. M. A. Arch. Neurol. 1:695-699 (Dec.) 1959 [Chicago].

Occasionally the ophthalmologist or the neurologist is confronted with a patient with bilateral papilledema associated with increased intracranial pressure, for which no cause can be found, even after extensive neurological examination and neurosurgical intervention. The signs and symptoms indicative of increased intracranial pressure simulate those of a cerebral tumor, and, therefore, the term "pseudotumor cerebri" has been applied to this condition. Some patients with the clinical features of pseudotumor cerebri exhibit a visual field defect in the form of a unilateral inferior nasal quadrantanopsia. Three such cases were observed for periods varying from 5 to 13 years at the Wills Eye Hospital, Philadelphia. It was noted in these cases that the inferior nasal quadrant defect remains essentially unchanged, without progression, and that it is not a threat to vision, provided that the original condition has been completely resolved.

Emphasis is placed upon the need to recognize the inferior nasal quadrantanopsia as a sector type of visual field defect which, in the presence of increased intracranial pressure, has no localizing significance and does not warrant exploratory neurosurgical intervention. Of several possible explanations considered, the one preferred is the concept of a gliosis of the optic nerve, commencing in the glial sheath of the nerve head on the temporal side.

A Restricted Form of Cerebellar Cortical Degeneration Occurring in Alcoholic Patients. M. Victor, R. D. Adams and E. L. Mancall. A. M. A. Arch. Neurol. 1:579-688 (Dec.) 1959 [Chicago].

The authors report observations on 50 alcoholic patients (46 men and 4 women) who presented a cerebellar syndrome. The most prominent abnormality was an ataxia of stance and gait and of the individual movements of the legs. The arms were relatively little affected, and nystagmus and dysarthria were usually absent. Instability of the trunk was common. The patients could be divided into 3 categories. In the first group, which comprised half of the patients, the disease evolved over a period of several weeks or months, after which it remained unchanged for many years. In the second group, the disease evolved over a period of several years, but in some of these patients the clinical condition eventually stabilized. In the third and smallest group, mild stationary signs of cerebellar disease had been present for several years; on this background there occurred a worsening of the cerebellar signs, but these, in turn, were again stabilized.

The essential pathological change, as observed in 11 autopsied cases, was a degeneration of all the neurocellular elements of the cerebellar cortex, particularly of the Purkinje cells, the changes being restricted to the anterior and superior aspects of the vermis and the hemispheres. The pathological changes were largely confined to that portion of the cerebellum which lies anterior to the primary fissure. The relation between the clinical and pathological findings is meaningful in the light of recent concepts concerning somatotopic localization in the cerebellum. The parts consistently involved in the pathological process, namely, the central lobule and the anterior folia of the anterior lobe, correspond to the "leg area" in the experimental animal; this is in keeping with the fact that ataxia of gait and incoordination of the legs are the most prominent clinical features.

Many etiological factors were considered, but only 2 seemed of importance—alcohol and malnutrition. Although the abuse of alcohol was a feature common to all the patients, 6 had actually been abstinent for varying periods of time before the onset of their disease. Fully 75% of the patients suffered from undernutrition when they were first seen. Malnutrition may also have been a factor in the remaining patients who came under observation years after the onset of their illness, after a period of abstinence from alcohol and improvement in their eating habits.

An extensive review of the literature (235 bibliographical references) disclosed 120 pathologically verified cases in which the disease process was limited to, or was predominant in, the cerebellar cortex. From this group it has been possible to derive the following subdivisions, each with distinctive clinical and pathological features: 1. Sporadic cases beginning in adult life, on a background of prolonged alcoholism, characterized clinically by a chronic course, usually with long periods of stability, and pathologically by predominance of degenerative changes in the anterior superior vermis and hemispheres. 2. Sporadic cases occurring in adult life, associated with carcinoma, characterized clinically by a subacute, steadily progressive course, and pathologically by diffuse and approximately equal degenerative changes in all portions of the cerebellar cortex. 3. Sporadic cases beginning in infancy and childhood, usually progressive and associated with mental retardation, characterized pathologically by diffuse changes in the cerebellar cortex, generally of greater severity in the hemispheres, and by lesions in other parts of the central nervous system. 4. Heredofamilial cases of cortical cerebellar degeneration. 5. Cases characterized pathologically by a selective degeneration of the granule-cell layer, and clinically by an onset in infancy or childhood and by mental retardation. 6. Miscellaneous cases. Considering the frequency with which this syndrome has been encountered on a background of alcoholism, and the stereotypy of the pathological and clinical picture, particularly in regard to the long periods of stability, the authors conclude that the restricted form of cortical cerebellar degeneration seen in alcoholics represents a clinicopathological entity.

Acetazolamide in the Treatment of Epilepsy. P. V. Arruda and C. S. Fonseca. Rev. Hosp. clín. 14:365-370 (Sept.-Oct.) 1959 (In Portuguese) [São Paulo, Brazil].

Sixty-two patients with an epileptic condition of at least 2 years' duration, who had been previously treated with different anticonvulsive drugs for more than a year without obtaining satisfactory results, were treated with acetazolamide in addition to the usual medication for epilepsy. There were 3 age groups. Seventeen patients were between 4 and 12 years; 12 were between 13 and 18 years; and 33 were between 19 and 48 years. Twenty-three patients were psychotic. The daily dose of acetazolamide was 375 mg. in 53 patients, 250 mg. in 4, 500 mg. in another 4, and 125 mg. in 1. The treatment lasted for 3 to 20 months, each patient being examined every 10 days at the beginning, then every month. As the results of the combined therapy became satisfactory, the doses of the usual anticonvulsive drugs were decreased. Acetazolamide became the only therapy in 6 patients.

The convulsive attacks were completely controlled under the treatment in 25 patients, including 8 of the 17 children in the 4-to-12-year age group. This control was obtained at the end of 3 to 5 months in 5 patients, 8 to 10 months in 4 patients, 11 to 15 months in 5 patients, and 16 to 20 months in another 5. The frequency and intensity of the attacks decreased in 20 patients, including 6 under 12 years of age, after a period of 8 to 20 months. The acetazolamide therapy had no effect on 11 patients, and in 6 the clinical picture became worse. There was improvement of the mental disorder in 8 of the psychotic patients, and no change in 13, although in 9 of these the convulsive attacks had been completely controlled. The psychic condition became worse in 2 patients. Electroencephalographic data were consistent with the clinical results, and in 12 of the patients whose attacks were controlled, the electroencephalogram became normal. The treatment was well tolerated. The findings indicate that, if the acetazolamide therapy is not effective during the first week, it should be discontinued.

GYNECOLOGY & OBSTETRICS

Emergency Arterenol Therapy in Obstetrics. J. C. G. Machado. Rev. brasil. med. 16:699-706 (Oct.) 1959 (In Portuguese) [Rio de Janeiro].

Arterenol was given as a vasoconstrictor to 32 patients admitted to the obstetric service of the Rocha Faria Hospital in Rio de Janeiro. The patients required emergency treatment for shock or an insufficient circulation caused by different conditions, such as uterine hemorrhage, rupture, abortion, placenta accreta, and retained placenta. The dose of arterenol varied from 2 to 15 cc., and the mode of administration was either intramuscular injection or intravenous perfusion in a dextrose solution. The therapy was successful in reversing the state of shock and in raising the blood pressure and maintaining a satisfactory level in 26 patients. Arterenol failed in 3 of 6 ectopic pregnancies, in 1 of 3 uterine ruptures, in 1 of 5 abortions, and in 1 of 2 placentae accretae. The intramuscular administration was effective in patients with recent venous collapse, in whom it was possible to refill the peripheral vessels and recanalize the veins. The intravenous perfusion was successful in raising and controlling the arterial pressure. Once the desired level was reached, the drip perfusion was slowed down. The average dose in perfusion was 4 ampuls of 1 cc. each in a dextrose solution. Arterenol is also effective in traction on nerve plexuses, especially if shock is recent. It is ineffective when the loss of blood is too great and/or when it is complicated by toxic hepatitis or lower nephron syndrome.

Hyperthyroidism in Pregnancy: Treating Hyperthyroidism During Pregnancy Without Impairing Fetal Thyroid. J. H. Holt. J. Kansas M. Soc. **60**:537-539 (Dec.) 1959 [Topeka].

Fetal loss and abnormalities have been reported when antithyroid drugs were used throughout pregnancy, and both uncontrolled hyperthyroidism and uncontrolled hypothyroidism were reported to be accompanied by a high incidence of fetal anomalies and monstrosities. Therapy of the pregnant woman with hyperthyroidism must be different from that of the nonpregnant woman, because the following substances are known to cross the placental barrier: iodine, radioiodine (I^{131}), antithyroid drugs of the thiourea type, and desiccated thyroid, and it is important that the normal physiology of the fetal thyroid not be interfered with.

The author presents the histories of 5 pregnant women with hyperthyroidism. Three of these were treated by antithyroid drugs (thiocarbamides) followed by a subtotal thyroidectomy. Hypothyroidism was carefully avoided during the preoperative medication. There were neither late complications of pregnancy nor fetal abnormalities. The fourth woman was 5½ months pregnant when she was found to have primary hyperparathyroidism. The recommendation that she undergo thyroidectomy after preparation with antithyroid drugs was refused, and the antithyroid preparation prescribed was taken irregularly and was discontinued during the last month of pregnancy; she gave birth to a microcephalic male infant. The case of the fifth woman with a nontoxic diffuse goiter associated with pregnancy was included in this series only to emphasize conservative management of thyroid disease during the last trimester of pregnancy. This patient was 8 months pregnant when she was found to have a nontoxic diffuse goiter. She gave birth to a normal girl, and a few days after delivery she was subjected to a thyroidectomy. The author concludes that careful preparation with the thiourea derivatives followed by surgery is a safe method for the management of hyperthyroidism during the first 2 trimesters of pregnancy.

Home on the Second Day: The Bradford Experiment: The Combined Maternity Scheme. G. W. Theobald. Brit. M. J. **2**:1364-1367 (Dec. 19) 1959 [London].

The most important period for detection of hypertension in pregnancy, for delaying its onset, and for preventing it from becoming an irreversible process; associated with proteinuria, is the period between the 24th and 34th weeks. In order that more beds might be available for the antenatal care of all primigravidas and of the multigravidas who had shown abnormalities in previous pregnancies, the staff of St. Luke's Maternity Hospital in Bradford, England, decided to decrease the number of lying-in beds. This was done by discharging a certain number of patients on the second day of puerperium. The rules established by the hospital for this early discharge were that the baby should be healthy and weigh at least 6½ lb. (2,948 Gm.), that the mother should be fit to move, and that the home conditions should be suitable. The domiciliary midwives inspect all homes before the patients are discharged, and the patients' physicians are informed.

During the first full year of operation of this program, 2,898 women were delivered of 2,969 babies; 741 (26%) were sent home within 48 hours after the delivery, to the care of their own physicians and to be visited by the domiciliary midwives. Only 3 of these mothers were rehospitalized, 2 because of secondary postpartum hemorrhage, and 1 because of fever. The combined maternity scheme, agreed upon by the hospital staff, the local health authorities, and general practitioners, has resulted in a better antenatal care program. Severe pregnancy toxemia has been almost eliminated from the city of Bradford. The method is not dangerous; it prevents the infant from becoming a culture medium for hospital staphylococci; and it may set a pattern in obstetrics and pediatrics.

Hormonal Mastopathy: A Clinical Study And Outline of Treatment. K. Cuningham and E. H. Wyse. M. J. Australia **2**:711-713 (Nov. 14) 1959 [Sydney].

The authors report clinical observations on 536 patients with hormonal mastopathy, who received treatment at the breast clinic of the Rachel Forster Hospital in Sydney. The patients, who were followed up for 8 years, were mostly in the premenopausal age group. In 75% of the patients, in whom pain, tenderness, swelling, and nodular areas, fluctuating in size, were present in the breast, the symptoms were relieved by the onset of menstruation. A quiescent period of 14 to 18 days ensued, but from the 18th day of the cycle onwards, discomfort increased, preexisting lumps became larger, and the whole breast became swollen until the onset of the next menstrual period. This led the authors to believe that hormonal mastopathy is due to an imbalance between estrogen and progesterone. Fibroadenoma was present in 32 patients; fibroadenosis, in 34; fibrocystic disease, in 189; hormonal mastopathy, in 249; mastopathy due to definite injury, in 10; and carcinoma supervening on hormonal mastopathy, in 22. Fibroadenosis was more common in patients under the age of 40, and the 32 patients with fibroadenoma were under 30. The majority of the patients with fibrocystic disease, however, were over 40. This suggests that, if the hormonal imbalance is of shorter duration, fibroadenosis occurs, but if it is prolonged over the age of 40, a fibrocystic condition will develop.

Treatment consisted of support to the breast, reassurance, administration of vitamin B_1 and luteal hormone, biopsy of all suspicious or persistent masses, and careful and continuous follow-up over a period of months or years. Surgical intervention was performed on 281 patients, 187 of whom had fibrocystic hyperplasia. To date, 249 patients with hormonal mastopathy have not been treated surgically. The high incidence of carcinoma (4.4%) supervening on hormonal mastopathy is significant, inasmuch as all 22 cases occurred in the premenopausal and menopausal age groups, in which the incidence of carcinoma is usually lower than in the age group of 50 or over. It is, therefore, suggested that hormonal mastopathy should be treated early and vigorously, and a careful follow-up, extending over a period of years, should be instituted.

PEDIATRICS

Neonatal Meningitis. E. K. Turner. M. J. Australia 2:806-808 (Nov. 28) 1959 [Sydney].

The author reports an unusual case of neonatal meningitis. The mother of the infant was said to have sinusitis, with a clear nasal discharge throughout pregnancy. At 8 weeks' gestation she developed a yellowish, nonspecific vaginal discharge, which had disappeared at term; at 36 weeks' gestation she developed rubella. A small hemorrhage of dark blood developed 22 hours before delivery, and occasional "spotting" continued until delivery. The mother seemed well, and the female infant looked normal at birth.

Jaundice appeared in the infant at the age of 14 hours, and it remained the predominant symptom. At first a diagnosis of fetal erythroblastosis was entertained, because of an ABO incompatibility between the blood groups of the mother and the newborn infant. The infant then showed gradual decreased action. Her blood group was B_3. Rh positive, and at 40 hours of age she had deep jaundice, the serum bilirubin content being 18 mg. per 100 cc. She resented movement and showed increased "startle" response if disturbed. Her cry was shrill; she was sucking poorly; and the fontanel felt woody. The lumbar puncture revealed a turbid cerebrospinal fluid, 6 ml. being removed; this fluid contained 7,300 polymorphonuclear leukocytes per cubic millimeter. On culture, a streptococcus, group B, weakly hemolytic, was grown. This streptococcus was identical with the one which had been cultivated from the mother's postpartum cervical swab and which was probably a normal inhabitant of her vagina.

When the infant was 41 hours old, treatment was instituted with chloramphenicol, given intravenously in doses of 100 mg. per kilogram of body weight; 1 million units of crystalline penicillin was given intravenously every third hour, and sulfadiazine was administered intramuscularly in a dose of 0.1 Gm. per kilogram of body weight. The infant died at the age of 63 hours. The autopsy confirmed the diagnosis of purulent meningitis, attributed to weakly hemolytic streptococci, group B. Infection had evidently been acquired during the infant's passage through the birth canal, although no perinatal trauma was present. The author also reviewed the case histories of 45 infants with neonatal meningitis in 2 hospitals in Melbourne. Twenty-eight of the infants died. The prognosis of neonatal meningitis is grave, despite early diagnosis and adequate therapy.

Needle Biopsy of the Liver: An Aid in the Differential Diagnosis of Prolonged Jaundice in Infancy. R. Kaye, C. E. Koop, B. M. Wagner and others. A. M. A. J. Dis. Child. 98:699-709 (Dec.) 1959 [Chicago].

The authors performed needle biopsy of the liver in 25 infants, between the ages of 3 weeks and 18 months, with prolonged jaundice, in whom hemoglobin concentration and prothrombin, bleeding, and coagulation times were found to be relatively normal. The jaundice was secondary to biliary atresia in 14 of the 25 infants; it was secondary to hepatitis in the remaining 11 infants. Accurate histological diagnosis for the purpose of differentiating biliary atresia from hepatitis requires samples of liver tissue which include portal as well as hepatic parenchymal cell areas. In biliary atresia the important findings are marked increase in fibrous tissue in the periportal areas, proliferation of bile ducts, intraductal biliary stasis, and maintenance of liver cord pattern. A histological diagnosis of hepatitis is made on the findings of distortion of the lobular architecture by swollen parenchymal cells, many of which are multinucleated giant cells, and of minimal or absent bile duct proliferation and fibrosis in the portal areas. All specimens obtained by needle biopsy will not yield material adequate for diagnostic purposes. In general, specimens of 6 mm. or more in length will prove to be suitable. According to the criteria described, 12 of the 14 biopsies obtained from the infants with biliary atresia and 6 of the 11 biopsies obtained from patients with hepatitis were adequate for diagnosis.

In 5 of the 14 patients with proved atresia of the bile ducts, the correct diagnosis was made on the basis of the biopsy specimen when certain clinical and laboratory findings were more suggestive of hepatitis. The actual or potential value of needle biopsy in avoiding unnecessary laparotomy has been described in 3 infants, in whom diagnostic biopsy specimens were obtained, and operation was withheld. Two of these patients are now clinically well, and the third is doing fairly well. The presence of small amounts of urobilinogen was noted in the urine of all 3 of these patients and in the stool of one of them; small amounts of urobilinogen, however, were seen also in 3 of the 5 patients with biliary atresia and in others reported in the literature. Although a presumptive diagnosis of the disease was made in each of the 3 patients with hepatitis, anatomic confirmation obtained by needle biopsy firmly established the basis for deferring exploratory laparotomy. Needle biopsy, by permitting early definitive diagnosis, may be an aid in avoiding the development of biliary cirrhosis in patients with types of biliary atresia amenable to surgical correction.

Inhalation of Excess Liquor as a Factor in the Production of Hyaline Membrane Atelectasis. K. Campbell. M. J. Australia 2:797-800 (Nov. 28) 1959 [Sydney].

The author has observed that the following conditions are usually associated with hyaline membrane atelectasis: inhalation of excess amniotic liquor, prematurity, typical "grunting" type of respiration, generalized edema and cyanosis, and a self-limited course. A combination of accidental hemorrhage, placenta praevia, and cesarean section is referred to as the excess liquor factor. The maximum incidence of hyaline membrane atelectasis has seemed to be in the group weighing 1,250 to 1,500 Gm. (2 lb. 12 oz. to 3 lb. 5 oz.). Death from hyaline membrane atelectasis takes place almost always before the 48th hour of life.

To test the theory that the inhalation of excess liquor is an essential factor in the production of hyaline membrane atelectasis, the author examined the hospital records of all infants weighing 750 Gm. (1 lb. 10.5 oz.) and more, born from 1955 through 1958, who lived from 1½ to just under 48 hours. There were 135 infants whose alveoli contained, and 223 infants (control series) whose alveoli did not contain, hyaline material. The cases were divided into 7 groups with birth weights of 750 to 999 Gm., 1,000 to 1,249 Gm., 1,250 to 1,499 Gm., 1,500 to 1,749 Gm., 1,750 to 1,999 Gm., 2,000 to 2,499 Gm., and 2,500 Gm. and over. The incidence of the excess liquor factor in the hyaline membrane atelectasis series was proportionally more than double that in the control series. In all groups except the 1,250-to-1,500-Gm. group, the incidence of the excess liquor factor was higher in the hyaline membrane atelectasis series than it was in the controls. This preponderance increases with each increase in weight.

In the 1,250-to-1,500-Gm. group, which is the largest and the most vulnerable, the incidence of the excess liquor factor was less in the hyaline membrane atelectasis series than it was in the controls. This suggests that in this group some special factor is operating. It is at the period of gestation from 30 to 32 weeks that there is clinically the greatest amount of liquor present relative to the size of the fetus. Under such circumstances there would always be a larger amount of liquor present at birth than usual, so that the excess liquor factor would be present in all infants of this group. This seems to explain the disagreement between this and the other groups. The author believes that practical measures designed to minimize the amount of liquor inhaled at birth would prevent the development of hyaline membrane atelectasis.

Infantile Nephrosis: Clinical, Biochemical, and Morphologic Studies of the Syndrome. H. G. Worthen, R. L. Vernier and R. A. Good. A. M. A. J. Dis. Child. 98:731-748 (Dec.) 1959 [Chicago].

The authors report on 12 infants in whom nephrosis developed during the first year of life and who were studied in the department of pediatrics of the Variety Club Heart Hospital in Minneapolis. Of the 12 infants, 7 were girls and 5 were boys. All the patients had the characteristic findings of the nephrotic syndrome, namely, edema, albuminuria, hypoalbuminemia, hypercholesterolemia, and elevation of the erythrocyte sedimentation rate. Microscopic hematuria was detected in at least one urine specimen from every patient. The symptoms, physical findings, and laboratory abnormalities were essentially the same as those of older children with idiopathic nephrosis. The infants, however, showed several unusual features, distinguishing them from the older children with the nephrotic syndrome: these features were the early age of onset (one month after birth in 6, and between the ages of 3 and 10 months in the other 6), a high familial incidence, refractoriness to treatment, and poor prognosis (8 of the 12 patients have already died).

Microscopic studies on biopsy or autopsy revealed varying degrees of glomerular fibrosis in the kidneys from 4 patients, while the kidneys from 5 patients did not show any glomerular abnormalities. The kidneys from the remaining 3 patients were of special interest microscopically, since a striking degree of dilatation of the proximal convoluted tubule was found. No cause for this unusual abnormal condition could be determined by microdissection of the kidneys. Electron-microscopic study of the glomeruli from 9 patients revealed fusion of the epithelial-cell foot processes. This abnormality of fine structure was identical with the lesion observed to the characteristic of older patients with nephrosis. The presence of this alteration of fine structure in glomeruli from patients with severe tubular dilatation suggests that the primary abnormality in the various patients with infantile nephrosis resides in the glomerulus.

No definite evidence is available at present to indicate whether or not the cause of infantile nephrosis is the same as that of idiopathic childhood nephrosis. The possible role of maternal toxemia has been discussed. The autoimmune mechanisms, which have been given etiological importance in childhood nephrosis by many workers, probably cannot be implicated as the cause of infantile nephrosis. The results of this study do not support the suggestion of other investigators that a metabolic defect, associated with crystalline deposits in the kidney, is the cause of infantile nephrosis.

A Case of Total Absence of Ganglion Cells in the Colon: Hirschsprung's Disease Without Megacolon. N. Genton and D. Pometta. Helvet. paediat. acta 14:383-395 (Oct.) 1959 (In French) [Basel, Switzerland].

The authors report on a 9-month-old girl with refractory constipation, repeated attacks of vomiting, and marked abdominal meteorism, who was admitted to the surgical department of the pediatric clinic of the University in Zurich, Switzerland, with a tentative diagnosis of megacolon (Hirschsprung's disease). Roentgenologic examination of the intestines with the aid of a barium enema revealed a normal diameter of the colon, an empty rectosigmoid, and the ascending, the transverse, and the descending colon filled with fecal material which could not be removed by repeated enemas or by the introduction of a rectal catheter. Laparotomy revealed a considerably dilated and hypertrophied ileal loop interposed between the intestinal wall and the cecum. The colon was not dilated. With the aid of a cecostomy the fecal material was removed from the cecum and the ascending colon. A biopsy of the cecal wall revealed total absence of ganglion cells. The cecostomy did not suffice to reduce the ileus. An ileostomy was performed, which reestablished the intestinal passage, but the condition of the infant deteriorated. Eventration with peritonitis occurred, and the patient died 6 weeks after her admission to the hospital.

This is a rare case of megacolon with total absence of ganglion cells in the colon. The diagnosis of aganglionic colon has been based on the history, the clinical picture, the roentgenographic findings, and the rectal biopsy. Only 2 cases of this type were collected from the literature; the patients were cured by an early ileostomy, followed after a few months by a total colectomy.

ENDOCRINOLOGY

Hyperinsulinism. R. Menguy. J. Oklahoma M. A. 52:797-804 (Dec.) 1959 [Oklahoma City].

The author reports on 2 men, aged 39 and 57 years, respectively, with organic hyperinsulinism, a symptom complex resulting from an excess of circulating insulin. In both patients the excess insulin was produced by a functioning tumor of the pancreatic islets of Langerhans. In the older man a prompt diagnosis was made, and full recovery resulted from distal pancreatectomy and splenectomy. The younger man was hospitalized repeatedly for recurrent attacks of unconsciousness, and a diagnosis of conversion reaction manifested by periods of amnesia and somnolence was made. One month later the patient, after having been comatose for 72 hours, was readmitted to the hospital, and this time a diagnosis of chronic brain syndrome of unknown cause and left cerebral cortical atrophy was made. After discharge the patient again had recurrent attacks of unconsciousness, lasting from 15 minutes to 5 days. He was rehospitalized, and a routine determination of the blood sugar level revealed a value of 29 mg. per 100 cc. The test was repeated, and a level of 33 mg. per 100 cc. was found. Only then a diagnosis of islet-cell tumor of the pancreas was made, and a round mass, 2 by 1 cm., was removed by wedge resection from the head of the pancreas. On microscopic examination of the operative specimen, the lesion was found to be a benign beta-cell adenoma. Despite successful removal of the functioning islet-cell adenoma, the patient had a poor result because of irreversible brain damage brought on by repeated severe hypoglycemic attacks. Unfortunately, throughout the patient's successive hospitalizations a psychiatric diagnosis served as a "mental block."

In most of the patients with organic hyperinsulinism, the results of surgical treatment are excellent. This is particularly true of those patients in whom the lesion is found at exploration, is single and benign, and can be removed by a partial pancreatectomy. Good late results can be expected in about 90% of the patients. When a blind distal pancreatectomy is performed because of failure to find a lesion, about 60% of the patients are cured of their symptoms, which can be summarized in the classical symptomatic triad (Whipple's triad) of attacks of hypoglycemic symptoms associated with fasting or exercise, accompanied by a blood sugar level lower than 50 mg. per 100 cc., and relieved by the administration of glucose. The most important aid to the diagnosis is an awareness on the part of the physician that hyperinsulinism may be responsible for such vague and unspecific symptoms as loss of consciousness, confusional state, weakness and fatigue, deep coma, sweating, drowsiness and stupor, lightheadedness, visual disturbances, amnesia, clonic convulsions, noisy behavior, and headache. In view of the nature of the presenting symptoms, it is not surprising that such diagnoses as epilepsy, psychosis, or inebriation are considered. Early diagnosis of this condition is of the utmost importance, because repeated hypoglycemic attacks may lead to irreversible brain damage. The only form of treatment is surgical.

Precocious Puberty Associated with Hepatoma. R. L. Reeves, H. Tesluck and C. E. Harrison. J. Clin. Endocrinol. 19:1651-1660 (Dec.) 1959 [Springfield, Ill.].

A boy, 8 years of age, was admitted to the hospital because of precocious sexual development, consisting of pubic hair, penis of adult size, many erections, and sore breast. There was no response to the cortisone suppression test. When first seen, evidence of gonadotropic activity was overlooked, and a tentative diagnosis of adrenal tumor was made in view of the increased excretion of urinary 17-ketosteroids. Both adrenals were explored through bilateral lumbodorsal incision, yielding no result. The patient was discharged, but readmitted 3 months later because of the presence of a hard epigastric, nontender mass. An abdominal exploration revealed a pseudoencapsulated tumor within the liver. A biopsy specimen was obtained, and the abdomen was closed. The patient died 20 days after the operation.

Microscopic study of the tumor indicated hepatic origin and suggested a hepatoma with a biliary duct component. At autopsy, no abnormal changes were found in the pineal gland, hypothalamus, or pituitary body, other than a possible increase in the number of amphophilic cells in the pituitary. Assay of the tumor showed that chorionic gonadotropic activity was present in a mean concentration of 2 I. U. per gram, net weight, of tumor tissue. This case represents a clear evidence of an endocrine disturbance from both clinical and laboratory standpoints. The tumor was almost certainly primary in the liver. It seems that this hepatic tumor had the capacity to elaborate gonadotropin—a function heretofore considered to be restricted to the pituitary, placenta, and chorionepithelioma.

Diabetes Insipidus Complicating Total Adrenalectomy. J. R. Rees and J. F. Zilva. J. Clin. Path. 12:530-534 (Nov.) 1959 [London].

The authors present the history of a woman who in 1947, at the age of 54 years, had undergone radical mastectomy and local irradiation because of carcinoma of the left breast. She remained well until 1957, when malaise, loss of weight, and bone pain developed. There was no local recurrence, but roentgenograms revealed extensive pulmonary and osseous metastases, involving the femurs, pelvis, and skull with erosion of the sella turcica. Oophorectomy and total adrenalectomy were performed. Recovery was uneventful with the daily administration of cortisone by mouth, but several months later, despite increasing the dose of cortisone to 125 mg. daily and taking extra salt, the woman's condition rapidly deteriorated, with mental confusion and dehydration.

Thirst and polyuria, together with dehydration and hemoconcentration, indicated diabetes inspidus, and treatment with vasopressin (Pitressin) tannate was started. The dehydration disappeared, and the blood pressure became normal, with weight gain, a positive fluid balance, and a fall in plasma protein and serum sodium levels. By the third day the patient's clinical state was satisfactory. She had received 1 ml. of Pitressin in oil intramuscularly each day (5 pressor units per milliliter), but from the 4th day on deterioration was observed. It was then discovered that aqueous Pitressin (20 pressor units per milliliter) had been given in error for the oily suspension of Pitressin and, despite a sixfold increase in dosage, had produced no effective over-all antidiuretic response. When this error was corrected, the diabetes insipidus was again controlled.

Later it was discovered that the dose of cortisone was insufficient to maintain a normal sodium balance in this patient. An unusually high dosage of steroid was required for maintenance, for the combination of endocrine effects proved difficult to treat. However, it appears that, if a satisfactory preparation of Pitressin is used, water balance is readily restored, and steroid dosage must then be adjusted according to the serum electrolytes and urinary sodium excretion.

Sarcoidosis and Hyperparathyroidism with Hypercalcemia: Special Usefulness of the Cortisone Test. J. M. Burr, J. J. Farrell and A. G. Hills. New England J. Med. 261:1271-1275 (Dec. 17) 1959 [Boston].

It has been discovered that in certain conditions giving rise to hypercalcemia and hypercalciuria excessive absorption of dietary calcium and elevated renal calcium clearance occur, and that in these conditions the administration of cortisone regularly restores normocalcemia and normocalciuria, provided that the excess of calcium is not due to hyperparathyroidism. A puzzling problem arises also when 2 conditions capable of causing hypercalcemia coexist; here, too, the response to cortisone may be helpful in diagnosis. This is demonstrated by the case history of a 57-year-old woman. The diagnosis of sarcoidosis was favored during her early period of hospitalization because of the coexistence of hypercalcemia and its sequelae, hyperglobulinemia and hepatosplenomegaly. However, the history of nephrolithiasis dating back 8 years, the hypertension, the rather low serum phosphorus concentrations, and especially the abnormally low value for the phosphorus reabsorption index necessarily raised the question of possible hyperparathyroidism. The failure of administered cortisone to affect the hypercalcemia and hypercalciuria was considered to exclude sarcoidosis as a cause of these, and led to the presumptive preoperative diagnosis of hyperparathyroidism. Surgical removal of a parathyroid adenoma, followed by prompt relief of hypercalcemia and hypercalciuria, confirmed the diagnosis of hyperparathyroidism and showed that the hypercalcemia had been caused by hyperparathyroidism. The diagnosis of sarcoidosis was established when histological evidence of the disease was obtained in the resected spleen and abdominal lymph nodes.

This is the third reported case of coexisting sarcoidosis and hyperparathyroidism with hypercalcemia. In a case presented by Snapper and associates in 1958, the diagnosis of sarcoidosis had already been established, but because of mild hypertension and persistently lowered serum phosphorus level with high renal phosphorus clearance, and because the patient's twin brother had had a parathyroid adenoma removed, coexisting hyperparathyroidism was suspected. Failure of the elevated levels of calcium in the serum and urine to fall under the influence of administered cortisone then led to exploration of the neck and removal of a parathyroid adenoma, with correction of the hypercalcemia and hypercalciuria. Westra and Visser earlier (in 1949) had described a patient with sarcoidosis, from whom a slightly hyperplastic parathyroid gland had been removed, with amelioration of the hypercalcemia. The authors emphasize the importance of the cortisone test in disorders accompanied by hypercalcemia.

Diagnostic Difficulties in Juvenile Hypothyreosis. C. Thorén and G. Sterky. Nord. med. 62:1607-1612 (Nov. 5) 1959 (In Swedish) [Stockholm].

Juvenile hypothyreosis often has an insidious onset and is difficult to diagnose, especially in patients without myxedema. High sedimentation reaction is an important symptom. Of 19 children with hypothyreosis seen in a 10-year period, 10 had sedimentation reaction over 20 mm. Electrocardiographic changes occurred in 8 cases. Marked constipation resistant to therapy is a prominent symptom. Iron-refractory anemia may be a symptom. The maximum pulse rate is probably lowered in the disease. Three cases in girls, aged 12 or 13 years, with high sedimentation reaction but otherwise different symptoms of hypothyreosis, are reported. In the instance with juvenile myxedema, with unspecific increase in the antistreptolysin titer, there were megacolon and kidney stone. The general lowering of the T waves was normalized during work, which indicates functional origin. Megacolon can occur in hypothyreosis without myxedema. One of the cases illustrates a typical disturbance in ossification, the so-called epiphysis dysgenesis, which is usually most characteristic in the head of the femur; marked regression resulted after a year's increased thyroid therapy.

Direct and Indirect Estimation of Pituitary Adrenocorticotropin Reserves in Man Following Adrenal Steroid Therapy. D. A. Holub, J. W. Jailer, J. I. Kitay and A. G. Frantz. J. Clin. Endocrinol. 19:1540-1552 (Dec.) 1959 [Springfield, Ill.].

The purpose of this study was to find out whether abnormalities in the storage and release of corticotropin (ACTH) take place in man after the administration of large amounts of adrenocortical steroids. Pituitary ACTH concentration was measured post mortem in 17 patients, 5 of whom were treated and 12 were not treated, with adrenal steroids before death. The mean pituitary ACTH concentration in the steroid-treated group was 99 milliunits per milligram, which value did not differ significantly from that in the untreated group. Individual values ranged from 28 to 228 milliunits per milligram. Neither the average daily dose of steroids nor the total duration of therapy appeared to be correlated with ACTH concentration in this group. The pituitary ACTH concentration in one patient of the steroid-treated group was relatively low (28 milliunits per milligram), although she received 3 times as large a total dose of steroids as any other patient. Pituitary histological structure appeared normal in all steroid-treated patients with the exception of the preceding one, in whom Crooke's changes were seen in the basophilic cells. Adrenal atrophy was marked in 4 patients of the steroid-treated group and was mild in 1.

The availability of ACTH for release was tested by using the adrenocortical inhibitor Su-4885 in 9 living persons. Four patients had received steroid therapy for prolonged periods of time, and 5 had not. The responses of 3 of the steroid-treated patients were similar to those seen in the control group. Pituitary ACTH insufficiency was exhibited by only one steroid-treated patient. The present findings suggest that most of the steroid-treated patients respond normally to stimulation of the pituitary gland. Depletion of pituitary ACTH might be found in patients who have received large doses of steroids over prolonged periods of time.

DERMATOLOGY

Griseofulvin in Treatment of Infections of Scalp Due to Microsporum Canis. M. Beare and D. Mackenzie. Brit. M. J. 2:1137-1140 (Nov. 28) 1959 [London].

The authors report on 50 children with various types of ringworm observed at the Royal Belfast Hospital for Sick Children, 19 of whom had infections of the scalp due to Microsporum canis. These 19 children were between the ages of 15 months and 12 years, and all were given griseofulvin orally in doses of 0.25 Gm. 3 times daily. The duration of treatment varied from 3½ to 10 weeks. Fungal invasion of the hair was stopped abruptly soon after the drug was given, and new areas of infection did not appear. Debris, probably intrafollicular, remained infected, and the organisms were recovered readily for long periods up to 14 weeks after treatment was started.

Wood's-light fluorescence usually disappeared in 1 to 6 weeks and, on the average, in 3 weeks. In only 1 of the 19 children was there any evidence of fluorescence at the tips of the hairs. In contrast to experiments on guinea pigs, in which fluorescence at the tips is common, fluorescent tips are only exceptionally found in children. In one rather unusual case in this series, however, fluorescence was observed 8 weeks after treatment was started; after the second week this fluorescence appeared at various distances from the surface of the scalp; positive cultures were obtained up to 12 weeks after the initiation of treatment; and microscopic examination often revealed a well-established infection in a nonfluorescent portion of hair. Only 2 of the 19 children had nausea, but it was not certain that the nausea recorded could be attributed to the drug. No other symptoms which might have been attributed to griseofulvin were observed.

None of the patients received any form of local application. Because this was a clinical trial in which the authors were determining the effects of griseofulvin alone, the children were told not to wash their hair or scrub the affected area. Future studies should be directed toward a method for the removal of infected debris. Such methods might include washing, scrubbing, and/or shaving the affected areas, and the application of local fungicides. It is apparent that, although griseofulvin is a most remarkable advance in antibiotic therapy, it is insufficient in itself to cure scalp ringworm (at least that due to M. canis) within a reasonably short period.

Griseofulvin in Treatment of Persistent Fungal Infections of the Skin. A. J. E. Barlow, F. W. Chattaway, K. G. Hargreaves and C. J. La Touche. Brit. M. J. 2:1141-1143 (Nov. 28) 1959 [London].

The authors report on 34 patients with persistent fungal infections of the skin who were treated with griseofulvin given orally in doses of 1 to 2 Gm. daily at the Royal Infirmary in Huddersfield and at the General Infirmary in Leeds, England. Of the 34 patients, 2 children with candidiasis and 1 man with tinea versicolor showed no clinical change as a result of treatment. In 2 men with typical cattle ringworm due to Trichophyton verrucosum, the primary lesions resolved over a period of 3 weeks, and it was felt that the duration of the infection was not significantly modified. Immediate symptomatic improvement resulted in one man with a vesicular infection of the instep due to T. mentagrophytes var. interdigitale, but scaling persisted for 5 weeks and viable fungus was present in the sole for 6 weeks. Reexamination during the next 3 months revealed the soles to be normal. In 2 patients with infection of smooth skin only by T. rubrum, each showed subjective improvement; scrapings became negative after 10 days and have remained so for 6 months in one patient, while in the other scrapings still remained positive after 3 weeks.

The remaining 26 patients had long-standing infection of multiple nails and skin by T. rubrum, previously resistant to numerous methods of treatment, including surgical avulsion of nails. They were treated with griseofulvin for periods of 3 to 20 weeks. Most of them improved, but in only one patient was the infection eradicated. Since griseofulvin is fungistatic and not fungicidal, its mode of action would seem to be by inhibiting fungal growth in its mycelial stage, so that infection is carried away by the outward growth of keratins. In the smooth skin the inhibitory effect of griseofulvin will cause the fungus to lose its foothold in the normal process of desquamation of soft keratin. Nail infection presents a different problem, since here keratin does not desquamate: hence it is necessary to wait for the nail to grow sufficiently for infection to be carried beyond the free edge. At least 4 months must be allowed for infection of finger nails to grow out, while well over a year would be required for infection to be eliminated from the nail of the big toe. Whether it would, therefore, be necessary to administer griseofulvin continuously or intermittently over such a long period can be proved only by trial and error.

Increasing use of griseofulvin will clarify the position about toxicity. In this series, 3 patients were unable to tolerate the drug, but despite noting some variation in the differential blood count, there is insufficient evidence to state that the drug has a toxic effect on the bone marrow. It is, however, important that this possibility is borne in mind. A combination of surgical removal of nails, with systemic administration of griseofulvin and possibly the subsequent use of topical fungicides, would offer the patient with chronic nail infection by T. rubrum the best chance of cure.

Colloid Degeneration of the Skin (Colloid Milium): A Report of Seven Cases. J. D. Guin and E. R. Seale. A. M. A. Arch. Dermat. 80:533-537 (Nov.) 1959 [Chicago].

The authors report on 7 patients with colloid degeneration of the skin (colloid milium), who were admitted over a 6-year period to the department of dermatology, Baylor University college of medicine, Houston, Texas. The patients were all men, ranging in age from 33 to 37 years. In general, this group of patients with colloid degeneration of the skin was similar to those described in the literature. The high incidence of this skin disease in southeast Texas can be attributed to the long summers and to the large number of fair-skinned people in this area. The pseudovesicles of colloid degeneration occurred over the ears, the malar region, and the posterior neck in some of the patients, but the dorsum of the hands—more often that of the left hand—was the most severely involved in all the patients. The greater involvement of the dorsum of the left hand can be explained by the exposure to the sun on the left while driving a car with the window down. None of the patients improved while on ascorbic acid therapy. One patient, however, showed definite improvement 6 months after the treatment with ascorbic acid had been discontinued; it was found that he had been indoors during this entire period. It seems, therefore, that the patient's improvement could be attributed to the avoidance of excess sunlight rather than to the ascorbic acid therapy. The cholesterol level in the blood was increased in 4 of the 5 patients tested. The significance of this finding remains to be determined.

UROLOGY

Gonorrhea Due to Penicillin- and Streptomycin-Resistant Strain. R. T. Bjørnstad and K. Noreik. Tidsskr. norske laegefor. 79:1167-1169 (Oct. 15) 1959 (In Norwegian) [Oslo].

A case of acute gonorrhea, which an aviator had contracted in Japan, was treated at the Rikshospital in Oslo. The patient had had symptoms of acute gonorrhea for 6 or 7 days. Both the clinical course and the lack of response to penicillin and determination of resistance indicated that the gonococcic strain was resistant to penicillin and streptomycin. This was borne out when treatment for 5 days with a total of 2 million units of penicillin and 2.5 Gm. of streptomycin was without avail. The condition also remained unchanged after the injection of 600,000 units of procaine penicillin. However, treatment with a total of 9.5 Gm. of tetracycline gave good results. Because of increased communication between the Far East and Norway, more rapid spread of gonococcic strains, such as the one isolated in this case, is probable, with possible introduction of the disease into Norway in its incubation period. For gonorrhea patients infected in the Far East, Epstein advocates 900,000 units of procaine penicillin G administered twice daily at 3-hour intervals for 3 days, or a total of 5.4 million units.

Comparative Bacteriologic Study of Urine Obtained from Children by Percutaneous Suprapubic Aspiration of the Bladder and by Catheter. C. V. Pryles, M. D. Atkin, T. S. Morse and K. J. Welch. Pediatrics 24:983-991 (Dec.) 1959 [Springfield, Ill.].

A comparative bacteriological study of urine obtained by catheter and by suprapubic aspiration was performed in a group of 42 children who were presumed free from clinical infection of the urinary tract, and who were undergoing elective surgery for conditions that did not involve manipulation of the urinary tract. There was complete diagnostic correlation between urine obtained by suprapubic aspiration and the clinical impression; there was 92.8% diagnostic correlation between the first few milliliters of urine obtained by catheter (C_1) and the specimens obtained by suprapubic aspiration; and there was a 97.5% diagnostic correlation between the second few milliliters of urine obtained by catheter (C_2) and the suprapubic specimens. Three patients had significant bacterial counts in specimens obtained by catheter, and on this basis alone a diagnosis of pyelonephritis might have been made erroneously. The C_2 specimens, however, showed a significant count in only one of the 3 patients, pointing out the importance of discarding the initial few milliliters of urine obtained by catheterization. In this patient, the suprapubic specimen was sterile, the C_2 specimen grew out 3,100 colonies of Escherichia coli per milliliter of urine, while a subsequent clean voided specimen did not exhibit significant growth. The patient remained in good health, and in view of the sterile specimen obtained by suprapubic aspiration, the authors believe that the organisms grown in the C_2 specimen were due to contamination. Gram stains of all specimens were negative for organisms.

On follow-up examination 1 to 5 months after the operation, all the patients were found to be free from infection of the urinary tract within a period of 4 to 6 months after catheterization. The authors believe that, while properly collected, clean voided specimens may be used in most instances for making the diagnosis of true bacteriuria in children, catheterization, when properly done, should not be withheld for fear of producing infection of the urinary tract. It must remain a necessary procedure in the diagnosis and management of infections of the urinary tract in the following cases: those in which there is urinary retention; those in which repeated study of clean voided specimens yields borderline or doubtful results; those in which the patient is so acutely ill that there is need for immediate antimicrobial therapy and no time for multiple specimens to be obtained; or those in which the patient is unable or unwilling to cooperate.

Prostatectomy: A Survey of 2,000 Cases. C. B. Thrasher and P. M. Beglin. California Med. 91:338-340 (Dec.) 1959 [San Francisco].

A statistical analysis was made of 2,000 consecutive cases in which prostatic operations were performed in the period from 1947 to 1957 at the Southern Pacific General Hospital, San Francisco. The operations included transurethral resection which was done in 1,327 instances; suprapubic prostatectomy, in 614; perineal prostatectomy, in 43; and retropubic prostatectomy, in 16. The mortality rates were lowest for transurethral resection (1.8%) and highest for retropubic prostatectomy (6.25%). Coronary artery disease and pulmonary embolism were the chief causes of death. It was generally felt that preliminary partial vasectomy previous to transurethral resection added very little to successful convalescence. Although distilled water was used routinely for irrigation during transurethral resection, there was no incidence of lower nephron nephrosis. The incidence of recurrence of prostatic obstruction was highest by far after transurethral resection.

Carcinoma of the Prostate with Metastases to the Testicle. C. Ney, J. J. Roth and C. A. Lopez. A. M. A. Arch. Surg. 79:1028-1031 (Dec.) 1959 [Chicago].

The authors report on an 85-year-old man with carcinoma of the prostate with metastases to the testis, who was admitted to the Morrisania City Hospital in New York, and on a 55-year-old man with secondary carcinoma of the testis arising from carcinoma of the prostate, who was admitted to the Lebanon Hospital in New York. In the first patient a transurethral resection of the prostate had been performed previously with removal of 11 Gm. of tissue; microscopic examination of the operative specimen revealed moderate glandular hyperplasia with fragments of adenocarcinoma of the prostate. The patient was advised to have an orchiectomy, which he refused. Seven years later he was readmitted to hospital, complaining of nocturia. This time bilateral orchiectomy was performed, and microscopic examination of the operative specimens revealed atrophy of the right testis, and in the left testis a well-differentiated adenocarcinoma of the same type as seen in the prostate previously. In the second patient a transurethral resection of the prostate had also been performed previously, with removal of 20 Gm. of tissue; microscopic examination of the operative specimen revealed nodular hyperplasia with fragments of papillary adenocarcinoma. Five years later, the patient was readmitted to hospital because of a 2-month history of discomfort in the left lower quadrant. For about one month he had noticed that the left testis had become hard and painful. A bilateral orchiectomy was performed. Microscopic examination of the operative specimens revealed metastatic papillary adenocarcinoma of the left testis, showing a similar pattern to that previously observed in the prostate.

The testis may become the seat of secondary tumors by any of 5 routes, i. e., by retrograde venous extension or embolism; by retrograde lymphatic extension; by arterial embolism; by way of the lumen of the ejaculatory ducts to reach the epididymis and testis; and by direct extension through the vas deferens but not within the lumen of the vas. The 2 patients did not show any involvement of the cord with tumor, and the authors assumed that metastases occurred by way of arterial embolization. Twenty-six previously published cases of secondary carcinoma of the testis arising from carcinoma of the prostate were collected from the literature. It is suggested that, even though this lesion has occurred rarely in the past, it may be found even less frequently in the future.

Cranberry Juice and the Antibacterial Action of Hippuric Acid. P. T. Bodel, R. Cotran and E. H. Kass. J. Lab. & Clin. Med. 54:881-888 (Dec.) 1959 [St. Louis].

Cranberry juice has been widely used in the Cape Cod area of Massachusetts in the treatment of infections of the urinary tract. Investigators had demonstrated that the urinary excretion of hippuric acid rose after the ingestion of cranberries (the berries of Vaccinium macrocarpon) or of cranberry juice. The structural similarity of hippuric acid to mandelic acid, which inhibits bacterial multiplication, was another indication that substances from cranberries might have antibacterial activity. The studies described were undertaken to investigate the antibacterial activity of hippuric acid and the effect of ingestion of cranberry juice on urinary acidity and hippuric acid excretion. Commercial cranberry juice, consisting of one part juice from pressed cranberries and 2 parts water, with added sugar, was used. It was found that cranberry juice, given in maximal tolerable amounts to normal subjects, increases the acidity of the urine slightly and increases the hippuric acid content of the urine by several grams a day. Hippuric acid, in concentrations of 0.02 to 0.04 M, is bacteriostatic at pH 5.0 for the common pathogens of the urinary tract, and its activity decreases about fivefold as the pH is raised to 5.6. Only occasionally does cranberry juice contribute enough hippuric acid to the urine to achieve concentrations which are bacteriostatic at pH 5.0. Hippuric acid, in doses of 12 to 14 Gm. per day, usually lowers the pH of the urine to 5.2 or less, and is excreted in sufficient concentration to induce inhibition of bacterial growth in urine at this pH. The data suggest that the use of hippuric acid as a urinary antiseptic deserves further study.

Nephrectomy in Cases of Hypertension. J. G. Yates-Bell. Brit. M. J. 2:1371-1375 (Dec. 19) 1959 [London].

Sixty-six patients underwent nephrectomy for unilateral renal disease associated with hypertension. These patients were divided into 3 groups: (1) 36 patients with hypertension; (2) 20 hypertensive patients with urinary disease; and (3) 10 patients, under 40 years of age, with urinary disease and slight hypertension. The criterion for considering the result as a cure was a reduction of 20 to 25%, plus a fall to 90 or 100 mm. Hg, in the diastolic pressure. The operation was successful in 12 patients (33.3%) in group 1, in 10 in group 2, and in 8 in group 3 (including 5 children under 14 years of age. The total percentage of cures, taking as a criterion the requirement of a 20% reduction in blood pressure, was 45.5%. In addition, some patients who did not fulfill the established requirements to be considered cured received durable benefits from the point of view of the hypertension. Hydronephrosis was the most frequent condition in this series and obtained the highest percentage (54%) of cures. The average age of the 14 patients with hydronephrosis who were cured was 29 years, whereas the average age of the 10 who were not cured was 44. The average age of the 5 patients with pyelonephritis who were cured was 18 years, and that of the 8 patients who were not cured was 44. The 8 children under 14 years present in the whole series were cured. The average age of the 30 patients successfully treated was 34 years, and the average age in the 36 failures was 44.

The author suggests that a diastolic pressure of 90 mm. Hg during one year should be required in order to claim a good result of nephrectomy for hypertension. However, patients who have been symptomatically cured for 3 years, with a 20% fall in the diastolic pressure, should also be included in the good-result group. The requirement of a maximum of 100 mm. Hg diastolic pressure is too lenient, whereas the requirement of a 25% reduction is too severe.

OPHTHALMOLOGY

Vitreous Opacities Diagnostic of Familial Primary Amyloidosis. H. E. Kaufman and L. B. Thomas. New England J. Med. 261:1267-1271 (Dec. 17) 1959 [Boston].

The authors call attention to the presence of vitreous opacities in primary amyloidosis, pointing out that Kantarjian and DeJong in 1953 first described vitreous opacities in a family with amyloidosis, and several other observers have reported similar cases. The authors report 2 patients in whom such vitreous opacities and loss of vision began 4 and 13 years, respectively, before any detectable systemic signs or symptoms of amyloidosis. Because these opacities had been seen only in familial primary amyloidosis, the case of the brother of one of the patients was investigated. He had died with gastrointestinal symptoms, a progressive and bizarre neuropathy, and finally congestive heart failure, but the diagnosis of amyloidosis had not been made clinically or on postmortem examination. Only upon reexamination of tissues from this patient were the massive deposits of amyloid that caused his death apparent.

Observations on the formation of vitreous opacities in primary amyloidosis suggest that they begin first around retinal blood vessels, causing an apparent perivasculitis. Later, the deposits accumulate near the vascular ciliary processes, then retrolentally and in the posterior vitreous, and finally they affect the central vitreous. Patients with amyloid vitreous occasionally have a sudden loss of vision after minimal trauma. This appears to be caused by a detachment of the vitreous body from its adhesions to the optic disk and posterior retina, resulting in a clumping of this opaque material in the visual axis.

In the hope that removal of the opacities might restore vision to otherwise apparently normal eyes, the authors attempted vitreous transplantation on 6 eyes of 4 patients. Only a small amount of opaque vitreous could be removed from 5 eyes in spite of vigorous attempts at withdrawal and lavage. Failure to remove the opacities seemed to be due to the fact that they are bound to the fiber structure of the vitreous. The authors comment on the differences between sporadic and familial primary amyloidosis, pointing out that vitreous opacities occur almost always in the familial type of amyloidosis. The finding of these vitreous opacities should suggest that not only the patient under observation but others in his family may be afflicted with primary amyloidosis.

Observations on Compensatory Adjustments in One-Eyed Persons. E. Zagora. Brit. J. Ophth. 43:596-600 (Oct.) 1959 [London].

The author reports observations on 140 one-eyed persons observed over a period of 8 years. These patients had normal, or nearly normal, vision in the remaining eye and no anomalies of the ocular movements. They were mostly persons who had lost one eye in childhood or in adult life through injury and were wearing a prosthesis. Patients with one amblyopic eye were not included in this series. In order to adjust themselves to the new visual conditions after the loss of one eye, many persons tend to assume a persistent compensatory head posture, which may be called "uniocular torticollis." The abnormal head postures adopted by one-eyed people may be classified as: tilting the head; turning the face; and depressing the chin. Persistent tilting of the head toward the chest represents an attempt to extend the relative field of vision. The face is usually turned toward the side of the lost eye. This has 2 advantages: 1. The nasal half of the visual field of the remaining eye is extended. 2. The remaining eye assumes temporarily the midposition of a single frontal visual organ. This alignment can give the one-eyed person information on the position of objects in space in relation to the median vertical plane through the body, and so helps him to undertake work in which symmetrical exactitude is important. Lowering the chin extends the field of vision of the remaining eye, especially in the lower nasal quadrant. Depressing the chin toward the chest causes the remaining eye to become slightly elevated in the orbit.

In fitting a one-eyed person with spectacles for the correction of refractive errors, care must be taken that the bridge, frames, and side-pieces are so designed as not to restrict any part of the nasal field of vision of the remaining eye. These measures will help the one-eyed person to hold his head straighter. If the nose is large, a plastic operation may improve the visual field, so that the compensatory head-tilt and face-turn become less pronounced. A few one-eyed persons (especially those who have been left with the dominant eye) have reported that they find it necessary to close the lids of the lost eye when looking at very distant objects or in difficult visual conditions, such as fog, rain, and reduced illumination. The lid closure appears to be carried out involuntarily.

Investigations on Clinical Aspects and Etiology of Epidemic Keratoconjunctivitis. R. Zintz and O. Vivell. Klin. Monatsbl. Augenh. 135:521-533 (no. 4) 1959 (In German) [Stuttgart, Germany].

In the region of Freiburg im Breisgau in south Germany, keratoconjunctivitis has occurred in recent years in epidemic form as well as sporadically. This gave the authors the opportunity to study its clinical and serologic aspects in 70 patients. In 50 of the 70 patients the keratoconjunctivitis took a typical course. The majority of these patients contracted the disorder in the course of an epidemic in a sanatorium. The incubation period ranged from 7 to 10 days. Irritation and foreign-body sensation were usually the first subjective symptoms. Conjunctival irritation and increased secretion were the first objective signs, and a few patients had swelling of the lid. In the further course, the conjunctival hyperemia increased, and sago-like nodules appeared. Chemosis and petechial hemorrhages in the conjunctiva were observed in some of the patients. Threads of grayish mucus with leukocytes could be observed in the conjunctival secretion. Swelling of the preauricular lymph nodes on the involved side occurred in all 50 patients 2 or 3 days after the onset of symptoms. In 47 of the 50 patients in whom the cornea became involved, the signs of irritation became more severe between the 7th and 12th days. Healing of the corneal infiltrations took place between the 13th and 26th days. The second eye usually became involved from 3 to 16 days after the onset, but the process was abortive in the second eye in 39 of the 50 patients, and in 26 of the patients the cornea of the second eye did not become involved. In the other 20 patients the course of the keratoconjunctivitis was atypical.

The results of the laboratory test on the 70 patients were compared with those on 10 healthy patients, serving as controls. The adenovirus complement-fixation test and the type-specific neutralization test against adenovirus, type 8, were performed. In 36 of the typical cases the complement-fixing antibodies increased during the course of the keratoconjunctivitis. In 16 of these 36 patients the neutralization test against type 8 adenovirus was carried out, and a conclusive increase in titer was observed in 8 of the 16 patients; in the other 8 patients the titer suggested that type 8 adenovirus was probably the etiological agent.

Among the 20 patients with atypical course, there were only 3 in whom the complement-fixing antibodies increased, and in 2 others the presence of neutralizing antibodies seemed probable. No serologic changes were observed in the 10 controls. The authors point out that type 8 adenovirus has been isolated from patients with the typical form of epidemic keratoconjunctivitis in many countries during the last several years. Transmission is frequently iatrogenic, probably by ophthalmological instruments and solutions. The conjunctiva seems to be a portal of entry for virus infections, but the authors suggest that at least in epidemic keratoconjunctivitis it might also offer a route for prophylactic measures. There are no recurrences after keratoconjunctivitis. It is suggested that the condition might be prevented by applying specific convalescent serum to the conjunctiva. Involvement of the other eye could also perhaps be prevented in this way.

OTOLARYNGOLOGY

Fatal Granulomatosis of the Respiratory Tract (Lethal Midline Granuloma-Wegener's Granulomatosis). I. M. Blatt, H. S. Seltzer, P. Rubin and others. A. M. A. Arch. Otolaryng. 70:707-757 (Dec.) 1959 [Chicago].

Data on 124 cases of lethal midline granuloma-Wegener's granulomatosis are presented—112 from the medical literature and 12 from the University of Michigan Medical Center in Ann Arbor. It is suggested that the rhinopharyngologic-midfacial disease, described by Stewart, and the rhinologic-systemic syndrome, described by Wegener, are one and the same disease process—a granulomatous necrotizing angiitis, primary in the respiratory tract with systemic involvement and invariably fatal. Through concentration of case material it has been possible to formulate the clinical manifestations of the period of active disease and to observe the effects of various methods of treatment. Surgical intervention appears to increase the morbidity and intensity of the ulceronecrotic destructive process in the midfacial and other areas of the body, thereby creating deformities shocking to behold. When adrenal steroid therapy is used, the patients are apparently spared the frightful destruction of bone and soft tissue, particularly in the facial area, so that the face remains intact.

The over-all therapeutic response is usually dramatic within a few days, and it is possible to extend the lives of these seemingly doomed people by months or even years. The antibacterial activity of the antibiotic drugs has been invaluable in eliminating secondary invaders. Ionizing irradiation may find its effectiveness in the treatment of this inflammatory lesion. Clinical, histological, and preliminary laboratory evidence is presented to suggest that the lethal midline granuloma-Wegener's granulomatosis complex is a hypersensitivity reaction evoked by an autoantigen-antibody mechanism.

Two New Methods for the Assessment of Central Auditory Functions in Cases of Brain Disease. J. Matzker. Ann. Otol. Rhin. & Laryng. 68:1185-1197 (Dec.) 1959 [St. Louis].

Present-day hearing tests (threshold audiograms, tuning-fork tests, speech tests, and recruitment measures) are not designed to give information about the state of the central portion of the auditory system. Matzker calls attention to the new methods for the assessment of central auditory functions developed by Bocca, of Milan, and to the test for sound localization described by Sanchez-Longo and Forster. He describes his own methods, namely, (1) the binaural test, which is based on the principle of binaural fusion, and (2) his test for sound localization, which employs a method of interaural time differences. He has used the binaural hearing test (bilateral integration) in more than 1,700 patients and the sound localization test in more than 400 patients. These tests appear to provide audiometric tools for the exploration of the central auditory pathways. The test results not only indicate that a central lesion is present but also, within limits, point to the location of such lesion. While a high score of mistakes in the binaural test is indicative of a functional failure of the synaptic connections within the brain stem, the deviation of the localization band to one side points to a cerebral lesion on the contralateral side or to a brain-stem lesion on the homolateral side. It appears that the dividing level above which contralateral localization, and below which homolateral localization, occurs is the ventral brain stem. In each individual case one has to make sure that a deviation observed was not caused by a unilateral peripheral impairment.

In contrast to the results obtained by Sanchez-Longo and Forster, the results of Matzker indicate that the occurrence of abnormal lateralization of sound is not limited to patients with pathological processes in the temporal lobe. When his modification of the testing technique is used, processes located in the frontal, parietal, and occipital lobes have also been found to contribute to an abnormal localization.

A New Technique for Stapes Mobilization. B. Cornish. J. Laryng. & Otol. 73:738-744 (Nov.) 1959 [London].

Stapes mobilization is now an established technique, and it is no longer the freeing of the footplate which is on trial but the various methods of achieving this. The author found that in the patients in whom he failed to achieve mobilization by the Rosen technique of pressure, applied to the region of the neck of the stapes, the cause was usually the inability to determine the anatomically correct line of force. This seemed to be due in most cases to the fact that the stapes was lying obliquely in 2 different planes. The same difficulty presented itself in mobilizing the footplate directly, and was enhanced by the inability to see the footplate clearly in many instances. These difficulties led to the study of variously sectioned temporal bones, from which it appeared that the ideal direction of force of any maneuver to mobilize the footplate must be in the line of the stapedius tendon. Working on this principle, the tendon was always fully exposed before attempting mobilization. This, in turn, led to further consideration of the mechanics of the stapedius muscle and the stapes. It seemed that, if the stapedius could be made to contract with sufficient force, it would possibly produce mobility of the stapes, or a fracture at an anatomically suitable site. Dissection of the stapedius showed that it usually has a bulk of muscle fibers which could exert a strong pull, if stimulated electrically. Faradic current was thought to be the most suitable as being nonpolarizing to the muscle.

The technique of the stapedial mobilization by electrical stimulation of the stapedius muscle is described. It has been successful in a significant number of cases. These are admittedly short-term, and the series is too small for any percentage results to be evaluated. However, it is not intended at this stage to prove that the results will be maintained, or that the hearing gain is any greater by this method, but rather that mobility can be achieved by simple physiological methods in a significant proportion of cases. The standard methods must still be resorted to in certain cases, but it is felt that this electrical stimulation is a well worthwhile initial maneuver in all cases of stapedial fixation.

Oral Cancer in Women: A Study of the Increasing Incidence. W. W. Dalitsch and S. J. Vazirani. Am. J. Surg. 98:869-874 (Dec.) 1959 [New York].

The impression that cancer of the oral cavity in women is increasing in frequency was obtained by the authors in the wards or clinics of the Cook County Hospital and the Research and Educational Hospitals in Chicago. To substantiate this clinical impression, they studied the records of these hospitals, which demonstrated this increase. Other investigators have found a similar trend. This increased incidence is associated with an increasing use of tobacco by women and suggests a causal relationship. A long duration of exposure to the use of tobacco prior to onset of symptoms is a consistent finding in women with oral cancer. To prevent oral cancer, physicians must educate their patients to avoid harmful habits, such as smoking; to seek early advice and aid, if any abnormality is suspected; and to practice self-examination of the oral cavity. They must also help to discover and remove, or correct, noxious influences, such as neglected oral hygiene; chronic dental infection and inflammation; mechanical, thermal, actinic, and chemical irritants; and early lesions, such as leukoplakia and benign growths.

Current Treatment of Sinusitis. K. M. Simonton. Journal-Lancet **79**:535-537 (Dec.) 1959 [Minneapolis].

Simonton, of the Mayo Clinic, points out misconceptions on the part of patients about sinusitis and discusses anatomic and physiological aspects of the nasal sinuses. Sinusitis is divided into the acute, subacute, and chronic forms. Acute sinusitis is a self-limiting disease, usually accompanied by acute infection in the nasal mucosa. Symptoms are malaise, nasal obstruction, serous to purulent discharge, and pain and tenderness in the region of the affected sinuses. Subacute infection results when resolution of acute inflammation is delayed by factors that impede drainage from the sinuses, such as septal spur or cystic turbinate, or pathological changes, such as edema, inflammatory swelling, or polyps. The symptoms are purulent or mucoid drainage; obstruction, which may be relieved by discharge of secretions; cough; pharyngitis; and sense of pressure in the face. Pain is unusual. Chronic infection supervenes as a result of irreversible changes which permanently impair the drainage of the sinus. This may follow a single severe infection or repeated episodes of acute infection. Common changes are metaplasia of the epithelium with loss of cilia, subepithelial fibrosis, and vascular changes. The end-result is fibrosis, which may be manifested as either atrophy or thickening of the tissues. Symptoms are persistent drainage and repeated respiratory infections. Pain occurs only with changes of pressure within the sinus.

The treatment of acute sinusitis starts with rest and supportive measures. Adequate warmth and humidity aid in putting the nasal mucosa at rest. Sulfonamides are inactivated by pus and are of limited value in sinusitis. Most organisms causing acute infections of the upper part of the respiratory tract are sensitive to penicillin and the broad-spectrum antibiotics, so that treatment can be started with any of these drugs, pending results of culture. The dosage should be adequate to reach organisms situated in purulent exudates in the sinus, and should be at least double the dosage used for infection in tissues. Use of the drug should be continued until cultures are negative, or until well after all symptoms have abated. Local therapy with vasoconstricting drugs aids drainage, but use of these drugs should be limited to 5 to 7 days to avoid drug-induced edema of the mucosa. Local heat aids in relief of pain and congestion, and small doses of roentgen rays are effective for relief of severe pain arising from acute sinusitis. Surgical treatment is contraindicated in acute infection except for trephination of the frontal sinuses in fulminating infection.

In subacute infection antibiotic drugs are best administered under bacteriological control. Lavage is the most effective treatment. The maxillary sinus is most subject to subacute infection. Evacuation of the reservoir of pus in this sinus usually allows resolution of infection in the frontal and ethmoidal sinuses.

In many cases of chronic sinusitis surgical treatment must establish new drainage pathways or eliminate factors obstructing drainage. The maxillary and sphenoidal sinuses present large areas of common wall with the nasal chamber. Removal of this wall provides a large opening for drainage, which seldom closes postoperatively. The walls of the ethmoid cells may be removed to create a cavity with free communication with the nose. In the frontal sinus the surgically created drainage pathway is long and narrow and must be lined with epithelium to prevent closure, preferably with nasal mucosa. Sinusitis is frequently found in association with chronic bronchiectasis, bronchitis, and asthma. Elimination of a focus in the sinuses may control, but seldom cures, infection in the lungs. The results of treatment of infection of the sinuses are gratifying.

The Treatment of Recent Bell's Palsy on a Rational Etiological Basis: Results of Cervical Sympathetic Block and Corticosteroid Therapy. F. B. Korkis. A. M. A. Arch. Otolaryng. **70**:562-569 (Nov.) 1959 [Chicago].

The author feels that the neurovascular theory offers the best explanation for paralysis of the facial nerve (Bell's palsy). It explains the sudden onset of the condition, the lack of general constitutional disturbance, the variability in the degree of severity of the paralysis, the differences in the time and degree of recovery, the possible precipitation by exposure to draft, the progression which is sometimes seen from an incomplete to a complete paralysis (secondary compression), and the possibility of recurrence. Mild cases are compatible with minor degrees of temporary spasm, and severe ones with long-lasting spasm, or thrombosis. The author summarizes observations on 65 patients with atraumatic facial palsy. This number included 7 patients with geniculate herpes (herpes oticus), which condition had been referred to as "Bell's palsy," although subsequently its true nature was established. These patients formed a control group, because herpes oticus is not a vasospastic process.

While formerly Bell's palsy was considered as requiring no active measures apart from reassurance, support of the paralyzed musculature, and physical therapy to maintain muscle tone, such an expectant outlook is outmoded today in the light of the neurovascular hypothesis. Rational treatment aims at rapid relief of angiospasm, prevention of secondary thrombosis, and reduction of swelling. Rapid vasodilatation is brought about by paralysis of the cervical sympathetic system by a stellate block. This can be accomplished by injecting a 1% solution of procaine into the vicinity of the ganglion. Cortisone is capable of reducing tissue edema in the absence of definite infection.

Stellate blocks, repeated at intervals of 2 or 3 days, were used by the author in some patients with Bell's palsy. In other cases he used cortisone, either in combination with cervical sympathetic blocks or as the sole therapeutic agent. Patients with Bell's palsy, who were treated with physical therapy, heat, and exercises, served as controls, together with the aforementioned 7 patients with herpes oticus.

The aim of this study was to determine the treatment most likely to give the greatest degree of recovery in the shortest possible time and to test the validity of the ischemic theory of origin of Bell's palsy. Vasodilatation, produced by paralysis of the cervical sympathetic system by shortening the duration and severity of the paralysis, was most effective; this supports the vasospastic hypothesis. Corticosteroid therapy was not combined with stellate blocks in most cases in this series because the author wished to determine the effectiveness of one form of therapy. However, the 2 treatments should be combined, for by the one vasospasm is relieved, and by the other secondary edema is reduced. There is still a place for decompression of the facial nerve in patients who fail to respond to this regimen, but this operation will be required less often than formerly. Decompression must be performed before prolonged edema has caused nerve atrophy.

The author feels that patients with Bell's palsy should be under the care of an otologist, for the diagnosis demands an examination of the auditory system to exclude other peripheral causes of facial paralysis. The otologist also is fitted to perform a stellate block, which is the logical treatment for the early case, and by following the course, he is in a better position to judge when decompression is needed.

Repair of Ossicular Defects with Ostamer. J. Sataloff. A. M. A. Arch. Otolaryng. 70:415-418 (Oct.) 1959 [Chicago].

The author used Ostamer, a polyurethane foam, at first in the ears of 25 cadavers in which defects were created in various parts of the ossicular chain. In repairing these ossicular defects, Ostamer was prepared by mixing together a viscous prepolymer with a viscous catalyst in the ratio of 4 to 1. The resultant mixture is a thick, extremely adhesive substance from which carbon dioxide and heat are liberated. On hardening, it swells to twice the original volume to form a very light porous plastic. Ostamer successfully restored the continuity of the ossicular chain in the ears of the cadavers. After this "practice period," Ostamer was used in 2 living patients, a 14-year-old boy and a 45-year-old woman.

The first patient had had a marked hearing impairment for 9 years after a right simple mastoidectomy. Two attempts to repair a large defect between the head of the stapes and the absent long process of the incus, which had probably been inadvertently damaged in the course of the mastoidectomy, with the aid of small pieces of bone or fibrous tissue had failed. A drop of Ostamer was placed on the stapedial head, and the end of the incus was pressed into the drop until it hardened. Results of a preoperative audiogram and one taken one week postoperatively indicated a substantial hearing improvement. In the second patient, who claimed unilateral insidious deafness for 3 years, the absence of the incus and a large perforation in the eardrum made columelization the procedure of choice. In preference to placement of a graft over this perforation, a drop of Ostamer was placed over the head of the stapes, and the edges of the perforation were embedded into the Ostamer filling the defect. There was a substantial improvement in hearing one week after the operation.

While Ostamer in its present form has been used to advantage in the repair of ossicular defects, it would be desirable that the material be modified, if possible, to prolong the hardening time and increase the elasticity.

PATHOLOGY

The Relation of the Morphology of Gastric Carcinoma to Long and Short Term Survival. C. H. Urban and G. McNeer. Cancer 12:1158-1162 (Nov.-Dec.) 1959 [Philadelphia].

The authors report on 25 men and 13 women who had survived more than 5 years after total or partial gastrectomy for cancer of the stomach (long-term survivors), and on 33 men and 20 women who had died of cancer of the stomach one year after the operation. Of these 91 patients from the Memorial Center for Cancer and Allied Diseases in New York, 74 were between the ages of 50 and 80 years, 14 were between the ages of 20 and 49 years, and the ages of 3 were unknown. The morphologic features associated with each of the patients were determined from the description of the gross operative specimen and its microscopic appearance. In general, the cancers of the 5-year survivors were small, superficial tumors of low histological grade, growing in a circumscribed fashion, and had not given rise to lymphatic metastases. Signet-ring cells made up only a minority of the tumor cells in these patients. By contrast, the patients who survived less than one year had larger tumors of high histological grade which penetrated diffusely and deeply into the gastric wall. Lymphatic metastases were generally present, and most of the tumor cells were of the signet-ring type.

The factors that differed most between the long-term and short-term survivors were pattern of growth, depth of penetration of the tumor into the gastric wall, and involvement of lymph nodes by metastases. These are considered to be useful prognostic criteria. Of these 3 factors, pattern of growth was by far the most striking one separating long-term and short-term survivors. Patients who survived more than 5 years with large cancers were found to have tumors exhibiting the "en bloc" pattern of growth. The long-term survivors with large tumors that exhibited the mixed pattern of growth also had tumors confined to the gastric wall which had not metastasized to lymph nodes. If a patient had a small cancer and died in less than one year, the cancer usually showed the signet-ring-cell pattern of growth and had penetrated through the serosa. These findings would appear to confirm the growth pattern as a fundamentally important characteristic of tumor morphology. It appears that certain features, such as increasing depth of penetration and increasing grade, are definitely associated, whereas depth of penetration and presence of lymph-node metastases appear to be independent of each other. Despite the numerous interrelationships that could be demonstrated, no clear pattern emerged which could be set down in the form of general rules for prognosis.

The Value of Routine Serologic Tests for Syphilis on Hospital Admission. R. E. Bell. Am. J. Clin. Path. 32:521-525 (Dec.) 1959 [Baltimore].

In many hospitals a serologic test is routinely administered to each adult patient admitted. Of 13,372 routine tests for syphilis in a large general hospital, 141 tests (1.06%) were reported positive. These represented 106 patients. The discovery of a positive serologic test for syphilis led to the diagnosis and treatment of 5 or possibly 6 persons. Of the 6 treated or probably treated, one was admitted to a mental hospital with neurosyphilis, and another died of advanced cardiovascular disease within a year. The maximal number of diseased persons discovered and successfully treated, therefore, was 4. The cost of finding these 4 has been estimated at $1,600 per case.

One-third of the positive reactors were more than 65 years of age. None of these had active disease or were treated, and the author feels that routine testing of older patients should be discontinued. However, although the number of new and unsuspected cases likely to be discovered by routine blood testing is very small, the clinical importance of the discovery cannot be overlooked. In addition, the information (pertaining to all positive tests) which is routinely sent to public health authorities is important for the maintenance of their records. Thus, continuation of the policy of routine testing on all hospital admissions, except children and those more than 60 years of age, may well be worthwhile.

Diagnosis of Clinical and Subclinical Salmonellosis by Means of a Serologic Hemagglutination Test. E. Neter, A. M. Drislane and A. H. Harris. New England J. Med. 261:1162-1165 (Dec. 3) 1959 [Boston].

A combined bacteriological and serologic study on patients with enteritis due to Salmonella organisms and their contacts revealed the occurrence of subclinical infection. Subclinical infection was diagnosed on the basis of a specific antibody (hemagglutinin) response of the subjects of study in the presence or absence of the pathogen in the feces. It is postulated that 2 types of Salmonella carriers exist, one associated with disease, clinical or subclinical, resulting in a specific antibody response, and the other without antibody response. The latter type of carrier is considered a "lumen" carrier. On the basis of the data obtained, it is suggested that Salmonella infection among contacts (household members and nurses) occurs more frequently than present statistics indicate. The combined bacteriological and serologic approach to the diagnosis of salmonellosis may eventually yield more accurate information on the true incidence of this disease, its epidemiology, and its clinical manifestations.

RADIOLOGY

The Value of Arteriography in the Diagnosis of Bone Tumors. B. Strickland. Brit. J. Radiol. 32:705-713 (Nov.) 1959 [London].

Although percutaneous arteriography cannot replace a biopsy in the diagnosis of osseous tumors, it may assist in their diagnosis, differential diagnosis, and management. Pathological vessels are present in malignant tumors in a typical pattern. They appear as deploying without purpose, keeping to no set course, and showing no progressive diminution in caliber. As they run through the mass of the tumor, their walls may be lined with tumor cells, and remain filled with contrast medium for a considerable time, owing to the lack of residual elasticity. An abrupt termination of an otherwise normal artery in the neighborhood of a bone tumor is also a fairly frequent finding in malignant disease, probably due to local thrombosis or infarction in the tumor itself.

Twenty-seven patients with tumors of different types and etiology were studied by arteriography. In 10 patients the findings indicated absence of malignancy in neoplasms which from clinical and radiologic data appeared to be malignant. In 3 patients the diagnosis of malignancy was either confirmed or suggested. Further confirmation was found during surgical treatment. In 8 patients arteriography showed that the vessels are deeply affected by radiotherapy. In 3 of these patients the findings showed the persistence of a still abnormal vascular pattern; in the other 5 they indicated a return to a normal pattern. However, later developments or surgical exploration demonstrated that tumor cells were still present. This shows that arteriographic data cannot demonstrate the effectiveness of the radiotherapy, although the pattern is very definitely affected by x-rays.

The meaning of arteriographic findings is more difficult to interpret in relation to metastases. The vascular pattern in metastatic tumors is roughly proportional to the vascularity of the primary tumor, but the site of the primary growth cannot be deduced from the vascular pattern of the metastases. The author believes that arteriography should be requested as a routine investigation before deep x-ray therapy, for the purpose of defining the limits of the growth, which are often different from the appearances of the plain x-ray film.

"Toxic" Segmental Dilatation of the Colon During the Course of Fulminating Ulcerative Colitis: Roentgen Findings. B. S. Wolf and R. H. Marshak. Am. J. Roentgenol. 82:985-995 (Dec.) 1959 [Springfield, Ill.].

The authors report on 11 patients with fulminating ulcerative colitis, associated with severe intrinsic inflammatory disease of the colon wall and localized colonic dilatation. Pathologically, this condition is characterized by acute inflammatory changes in all coats of the colon with areas of necrosis; clinically, it is marked by extreme toxicity and high frequency of perforation. Roentgenologic changes can best be detected by simple roentgenogram. Barium enema examination is unnecessary and undesirable. Characteristic roentgenologic changes in patients with toxic segmental dilatation of the colon consist of (1) marked distention of one or several parts of the colon, (2) obliteration of the haustral and mucosal pattern, (3) irregular contour of the colon, with multiple deep projections indicative of ulceration, (4) numerous nodular pseudopolypoid intraluminal protrusions, (5) a lack of redundancy or a relative shortening of the colon, and (6) an inability of the colon to contract normally due to a loss of tone. Toxic segmental dilatation may develop within 3 or 4 days. Normal tone may be restored within a period of 1 or 2 weeks after the performance of a cecostomy. From the roentgenologic point of view, there must be considered differentiation from paralytic ileus or mechanical intestinal obstruction of the colon, from megacolon (Hirschsprung's disease), from "sentinel" dilatation during the course of acute pancreatitis, from markedly dilated loops of small intestine in ileojejunitis, and from marked colonic dilatation occasionally seen in sprue. None of these conditions show the remarkable localized colonic dilatation in association with severe intrinsic inflammatory disease of the colon wall.

Observations on the Small Bowel Pattern Associated With the Zollinger-Ellison Syndrome. J. M. Weber, S. Lewis and K. H. Heasley. Am. J. Roentgenol. 82:973-977 (Dec.) 1959 [Springfield, Ill.].

The authors describe the appearance of a small intestine pattern, as observed in 3 patients with the Zollinger-Ellison syndrome, and they suggest that the pattern may prove to be diagnostic or highly suggestive of the syndrome. Roentgenologic studies of the small intestine in these 3 patients revealed a distinctive lacy, cobweb-like pattern. It is believed that marked motor irritability associated with hypersecretion might be the possible mechanism producing the roentgenologic pattern, as well as the diarrhea which was a prominent symptom in the 3 patients. It is recommended that roentgenologic studies of the small intestine be performed in all those patients in whom the diagnosis of the Zollinger-Ellison syndrome is being considered. This includes patients with intractable diarrhea, even though peptic ulcer symptoms are not present.

The Incidence of Colonic Diverticulosis. C. C. Smith and W. R. Christensen. Am. J. Roentgenol. 82:996-999 (Dec.) 1959 [Springfield].

The authors reviewed 1,016 consecutive barium enema studies and analyzed the results to provide some indication of the actual incidence and distribution of diverticulosis. This group of patients is not the result of random population sampling, but it is rather typical of hospital and outpatient clinics where roentgenologic services are readily available. Under these circumstances, a low incidence of colonic disease is to be expected, and some resemblance to the general population is present. Of the 1,016 patients, 21.8% had diverticulosis; their average age was 70.4 years. No difference in incidence between male and female patients was noted. In half of the patients the abnormality involved a single segment, and in the other half more than one segment was affected. In 73% of the patients the descending and sigmoid areas were most frequently affected by diverticulosis. It is of interest that the older patients did not show a higher incidence of generalized disease than the younger. No obvious association with malignancy of the colon has been observed. Once manifested, the disease does not appear to be progressive.

BOOK REVIEWS

Fundamentals of Modern Allergy. Edited by Samuel J. Prigal, M.D. Sponsored by New York Allergy Society. Cloth. $18.50. Pp. 690, with illustrations. Blakiston Division, McGraw-Hill Book Company, Inc., 330 W. 42nd St., New York 36; 95 Farringdon St., London, E. C. 4, England; 253 Spadina Rd., Toronto 4, Canada, 1960.

This volume is a compilation of 63 essays written for and published in the *New York State Journal of Medicine*. Except for several guest writers, the authors of the papers are members of the New York Allergy Society. The readers for whom these essays were written required a brief, often superficial, statement of difficult problems in allergy. Such complex problems as atopic dermatitis, gastrointestinal allergy, and food allergy are each discussed in 5 to 13 pages.

The superficial content of most of the essays is only one objection to the book. Another is the absence of order in organization. The editor assumed the difficult task of trying to organize 63 brief essays by 51 authors into a textbook. The only evidence of organization is the grouping of the various essays in the following sections: (1) Mechanics and Causal Factors in Allergy, (2) Tests, Procedures, and Technics for Diagnosis of Allergic Conditions, (3) Manifestations and Forms of Allergy, (4) Allergy in Childhood and Old Age, and (5) General Treatment and Prophylaxis in Allergy. As individual papers published in a state medical journal, these contributions served a useful purpose. Their inclusion in one published volume fails to make the book either a textbook for the novice in allergy or a reference book for the trained allergist.

Diagnostic Radioisotopes. By Charles A. Owen, Jr., M.D., Ph.D., Associate Professor of Clinical Pathology, Mayo Foundation, Graduate School, University of Minnesota, Rochester. Cloth. $15.75. Pp. 425, with 71 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This volume, specifically limited to the diagnostic aspects of the use of radioisotopes in medicine, should be useful to many physicians interested in acquiring a survey knowledge of this field. It is particularly comprehensive in dealing with tests of thyroidal function and the applications of radioisotopes to hematological problems, the two fields which represent a major section of present diagnostic radioisotope use. In such a rapidly changing field as the development of radioisotopic procedures, the time lag between preparation of a book and its publication is particularly noticeable, and in this instance the latest references are from the literature of 1956. Important new developments such as the work of Pochin with the short half-life iodine-132 and the more recent chromium-51 sequestration studies are missing. Good organization, clear writing, and an excellent bibliography are noteworthy. There are 528 bibliographic references to thyroid studies alone.

The book is mainly clinically oriented. Only 55 pages are devoted to measurement methods, and these do not seem adequate to carry the beginner to the point of sufficient familiarity with instrumentation methods at which accurate and reproducible results might be expected. The treatment of radiation protection is casual, and while the hazards in the use of diagnostic quantities of radioisotopes are small they are of sufficient importance to merit more than passing reference. In conjunction with other textbooks and the more recent literature, this volume is a worthwhile addition to the library of physicians who wish to become more familiar with the diagnostic applications of radioisotopes in clinical medicine.

Biophysical Science: A Study Program. Planned and edited by J. L. Oncley, editor-in-chief, and others for Biophysics and Biophysical Chemistry Study Section of National Institutes of Health, Public Health Service, United States Department of Health, Education, and Welfare. Published in Reviews of Modern Physics, January and April, 1959. Cloth. $6.50. Pp. 568; 27, with illustrations. John Wiley & Sons, Inc., 440 Fourth Ave., New York 16, 1959.

This collection of 61 papers is based on the study program held in Boulder, Colorado, in the summer of 1958. These papers cover a wide range of subjects, including molecular biology and the physical basis of life processes; molecular configuration of synthetic and biological polymers; physicochemical characterization of macromolecules; proteins and their interactions; mechanisms of enzyme action; coding and information theory; radiation inactivation of enzymes, nucleic acids, and bacteriophages; membrane transport; nature of the nerve impulse; sensory performance of organisms; and hormone regulation.

They are summaries of present knowledge as well as carefully documented excursions into the more basic physical and chemical foundations of important biological phenomena. Several are of particular and current interest to the physician. In his paper, "Hormone Regulation," Stetten has summarized our present knowledge of the chemical structure of insulin, glucagon, and the hormones of the posterior pituitary gland. He has explained the effects of these hormones in terms of enzymatic and other cellular mechanisms, for example, the role of insulin in the diabetic organism in increasing the permeability of the muscle cell to glucose and in reversing the increased activity of glucose-6-phosphatase. In his paper, "Blood Coagulation—A Study in Homeostasis," Waugh had surveyed the various components and factors involved in this process, the way in which they interact, and the aspects which need future study. The isolation and purification of enzymes which carry out the synthesis of ribonucleic and desoxyribonucleic acids have been of outstanding interest in the past few years. These and related recent advances in this important and crucial field are reviewed by Kornberg in "Biosynthesis of Nucleic Acids."

The content of many of the papers may appear quite remote from the concerns of everyday medical practice, but as the history of progress in medicine and other sciences has shown, there is an unceasing and dynamic flow of theory into practice. The present volume is highly recommended to the clinical investigator as an authoritative survey of rapidly expanding fields which may, in one way or another, affect his own research. This book should benefit physicians who are curious about the chemical and physical foundations of biology and who wish to obtain a glimpse of the matrix of medical knowledge in the forseeable future.

Measurement of Subjective Responses: Quantitative Effects of Drugs. By Henry K. Beecher, M.D., Henry Isaiah Dorr Professor of Research in Anæsthesia, Harvard University, Boston. Cloth. $12.75. Pp. 494. Oxford University Press, 417 Fifth Ave., New York 16, 1959.

This book is an expansion in depth as well as in length of a review on the measurement of pain published in *Pharmacological Reviews* several years ago. In the present volume, Dr. Beecher has explored the difficult and complex field of measurement of subjective responses and has produced an interesting and provocative book. He has revised the section on methods for the evaluation of pain and discusses the characterization and measurement of such phenomena as mental clouding, sedation, euphoria, dysphoria, nausea, hunger, anxiety, itching, and the subjective and objective components of cough. A discussion of placebo reactors, psychotomimetic drugs, and the quantitative effects of anesthetic substances on subjective state is also included. Since the author is a pioneer in the field of measurement of subjective response, it is not surprising that much of the work reviewed is either from his laboratory or from the laboratories of investigators who were trained in his methods at the Massachusetts General Hospital.

The major criticism of the book is that its approach still has the savor of a review and does not really provide a unifying concept of the field of quantification of subjective responses. Perhaps this is all that is possible in view of the present state of knowledge in this field. Dr. Beecher has written a useful and stimulating book which should be of interest to workers in the behavorial sciences, to pharmacologists, to all who work with the evaluation of drugs affecting subjective states, and to those who are dissatisfied with clinical impressions alone as a measure of drug activity in man. Research workers in fields where experimental design is critical would do well to read it and reflect on some of the problems it poses. A comprehensive bibliography further enhances its value.

Complete Child Care in Body and Mind: A Modern Parents' Guide to the Healthy Growth and Development of the Newborn, the Infant, the Child and the Adolescent. By I. Newton Kugelmass, M.D., Ph.D., Sc.D. Cloth. $6.95. Pp. 415. Twayne Publishers, Inc., 31 Union Sq. W., New York 3, 1959.

This fact-packed volume contains the story of childhood health care from birth through adolescence. It is a plain book with no fancy art work, no glossy prints, no color plates, and no typographical embellishments. It is perhaps best described as a working book, into which the author has put a world of information. Since the author is no amateur in this area, he has arranged his material in an attractive and logical manner. The volume is divided into five parts, dealing with the infant, the preschool child, the school child, the preadolescent, and the adolescent. These parts contain detailed discussions that clarify the many questions which inevitably occur to all parents.

There are 28 tables in the book, most of which present detailed information about feeding schedules, menus, and choice of special-purpose foods. There are height-weight charts, information about caloric values of common foods, and two interesting tabulations dealing with identification of various stages of personality development and graduation from immature to mature attitudes. As the author suggests, the volume should be of much interest and assistance to parents, nurses, and teachers since it considers child development against the background of newer information regarding physical and psychological needs in all growth periods. An extensive index adds to practical usefulness of the book.

Proceedings of the World Congress of Gastroenterology and the Fifty-ninth Annual Meeting of the American Gastroenterological Association, Washington, D. C., U. S. A., May 25th through 31st, 1958. Volumes I and II. Cloth. $20. Pp. 714; 715-1363, with illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2, 1959.

The great number of authoritative participants in the Congress here reported made it possible to develop two types of presentation: symposiums dealing with topics of great importance and world-wide interest and original contributions of basic scientific and clinical value. One symposium covered the epidemiologic and clinical features of peptic ulcer throughout the world with panel discussions and summarized conclusions on the total presentations. There were symposiums on the malabsorption syndrome, nutrition and its effects of the liver and pancreas, intestinal infections and infestations, and the education of the gastroenterologist with particular emphasis on the future of the field of gastroenterology. Original contributions covered gastrointestinal physiology, intestinal infections and infestations, affections of the pancreas and biliary tract, peptic ulcer from the standpoint of etiology and epidemiology, intestinal malabsorption, nutritional and physical aspects of affections of the liver and pancreas, upper gastrointestinal hemorrhage, pathological and clinical features of affections of the intestines, gastric carcinoma, and gastric surgery.

These proceedings, which in many instances point out the geographical, racial, and national differences in epidemiology and in clinical behavior patterns of disease, are highly significant and may become a standard reference work. Anyone interested in any phase of gastroenterology and nutrition cannot afford to be without them.

Pyelonephritis. By Fletcher H. Colby, M.D. Cloth. $7.50. Pp. 214, with 95 illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2, 1959.

In this book the relations of pyelonephritis to uremia, obstructive uropathy, diabetes, pregnancy, and hypertension are illustrated by case histories. The forms encountered in infancy and childhood and the evolution from acute or latent subclinical disease are fully discussed. The literature and history of knowledge of pyelonephritis are also given. This is a brief but well-balanced monograph by a careful observer with great experience in the field. His discussion of therapy and his discouraging report on the value of antibiotics in the chronic or subacute disorder should be read by every internist and pediatrician. The techniques for identifying unilateral disease as a possible cause of hypertension and the way in which diabetes, hypertension, and proteinuria predispose the kidney to hematogenous infection are not stressed. However, these are of more concern to specialists and pathologists than to the larger group for which this book was written.

Angiologie Pathologie, Klinik und Therapie der peripheren Durchblutungsstörungen. Herausgegeben von Prof. Dr. Max Ratschow, F.A.C.A. Unter Mitarbeit von W. Block et al. Cloth. 174 marks; $41.45. Pp. 831, with 373 illustrations. Georg Thieme Verlag, Herdweg 63, (14a) Stuttgart, West Germany; [Intercontinental Medical Book Corporation, 381 Fourth Ave., New York 16], 1959.

This massive volume is a typical example of Germanic thoroughness, of systematic treatment of an enormous literature, and of great pride in national accomplishment. Some of the chapters written by preclinical scientists are of the highest order. Many of the clinical chapters are belated statements of American and British work with little originality and much generalization. The production of the book, including paper, printing, and illustrations, is excellent. It is an example of the rapid recovery Germany has made in the technical field. It is doubtful, however, that the American reader would benefit much from reading this "hypertrophic" textbook. It furnishes a lucid account of vascular allergies and still advocates use of fresh calf pituitary implants in persons with Raynaud's disease. A final short chapter on the aspects of vascular disease as it relates to the state insurance system is highly revealing. Endless litigation and conflicting testimony of experts is reminiscent of some of the files confronting the compensation boards of the Veterans Administration.

Rheumatic Fever: Epidemiology and Prevention. The Proceedings of a Seminar held at the International Children's Centre, Paris, 25-27 September 1956. Editors: R. Cruickshank, M.D., Ch.B., F.R.C.P., and A. A. Glynn, M.D., B.S., M.R.C.P. Cloth. $5.50. Pp. 193, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 24-25 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, Canada, 1959.

This symposium was first published in French. The material is covered in four parts: (1) the biology of group A hemolytic streptococci, (2) the epidemiology of infection with group A hemolytic streptococci, (3) the epidemiology of rheumatic fever, and (4) the prevention of rheumatic fever. Neither the diagnosis nor the treatment of rheumatic fever were dealt with at this conference. The papers are well illustrated, comprehensive references are listed, and the material is presented cohesively. The editors have accomplished their goal in presenting the English version of the conference. The monograph should serve a useful purpose for those interested in the epidemiology and prevention of rheumatic fever.

Diseases of the Nose, Throat and Ear: A Handbook for Students and Practitioners. By I. Simpson Hall, M.B., Ch.B., F.R.C.P.E., Surgeon to Royal Infirmary, Edinburgh. Seventh edition. Cloth. $5. Pp. 467, with illustrations. Williams & Wilkins Company, 428 E. Preston St., Baltimore 2; E. & S. Livingstone, Ltd., 16 and 17 Teviot Pl., Edinburgh 1, Scotland, 1959.

This handbook was conceived primarily for the use of students and practitioners. It is written from the experience of its author, a fact which is responsible for its many virtues and perhaps for some of its limitations. Because of its intended audience and its self-imposed restrictions, much detail is omitted, primarily in the field of operative procedure. This is altogether proper. It is for these reasons and for its general high tone of excellence that this work may be highly recommended to those for whom it was written.

QUESTIONS AND ANSWERS

THREATENED ABORTION

To the Editor:—*Would you summarize the treatment for threatened abortion? What management is best for the woman who repeatedly aborts in the early stage of pregnancy? What is the role of the new synthetic progestational hormones?* M.D., Wisconsin.

Answer.—The term threatened abortion is ill-defined, for it is often applied to all women having vaginal bleeding in the early weeks of pregnancy, which has authoritatively been stated to occur in 20 to 25% of all pregnancies. Since only 8 to 10% of women abort, vaginal bleeding per se is not synonymous with a threatened abortion. It is evident that the chance of a cure for women with the single sign of vaginal bleeding, without therapy, is 50% or more, a fact to be kept in mind when assessing the value of the various forms of therapy.

Common sense dictates bed rest for a few days for patients confronted with so-called threatened abortion, but it is questionable whether other therapy is required or indicated. Since it is believed that the conceptus is rarely normal when the abortion occurs by the 10th or the 12th week, it is doubtful that any form of therapy is indicated once bleeding occurs in the patient destined to abort in the first trimester. The abortion is presumably the result of a germ plasm defect or of faulty implantation.

To be most effective, treatment of the woman who has had repeated abortions should begin prior to conception and be directed toward improvement of the general health of the patient and of the blood supply to the future implantation site. To achieve the latter, the administration of small amounts of progesterone or diethylstilbestrol during the secretory phase of the cycle has been advocated. Although sex reversal of the fetus has followed sex steroid therapy, the incidence is extremely low. This condition is temporary and thus reversible, and it is most likely to occur from the administration of progesterone-like compounds with an androgenic component. The latter is lacking in some compounds, however, and such progesterone-like synthetic substances without an androgenic effect, or progesterone itself, should be considered part of the therapy.

Women who lose the conceptus after the first trimester and before the period of medical viability may have incompetent cervixes. The inquirer is referred to published papers for consideration of this difficulty.

In summary, in the so-called chronic aborter, the time at which the conceptus has been lost should be established, and whether it is anatomically normal or abnormal. If the abortion occurs in the first trimester, preconceptional treatment as outlined is indicated. In those who abort later, the major item in the treatment includes copious amounts of rest and sex-steroid therapy, and the question of surgery for the incompetent cervix should be considered. Considerable credence has been given to the value of psychotherapy, but this should be within the capabilities of any well-informed and understanding physician.

Until more is known of the fundamental biology of the factors which control the reproductive cycle the treatment of premature loss of pregnancy, including the various types of abortion, must remain empirical. This permits marked differences of opinion regarding preferred forms of treatment.

LOSS OF HEARING IN CHILDREN

To the Editor:—*What would cause a progressive loss of hearing in a 3½-year-old girl? Her general physical health is normal. Her tonsils and adenoids are not enlarged, and the light reflex from both tympanic membranes is normal. The loss of hearing is apparently not secondary to other causes. The child is right-handed and her visual orientation is normal. She has difficulty in understanding what is being said and in obeying simple commands given in conversational tones but responds to a loud voice at close range. She herself speaks quietly and frequently whispers; her speech is slurred to the point of unintelligibility. In a sound-field test she consistently responds both to the spoken word and to noise signals at levels between 40 and 60 db. of normal.*

J. Philip Fox, M.D., Cincinnati.

Answer.—The diagnosis of impairments of hearing in children of preschool ages is difficult because of their inability to communicate normally and their related handicap in performing formal tests.

In "Auditory Disorders in Children" (New York, Grune & Stratton, Inc., 1954) Professor Myklebust describes four possible causes of delayed acquisition of speech in a child. The most common cause, occurring in 50%, is a severe impairment of hearing, which usually is congenital. If the impairment does

---

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any medical or other organization unless specifically so stated in the reply. Anonymous communications cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

not exceed 40 or 50 db. in the frequencies of normal conversational tones, the child will learn to talk at nearly the normal rate. The greater the impairment of hearing, the longer the delay in acquisition of speech, and, when the loss of hearing exceeds 70 or 80 db., the child cannot learn to talk without special training. Often the parents are not aware of their child's loss of hearing until they notice his delay in learning to talk. A mild or moderate impairment in hearing may be present from birth but may not become apparent until the child is 3 or 4 years of age. The parents then assume that there is a progressive loss, when actually the *hearing is at a stable level.*

The second most frequent cause for delayed acquisition of speech is brain damage, presumably incurred at birth, which affects the speech centers and produces aphasia. These children's responses to sound are inconsistent, and other evidences of brain damage will be present. The third cause for delayed acquisition of speech is mental retardation or feeblemindedness, and the fourth is an emotional disturbance of an infantile autistic type.

In the child described, the difficulty is likely to be caused by more than a mere impairment in hearing, and a psychoneurological study is indicated. She apparently had normal auditory function at one time, which suggests the possibility of progressive nerve deterioration. The latter is a rare condition which occurs on a familial basis.

CONVERSION OF TUBERCULIN SKIN TEST

To the Editor:—*Does current scientific opinion hold that patients who are PPD (purified protein derivative) converters (those who, having had a negative reaction one year previously, show a positive reaction to a skin test with purified protein derivative of Mycobacterium tuberculosis) should receive treatment if they have no other clinical or roentgenologic signs of active tuberculosis?* *M.D., Arizona.*

Answer.—The conversion from a negative to a positive reaction to the tuberculin skin test usually means that the patient has had a recent infection with tubercle bacilli. There are other situations in which conversion from a negative to a positive reaction actually occurs or seems apparent, but they are of purely academic interest and need not be discussed here.

Clinicians differ in their opinions about the proper management of patients who are first-infection "converters." Current research projects are attempting to solve this problem but have not as yet brought forth a consistent or wholly acceptable approach. Some phthisiologists believe that no treatment need be given unless the patient has demonstrable lesions or presents clinical signs of the disease. This has been the method used in the past, and, under good medical observation, it is still entirely acceptable. Some physicians advocate treatment for prophylactic reasons, since fulminating manifestations of tuberculosis may develop in this type of patient. Other physicians treat all converters radically, irrespective of the clinical and roentgenographic findings, especially those who have strongly positive tuberculin reactions. The number of physicians who believe that all converters should be treated is increasing, and practically all agree that children under 2 years of age should receive treatment with isoniazid for one year or until the tuberculin reaction has disappeared.

It is clear that there is as yet no uniform opinion about age groups to be treated. A fair composite plan for those patients who have a converted reaction would be to treat every child under 3 years of age, irrespective of the magnitude of the reaction; other children and adults with positive (3 to 4+) reactions should be treated with isoniazid for at least one year. Their progress should then be followed for one to two years by means of roentgenographic study and clinical observation.

IRRIGATION OF THE EAR CANAL

To the Editor:—*Is it possible for water to remain on the tympanic membrane and give the patient a feeling of blockage after removal of wax from the ear canal by the irrigation method?* *M.D., Rhode Island.*

Answer.—It is possible for water remaining on the tympanic membrane to give the patient a feeling of blockage for a short length of time, but if the drum is wiped with a cotton applicator this sensation usually disappears. If the drum is not wiped dry, the feeling of fulness may persist for an hour or two. If it persists longer than this, it can mean that some other condition is present, such as edema of the tympanic membrane due to irritation by a foreign body. One must rule out other possibilities such as slight loss of hearing.

CEREBRAL PALSY AND CESAREAN SECTION

To the Editor:—*What percentage of persons with cerebral palsy are delivered by cesarean section, and how does this number compare with the percentage of cesarean sections performed in the United States?* *Kurt Schnitzer, M.D., Santa Ana, Calif.*

Answer.—Eastman and Kohl, in the last two years, did a retrospective study of cerebral palsy. Of 383 patients with brain damage, 10 infants, or 2.6%, were delivered by cesarean section. In a control series of 364 infants (each now normal and healthy), 7, or 1.9%, were delivered by cesarean section. Eastman's and Kohl's figures on the total number of cesarean sections performed are 3% in the control group of women and 4.2% in that of women with cerebral palsy.

These figures of 3 and 4.2%, respectively, probably have little significance, for they include cesarean sections performed on women having abruptio placentae, placenta previa, preeclampsia, diabetes, and other conditions which might affect the health of the baby. The investigators were unable to demonstrate that elective cesarean section performed before the onset of labor reduces the incidence of cerebral palsy by elimination of the trauma caused by mechanical forces during the second stage of labor.

VENIPUNCTURE TECHNIQUE

To the Editor:—*After performance of a venipuncture in the area of the antecubital space, it is common practice to place a sterile cotton ball over the vein and instruct the patient to flex his arm. It has been suggested that this procedure be changed to application of direct pressure with a sterile cotton ball to the site of the venipuncture while the patient elevates and extends his arm to minimize the extravasation of blood. Which method is better?*

M.D., New York.

Answer.—While the needle is being withdrawn, a pad of wool or gauze should be pressed on the site of venipuncture, and the patient should be instructed to keep his arm straight and to raise it. Pressure should be maintained on the pad by the patient or some one else. The practice of retaining the pad in position by flexing the elbow is less satisfactory; not only is less pressure brought to bear on the vein at the site of puncture, but pressure may actually be applied proximal to the site of puncture and thus promote bleeding. (Mollison, P. L.: Blood Transfusion in Clinical Medicine, ed. 2, Springfield, Ill., Charles C Thomas, Publisher, 1957, p. 4.)

ALLERGY TO ARTIFICIAL EYE

To the Editor:—*What is the incidence of allergic reaction to a plastic implant in the orbit? A patient on whom an eye enucleation and evisceration has been performed is wearing a plastic artificial eye made of methyl methacrylate. It is claimed that the vision in the remaining eye is affected because of an allergic reaction to the artificial one, although there has been no evidence of inflammation. How often does this condition occur, and what other plastics can be used?*

M.D., New York.

Answer.—Allergic reactions have been reported to methyl methacrylate in dental prostheses and in artificial fingernails. Macivor (*Canad. M. A. J.* 62:164 [Feb.] 1950) reviewed 100 patients with plastic prostheses; 8 had a contact allergy, 6 from artificial eyes and 2 from partially exposed implants. The artificial eyes were composed of methyl methacrylate. Practically all plastic orbital implants on the market are made of plastics that are polymers of methyl methacrylate.

The patient should have a patch test with the liquid monomer or powdered polymer of the suspected plastic. Substitution of a glass or gold implant, however, would probably be the most direct method of management.

No effect is likely to occur in the remaining eye, provided all uveal tissue was removed at the time of operation.

BAN ON SMOKING IN GYMNASIUMS

To the Editor:—*What scientific study could be used as a reference for the ban on smoking in a basketball area or a gymnasium?*

Frank Vinson, M.D., Fort Valley, Ga.

Answer.—A suitable reference is the study by Karpovich and Hale, entitled "Tobacco Smoking and Athletic Performance" (*J. Appl. Physiol.* 3:616 [April] 1951).

RETROBULBAR NEURITIS AND PREGNANCY

To the Editor:—*A woman had retrobulbar neuritis of the left eye when she was 16 years of age. Since then she has been well, except for an episode of retrobulbar neuritis in her right eye, which gradually cleared, one month after her second pregnancy; neurological findings were normal. What advice should one give this patient with regard to future pregnancies?*

Harold C. Blog, M.D., Huntington, N.Y.

Answer.—Since no etiological diagnosis of the retrobulbar inflammation has been made in this patient, no specific answer can be given. Assuming that diagnostic studies have been performed, and that the patient does not have any progressive type of vascular, inflammatory, or neoplastic lesion, only a general consideration of her problem can be given.

Quantitative perimetry, roentgenographic studies of the skull and optic foramen, electroencephalography and studies of spinal fluid dynamics and chemistry should be carried out. Remote causes of retrobulbar neuritis such as diabetes, alcohol and tobacco amblyopia, lead or lead-salt poisoning, and the like should be excluded. Retrobulbar neuritis commonly occurs in women under 35 years of age, and, since this is the maximal child-bearing period, the occurrence of this disease one month after the second pregnancy does not indicate a causal relationship between pregnancy and the disease. Moreover, this patient had an attack at the age of 16 years when she presumably was not pregnant, and she has had two pregnancies without developing signs of the disease; the condition recurred only after termination of the second pregnancy. Although there are reports in the literature that pregnancy can be responsible for the onset of retrobulbar neuritis, this relationship must be studied and established before it can be applied to the individual patient.

CEPHALALGIA

To the Editor:—*A 40-year-old housewife has complained of cephalalgia for 18 months. Neurosurgeons have performed neurectomies of the greater and lesser occipital areas, with severance of all nerves in the right inferior portion of the head. She had obtained temporary relief from pain and now experiences an intermittent, burning, dull ache along the maxillary division of the trigeminal nerve and pain in the region of both mastoid processes. Since the patient has a great degree of psychic overlay, administration of tranquilizers has been of some benefit. Various analgesics, including tablets containing salts of dihydrohydroxycodeinone and homatropine plus acetylsalicylic acid, acetophenetidin, and caffeine citrate (Percodan); tablets containing ethoheptazine citrate and acetylsalicylic acid (Zactirin); and, at one time, anileridine (Leritine) dihydrochloride, have been used. A series of vitamin B^{12} injections has also been prescribed. What suggestions can be given for alleviation of the pain?*

Bruce C. McIntyre, M.D., Whitefish, Mont.

Answer.—In 1947, Gardner and co-workers undertook treatment of patients with unilateral head pain by division of the greater superficial petrosal branch of the seventh cranial nerve. The rationale of their procedure stemmed from the collaborative work of Cobb and Finesinger with Chorobski and Penfield, who had shown that this nerve contains secretory fibers for the lacrimal glands, vasodilator fibers for the mucous membranes of the nasal cavity, and afferent fibers, from the dura mater, the internal carotid artery, and the sphenopalatine ganglion, to the cells in the geniculate ganglion and that it conveys vasodilator impulses to the ipsilateral cerebral hemispheres. Gardner and associates, inferring that parasympathetic impulses transmitted by the petrosal nerve caused unilateral lacrimation, unilateral swelling, secretion of the nasal mucosa, and unilateral head pain, sectioned this nerve in 26 patients with unilateral cephalalgia. While in about one-third of the patients the headache was eliminated immediately after the operation, in another third there was only some diminution of pain, and in the remaining third none at all. The pain of unilateral cephalalgia has not been significantly reduced or eliminated by division of the fifth or ninth cranial nerves, and, with the exception of patients with cranial or temporal arteritis, surgical resection of nerves or arteries in the head has not proved to be of therapeutic value for vascular headaches. It is also well known that headaches, after management by such other therapeutic procedures as desensitization to histamine, recur in these patients in situations of tension, desperation, or exhaustion. Mood reactions in these patients, which are characterized by long-standing resentment, hostility, and anger, precede and persist in the interval between attacks. The administration of ergotamine tartrate will successfully abort many individual attacks of cephalalgia, but no medication can be expected to prevent the recurrence of attacks. It is necessary to insist that these patients follow through with a detailed regimen of work and recreation that brings them satisfaction and permits them to have adequate periods of rest and to prescribe measures to induce relaxation such as massage, long, warm tub baths two or three times a day, exercise, and small amounts of a sedative or analgesic agent. Most important is the direction of therapeutic attention at the patients' destructive attitudes and moods, and the life situations in which they occur, that precipitate the attack. Headaches can be effectively modified in most patients by these measures.

VENOCLYSIS AND THROMBOPHLEBITIS

To the Editor:—*What is the incidence of thrombophlebitis after injection of a 50% dextrose solution into a patient's antecubital vein? What is the incidence if a 5% dextrose solution is used?*

H. James Byrne, M.D., Glendale, Calif.

Answer.—Etiological factors which are not specific but are contributory in causing thrombophlebitis include the rubber or plastic tubing equipment, the tonicity and pH of the infusion fluid, and the duration of the infusion. The incidence of thrombophlebitis as a result of infusion can be reduced by (1) a change in the site of the venipuncture every eight hours, and (2) injection of irritant solutions into a large blood vessel in which they will be diluted rapidly. A 50% dextrose solution should be infused through a plastic tube that has been passed up a brachial vein to its junction with the subclavian (Mollison, P. L.: Blood Transfusion in Clinical Medicine, ed. 2, Springfield, Ill. Charles C Thomas, Publisher, 1956, pp. 425-426). The incidence of thrombosis after injection of a 5% dextrose solution into an antecubital vein is negligible, according to the experience of a transfusion unit in a large midwestern hospital. Most of the complications arise when drugs are added to the solution. Tabulation of the incidence of thrombophlebitis due to infusion of a 50% dextrose solution has not, apparently, been done.

Aid for Medical Schools . .
U. S. Medical Research Role . .

ADMINISTRATION RENEWS OPPOSITION TO FORAND APPROACH

A significant development in the controversy over government medicine schemes was the decision by the Eisenhower administration not to propose at this time any alternate to the controversial Forand bill.

Equally important, the administration emphatically renewed its opposition to any type of proposal such as Forand's to broaden the social security mechanism by providing partial financing of medical and hospital bills for some of the aged population.

The administration's stand was revealed by Arthur S. Flemming, Secretary of Health, Education, and Welfare, in testimony before the House Ways and Means Committee that was considering the Forand bill and other changes in the social security program. "I want to make it clear," he said, "that as an administration we will oppose any program of compulsory health insurance."

Opponents of plans to inject the federal government further into the medical and hospital field had feared that any administration "alternative" during this election year would only have spurred Forand bill backers to push their own plan.

There had been indications earlier this year that the administration might offer the Ways and Means Committee at its sessions on social security some program in the field of health care for old persons. However, President Eisenhower decided against this.

While the administration's position was a heartening development as far as the medical profession was concerned, it by no means signaled the end of the matter in Congress. Rep. Aime Forand (D., R. I.) second-ranking Democrat on the Ways and Means Committee and sponsor of the disputed health-care-for-the-elderly bill, filed a discharge petition to try to bypass the Committee and bring the measure up on the House floor for a vote.

Forand apparently took the action because of a belief that a majority of the Committee was opposed to his measure. The discharge petition is a seldom-used maneuver aimed at having the full House take up legislation without the usual necessity of Committee approval. To succeed, a majority of the House membership—219 members—must sign the petition.

In his testimony, HEW Secretary Flemming did not write off the possibility that at some later date the administration might come up with an alternate program. Stating that further consultations would be held with experts in the field, Flemming said, "It is . . . not possible to predict the length of time that it will take for these consultations.

"Moreover, I am not now in a position to predict how long it will take to resolve the basic issues . . .," he added.

Even if an alternative administration program is developed before this session of Congress adjourns, probably sometime in July, in all likelihood it would be too late for Congressional action this year.

Noting that last year he had testified that, under the Forand bill, "The pattern of health coverage of the aged would be frozen in a vast and uniform governmental system," Flemming told the Committee that in view of progress made by free-enterprise, voluntary means, "We are all the more convinced that it would be very unwise for our government to take any step that would lead to such a result."

Listing his objections to the Forand measure, Flemming noted "very significant steps that the federal government has taken in recent years to help deal with hazards of old age." These included increases in payments to social security beneficiaries, stepped-up medical research programs, funds for hospital construction, and special housing projects for the elderly.

Furthermore, the cabinet officer pointed out, Congress has provided for a White House Conference next January on all aspects of aging problems.

"Very significant advances" have been made in recent years in extending the benefits of health insurance to people 65 years of age and over, Flemming testified, with about 42% of persons in this age group now covered by some protection against the cost of hospital care. And private companies are aggressively entering the field to provide better protection for older persons, he added.

At the same time, Flemming said, "there still will be aged persons who will have no protection but would be willing to participate in voluntary programs if provided with policies at rates they could afford to pay." The administration has been investigating the feasibility of a program "that would help accelerate rather than impede the present voluntary approach to this problem," Flemming said.

In considering a program, the following principles were being kept in mind, according to the secretary: no compulsion; nothing to stifle private initiative; strengthen and stimulate the existing private system; preserve and strengthen the private relationships which now characterize the rendering of health services; opportunity for all aged to participate; and availability to the aged—particularly in the low income groups—of protection against catastrophic and long-term illnesses.

One plan under consideration, he disclosed, would involve federal payments to help the states provide the difference between the amount paid by policy holders in low income groups and the actual cost of the policy. "In exploring this question, we are keeping in mind the fact that the states would be authorized to contract with private groups for the insurance."

In other testimony, Flemming officially backed the main provisions of another bill before the Committee that would liberalize the social security program for the totally and permanently disabled. The

'LANOXIN'® brand DIGOXIN

formerly known as Digoxin 'B.W. & Co.'®

"If one digitalis agent were to be recommended for its adaptability to the many and varied clinical contingencies, we believe Digoxin would be [a] drug of choice."

Lown, B., and Levine, S. A.: Current Concepts in Digitalis Therapy, Boston, Little, Brown & Company, 1954, p. 23, par. 2.

major provision of this bill would remove the present requirement that a beneficiary be at least 50 years of age before receiving payments. Instead, there would be no age limitation.

Flemming also proposed that social security coverage be extended to self-employed physicians, a move opposed by the American Medical Association.

REPUBLICAN GROUP ASSAILS FORAND LEGISLATION

The 10 Republican members of the House Ways and Means Committee joined in a unanimous attack on the Forand measure as an unsound approach to the problems of the aging.

Displaying solid-front opposition to the principle of tacking health care programs onto the social security mechanism, the GOP lawmakers concurred in the statement of HEW Secretary Flemming criticizing the Forand measure.

"Our opposition to the Forand bill does not preclude our genuine interest in contributing to the solution of the problems of the aged," the lawmakers stated. "Many federal programs are already in operation to alleviate these problems. We join . . . in supporting a program of thorough and effective study toward finding answers to the health problems confronting our society."

The Republicans listed four major points in criticizing the controversial Forand bill:

1. It is discriminatory because it excludes, among others, 4 million aged who through no fault of their own do not have social security protection, as well as "the millions of Americans in the working force along with their families who may have just as urgent medical-economic problems as the aged."
2. It is unsoundly financed . . . the proposed social security tax increase would not cover the cost of such a program.
3. It disregards the progress that has been made in recent years by the medical profession and the insurance industry to provide health care to the aged.
4. It would preempt the work now in progress for the White House Conference on the Aging next year.

The Republicans signing the document were Representatives Noah M. Mason (Ill.), John W. Byrnes (Wis.), Howard H. Baker (Tenn.), Thomas B. Curtis (Mo.), Victor A. Knox (Mich.), James B. Utt (Calif.), Jackson E. Betts (Ohio), Bruce Alger (Texas), Albert H. Bosch (N. Y.), and John A. Lafore (Pa.).

ADMINISTRATION WEIGHS MEDICAL SCHOOL AID PLAN

A program to furnish federal aid for the construction of medical schools was under top-level administration consideration. U. S. Public Health Service Surgeon General Leroy Burney told Congress that "there is under consideration by the administration, without any action up to the present time at least, proposed legislation which would provide grants for the construction of teaching facilities for medical schools, dental schools, schools of osteopathy, and schools of public health."

Last fall, a special consultant group on medical education, appointed by the U. S. Public Health Service, recommended in a lengthy report illion-dollar, 10-year program of federal match- grants to help construct 20 to 24 new medical schools and expand existing ones.

Dr. Burney told a House appropriations subcommittee that this report "has received very wide interest and study and I think has done a great deal to alert not only the professional groups but the public in general as to the very, very urgent problem of health manpower."

Arthur S. Flemming, Secretary of Health, Education, and Welfare, told the same subcommittee, "We have got the obligation of developing an action program designed to take care of the problem." Pressed about specifics, he said he was "not yet crossing the bridge as to what should be the role of the federal government in dealing with it."

The American Medical Association has endorsed the principle of a temporary program of federal aid to help build new medical schools.

CAUTIONS AGAINST TOO MUCH FEDERAL MEDICAL RESEARCH

Secretary of Health, Education, and Welfare Arthur S. Flemming said it would be a "sad day" if the federal government ever financed most of the medical research in this country.

He told Congress that in his travels about the country he was often asked why individual persons should contribute to private charities such as the Heart Association and the Cancer Society in view of the amount that the federal government is putting up for this purpose.

"First of all, I point out that these groups are doing things other than research," Flemming told a House appropriations subcommittee. "I mean that they are engaged in the actual rendering of service. That is one reason why people should continue to give."

"The second thing that I point out is that in my judgment these organizations ought to continue to get money for research so we will never reach the point where the federal government will be putting up 80 or 90% for research. That will be a sad day for medical research."

MISCELLANY

Congress was asked by the administration to make it a federal crime to assault or otherwise interfere with Food and Drug Administration inspectors and other agents of the Department of Health, Education, and Welfare while they are officially engaged in their work. Such a law now applies to the Justice Department employees and certain other federal enforcement branches.

The Senate Finance Committee approved legislation authorizing taxpayers a full deduction on federal income tax for medical expenses paid for dependent parents 65 years or older. At present there are limitations on such deductions by those with dependent parents. Persons aged over 65 years who are not dependent under current law are entitled to full deductions for medical expenses.

Legislation to set up clinics to treat narcotics addicts and give them limited quantities of drugs was introduced by Rep. Victor Anfuso (R., N. Y.). Under the bill, the federal government would provide up to 5 million dollars in grants to the states to help them set up the out-patient clinics.
